1 **Executive Summary**

2 **Land degradation affects people and ecosystems throughout the planet and is both affected by**
3 **climate change and contributes to it.** In this report, land degradation is defined as a *negative trend*
4 *in land condition, caused by direct or indirect human-induced processes including anthropogenic*
5 *climate change, expressed as long-term reduction or loss of at least one of the following: biological*
6 *productivity, ecological integrity, or value to humans.* Forest degradation is land degradation which
7 occurs in forest land. Deforestation is the conversion of forest to non-forest land and can result in land
8 degradation. {4.1.3}

9 **Land degradation adversely affects people's livelihoods (*very high confidence*) and occurs over a**
10 **quarter of the Earth's ice-free land area (*medium confidence*).** **The majority of the 1.3 to 3.2**
11 **billion affected people (*low confidence*) are living in poverty in developing countries (*medium***
12 ***confidence*).** Land use changes and unsustainable land management are direct human causes of land
13 degradation (*very high confidence*), with agriculture being a dominant sector driving degradation
14 (*very high confidence*). Soil loss from conventionally tilled land exceeds the rate of soil formation by
15 >2 orders of magnitude (*medium confidence*). Land degradation affects humans in multiple ways,
16 interacting with social, political, cultural and economic aspects, including markets, technology,
17 inequality and demographic change (*very high confidence*). Land degradation impacts extend beyond
18 the land surface itself, affecting marine and freshwater systems, as well as people and ecosystems far
19 away from the local sites of degradation (*very high confidence*). {4.1.6, 4.2.1, 4.2.3, 4.3, 4.6.1, 4.7,
20 Table 4.1}

21 **Climate change exacerbates the rate and magnitude of several ongoing land degradation**
22 **processes and introduces new degradation patterns (*high confidence*).** Human-induced global
23 warming has already caused observed changes in two drivers of land degradation: increased
24 frequency, intensity and/or amount of heavy precipitation (*medium confidence*), and increased heat
25 stress (*high confidence*). Global warming beyond that of present-day will further exacerbate ongoing
26 land degradation processes through increasing floods (*medium confidence*), drought frequency and
27 severity (*medium confidence*), intensified cyclones (*medium confidence*), and sea-level rise (*very high*
28 *confidence*), with outcomes being modulated by land management (*very high confidence*). Permafrost
29 thawing due to warming (*high confidence*), and coastal erosion due to sea level rise and impacts of
30 changing storm paths (*low confidence*), are examples of land degradation affecting places in which it
31 has not typically been a problem. Erosion of coastal areas because of sea level rise will increase
32 worldwide (*high confidence*). In cyclone prone areas the combination of sea level rise and more
33 intense cyclones will cause land degradation with serious consequences for people and livelihoods
34 (*very high confidence*). {4.2.1, 4.2.2, 4.2.3, 4.4.1, 4.4.2, 4.9.6, Table 4.1}

35 **Land degradation and climate change, both individually and in combination, have profound**
36 **implications for natural resource-based livelihood systems and societal groups (*high***
37 ***confidence*).** The number of people whose livelihood depends on degraded lands has been estimated
38 to ~1.5 billion worldwide (*very low confidence*). People in degraded areas who directly depend on
39 natural resources for subsistence, food security and income, including women and youth with limited
40 adaptation options, are especially vulnerable to land degradation and climate change (*high*
41 *confidence*). Land degradation reduces land productivity and increases the workload of managing the
42 land, affecting women disproportionately in some regions. Land degradation and climate change act as
43 threat multipliers for already precarious livelihoods (*very high confidence*), leaving them highly
44 sensitive to extreme climatic events, with consequences such as poverty and food insecurity (*high*
45 *confidence*), and in some cases migration, conflict and loss of cultural heritage (*low confidence*).
46 Changes in vegetation cover and distribution due to climate change increase risks of land degradation
47 in some areas (*medium confidence*). Climate change will have detrimental effects on livelihoods,

1 habitats, and infrastructure through increased rates of land degradation (*high confidence*) and from
2 new degradation patterns (*low evidence, high agreement*). {4.1.6, 4.2.1, 4.7}

3 **Land degradation is a driver of climate change through emission of greenhouse gases and**
4 **reduced rates of carbon uptake (*very high confidence*).** Since 1990, globally the forest area has
5 decreased by 3% (*low confidence*) with net decreases in the tropics and net increases outside the
6 tropics (*high confidence*). Lower carbon density in re-growing forests compared to carbon stocks
7 before deforestation results in net emissions from land use change (*very high confidence*). Forest
8 management that reduces carbon stocks of forest land also leads to emissions, but global estimates of
9 these emissions are uncertain. Cropland soils have lost 20-60% of their organic carbon content prior
10 to cultivation, and soils under conventional agriculture continue to be a source of greenhouse gases
11 (*medium confidence*). Of the land degradation processes, deforestation, increasing wildfires,
12 degradation of peat soils, and permafrost thawing contribute most to climate change through the
13 release of greenhouse gases and the reduction in land carbon sinks following deforestation (*high*
14 *confidence*). Agricultural practices also emit non-CO₂ greenhouse gases from soils and these
15 emissions are exacerbated by climate change (*medium confidence*). Conversion of primary to
16 managed forests, illegal logging and unsustainable forest management result in greenhouse gas
17 emissions (*very high confidence*) and can have additional physical effects on the regional climate
18 including those arising from albedo shifts (*medium confidence*). These interactions call for more
19 integrative climate impact assessments. {4.2.2, 4.3, 4.5.4, 4.6}

20 **Large-scale implementation of dedicated biomass production for bioenergy increases**
21 **competition for land with potentially serious consequences for food security and land**
22 **degradation (*high confidence*).** Increasing the extent and intensity of biomass production through
23 e.g. fertiliser additions, irrigation or monoculture energy plantations can result in local land
24 degradation. Poorly implemented intensification of land management contributes to land degradation
25 (e.g., salinisation from irrigation) and disrupted livelihoods (*high confidence*). In areas where
26 afforestation and reforestation occur on previously degraded lands, opportunities exist to restore and
27 rehabilitate lands with potentially significant co-benefits (*high confidence*) that depend on whether
28 restoration involves natural or plantation forests. The total area of degraded lands has been estimated
29 at 1-6 Mkm² (*very low confidence*). The extent of degraded and marginal lands suitable for dedicated
30 biomass production is highly uncertain and cannot be established without due consideration of current
31 land use and land tenure. Increasing the area of dedicated energy crops can lead to land degradation
32 elsewhere through indirect land use change (*medium confidence*). Impacts of energy crops can be
33 reduced through strategic integration with agricultural and forestry systems (*high confidence*) but the
34 total quantity of biomass that can be produced through synergistic production systems is unknown.
35 {4.1.6, 4.4.2, 4.5, 4.7.1, 4.8.1, 4.8.3, 4.8.4, 4.9.3}

36 **Reducing unsustainable use of traditional biomass reduces land degradation and emissions of**
37 **CO₂, while providing social and economic co-benefits (*very high confidence*).** Traditional biomass
38 in the form of fuelwood, charcoal and agricultural residues remains a primary source of energy for
39 more than one-third of the global population leading to unsustainable use of biomass resources and
40 forest degradation and contributing around 2% of global greenhouse gas (GHG) emissions (*low*
41 *confidence*). Enhanced forest protection, improved forest and agricultural management, fuel-switching
42 and adoption of efficient cooking and heating appliances can promote more sustainable biomass use
43 and reduce land degradation, with co-benefits of reduced GHG emissions, improved human health,
44 and reduced workload especially for women and youth (*very high confidence*). {4.1.6, 4.5.4}

45 **Land degradation can be avoided, reduced or reversed by implementing sustainable land**
46 **management, restoration and rehabilitation practices that simultaneously provide many co-**
47 **benefits, including adaptation to and mitigation of climate change (*high confidence*).** Sustainable

1 land management is a comprehensive array of technologies and enabling conditions, which have
2 proven to address land degradation at multiple landscape scales, from local farms (*very high*
3 *confidence*) to entire watersheds (*medium confidence*). Sustainable forest management can prevent
4 deforestation, maintain and enhance carbon sinks and can contribute towards greenhouse gas
5 emissions reduction goals. Sustainable forest management generates socio-economic benefits,
6 provides fiber, timber and biomass to meet society's growing needs. While sustainable forest
7 management sustains high carbon sinks, the conversion from primary forests to sustainably managed
8 forests can result in carbon emission during the transition and can result in loss of biodiversity (*high*
9 *confidence*). Conversely, in areas of degraded forests, sustainable forest management can increase
10 carbon stocks and biodiversity (*medium confidence*). Carbon storage in long-lived wood products and
11 reductions of emissions from use of wood products to substitute for emissions-intensive materials also
12 contribute to mitigation objectives. {4.8, 4.9, Table 4.2}

13 **Lack of action to address land degradation will increase emissions and reduce carbon sinks and**
14 **is inconsistent with the emission reductions required to limit global warming to 1.5°C or 2°C.**
15 **(*high confidence*).** Better management of soils can offset 5–20% of current global anthropogenic
16 GHG emissions (*medium confidence*). Measures to avoid, reduce and reverse land degradation are
17 available but economic, political, institutional, legal and socio-cultural barriers, including lack of
18 access to resources and knowledge, restrict their uptake (*very high confidence*). Proven measures that
19 facilitate implementation of practices that avoid, reduce, or reverse land degradation include tenure
20 reform, tax incentives, payments for ecosystem services, participatory integrated land use planning,
21 farmer networks and rural advisory services. Delayed action increases the costs of addressing land
22 degradation, and can lead to irreversible biophysical and human outcomes (*high confidence*). Early
23 actions can generate both site specific and immediate benefits to communities affected by land
24 degradation, and contribute to long-term global benefits through climate change mitigation (*high*
25 *confidence*). {4.1.5, 4.1.6, 4.7.1, 4.8, Table 4.2}

26 **Even with adequate implementation of measures to avoid, reduce and reverse land degradation**
27 **there will be residual degradation in some situations (*high confidence*).** Limits to adaptation are
28 dynamic, site specific and are determined through the interaction of biophysical changes with social
29 and institutional conditions. Exceeding the limits of adaptation will trigger escalating losses or result
30 in undesirable changes, such as forced migration, conflicts, or poverty. Examples of potential limits to
31 adaptation due to climate change induced land degradation are coastal erosion where land disappears,
32 collapsing infrastructure and livelihoods due to thawing of permafrost, and extreme forms of soil
33 erosion. {4.7, 4.8.5, 4.8.6, 4.9.6, 4.9.7, 4.9.8}

34 **Land degradation is a serious and widespread problem, yet key uncertainties remain**
35 **concerning its extent, severity, and linkages to climate change (*very high confidence*).** Despite the
36 difficulties of objectively measuring the extent and severity of land degradation given its complex and
37 value-based characteristics, land degradation represents, like climate change, one of the biggest and
38 most urgent challenges for humanity (*very high confidence*). The current global extent, severity and
39 rates of land degradation are not well quantified. There is no single method by which land degradation
40 can be measured objectively and consistently over large areas because it is such a complex and value
41 laden concept (*very high confidence*). However, many scientific and locally-based approaches,
42 including the use of indigenous and local knowledge, exist that can assess different aspects of land
43 degradation or provide proxies. Remote sensing, corroborated by other data, can generate
44 geographically explicit and globally consistent data that can be used as proxies over relevant time
45 scales (several decades). Few studies have specifically addressed the impacts of proposed land-based
46 negative emission technologies on land degradation. Much research has tried to understand how
47 livelihoods and ecosystems are affected by a particular stressor, for example drought, heat stress, or
48 water logging. Important knowledge gaps remain in understanding how plants, habitats and

- 1 ecosystems are affected by the cumulative and interacting impacts of several stressors, including
- 2 potential new stressors resulting from large-scale implementation of negative emission technologies.

1 **4.1 Introduction**

2 **4.1.1 Scope of the chapter**

3 This chapter examines the scientific understanding of how climate change impacts land degradation,
4 and vice versa, with a focus on non-drylands. Land degradation of drylands is covered in Chapter 3.
5 After providing definitions and the context (Section 4.1) we proceed with a theoretical explanation of
6 the different processes of land degradation and how they are related to climate and to climate change,
7 where possible (Section 4.2). Two sections are devoted to a systematic assessment of the scientific
8 literature on status and trend of land degradation (Section 4.3) and projections of land degradation
9 (Section 4.4). Then follows a section where we assess the impacts of climate change mitigation
10 options, bioenergy and land-based technologies for carbon dioxide removal (CDR), on land
11 degradation (Section 4.5). The ways in which land degradation can impact climate and climate change
12 are assessed in Section 4.6. The impacts of climate related land degradation on human and natural
13 systems are assessed in Section 4.7. The remainder of the chapter assesses land degradation mitigation
14 options based on the concept of sustainable land management: avoid, reduce and reverse land
15 degradation (Section 4.8), followed by a presentation of eight illustrative case studies of land
16 degradation and remedies (Section 4.9). The chapter ends with a discussion of the most critical
17 knowledge gaps and areas for further research (Section 4.10).

18 **4.1.2 Perspectives of land degradation**

19 Land degradation has accompanied humanity at least since the widespread adoption of agriculture
20 during Neolithic time, some 10,000 to 7,500 years ago (Dotterweich 2013; Butzer 2005; Dotterweich
21 2008) and the associated population increase (Bocquet-Appel 2011). There are indications that the
22 levels of greenhouse gases (particularly carbon dioxide and methane) of the atmosphere started to
23 increase already more than 3,000 years ago as a result of expanding agriculture, clearing of forests,
24 and domestication of wild animals (Fuller et al. 2011; Kaplan et al. 2011; Vavrus et al. 2018; Ellis et
25 al. 2013). While the development of agriculture (cropping and animal husbandry) underpinned the
26 development of civilisations, political institutions, and prosperity, farming practices led to conversion
27 of forests and grasslands to farmland, and the heavy reliance on domesticated annual grasses for our
28 food production meant that soils started to deteriorate through seasonal mechanical disturbances
29 (Turner et al. 1990; Steffen et al. 2005; Ojima et al. 1994; Ellis et al. 2013). More recently,
30 urbanisation has significantly altered ecosystems, see further Cross-chapter Box 4 on Climate Change
31 and Urbanisation, Chapter 2. Since about 1850, about 35% of the human caused emissions of CO₂ to
32 the atmosphere comes from land as a combined effect of land degradation and land-use change (Foley
33 et al. 2005) and about 38% of Earth's land area has been converted to agriculture (Foley et al. 2011),
34 see Chapter 2 for more details.

35 Not all human impacts on land result in degradation according to the definition of land degradation
36 used in this report (see 4.2.1). There are many examples of long-term sustainably managed land
37 around the world (such as terraced agricultural systems and sustainably managed forests) although
38 degradation and its management are the focus of this chapter. We also acknowledge that human use of
39 land and ecosystems provides essential goods and services for society (Foley et al. 2005; MEA
40 (Millennium Ecosystem Assessment) 2005).

41 Land degradation was long subject to a polarised scientific debate between disciplines and
42 perspectives in which social scientists often proposed that natural scientists exaggerated land
43 degradation as a global problem (Blaikie and Brookfield 1987; Forsyth 1996; Lukas 2014; Zimmerer
44 1993). The elusiveness of the concept in combination with the difficulties of measuring and
45 monitoring land degradation at global and regional scales by extrapolation and aggregation of
46 empirical studies at local scales, such as the Global Assessment of Soil Degradation database

1 (GLASOD) (Sonneveld and Dent 2009) contributed to conflicting views. The conflicting views were
2 not confined to science only, but also caused tension between the scientific understanding of land
3 degradation and policy (Andersson et al. 2011; Behnke and Mortimore 2016; Grainger 2009; Toulmin
4 and Brock 2016). Another weakness of many land degradation studies is the exclusion of the views
5 and experiences of the land users, whether farmers or forest dependent communities (Blaikie and
6 Brookfield 1987; Fairhead and Scoones 2005; Warren 2002; Andersson et al. 2011). More recently,
7 the polarised views described above have been reconciled under the umbrella of Land Change
8 Science, which has emerged as an interdisciplinary field aimed at examining the dynamics of land
9 cover and land-use as a coupled human–environment system (Turner et al. 2007). A comprehensive
10 discussion about concepts and different perspectives of land degradation was presented in Chapter 2
11 of the recent report from the Intergovernmental Platform on Biodiversity and Ecosystem Services
12 (IPBES) on land degradation (Montanarella et al. 2018).

13 In summary, agriculture and clearing of land for food and wood products have been the main drivers
14 of land degradation for millennia (*high confidence*). This does not mean, however, that agriculture and
15 forestry always cause land degradation (*high confidence*); sustainable management is possible but not
16 always practiced (*high confidence*). Reasons for this are primarily economic, political and social.

17 **4.1.3 Definition of land degradation**

18 To clarify the scope of this chapter it is important to start by defining land itself. The Special Report
19 on Climate Change and Land (SRCCL) defines land as “the terrestrial portion of the biosphere that
20 comprises the natural resources (soil, near surface air, vegetation and other biota, and water), the
21 ecological processes, topography, and human settlements and infrastructure that operate within that
22 system” (Henry et al. 2018), adapted from (FAO 2007; UNCCD 1994).

23 Land degradation is defined in many different ways within the literature, with differing emphases on
24 biodiversity, ecosystem functions and ecosystem services (e.g., Montanarella et al. 2018). In this
25 report, land degradation is defined as a *negative trend in land condition, caused by direct or indirect*
26 *human-induced processes including anthropogenic climate change, expressed as long-term reduction*
27 *or loss of at least one of the following: biological productivity, ecological integrity or value to*
28 *humans*. This definition applies to forest and non-forest land: forest degradation is land degradation
29 that occurs in forest land. Soil degradation refers to a subset of land degradation processes that
30 directly affect soil.

31 The SRCCL definition is derived from the IPCC AR5 definition of desertification, which is in turn
32 taken from the UNCCD: “Land degradation in arid, semi-arid, and dry sub-humid areas resulting from
33 various factors, including climatic variations and human activities. Land degradation in arid, semi-
34 arid, and dry sub-humid areas is a reduction or loss of the biological or economic productivity and
35 integrity of rainfed cropland, irrigated cropland, or range, pasture, forest, and woodlands resulting
36 from land uses or from a process or combination of processes, including processes arising from
37 human activities and habitation patterns, such as (1) soil erosion caused by wind and/or water; (2)
38 deterioration of the physical, chemical, biological, or economic properties of soil; and (3) long-term
39 loss of natural vegetation” (UNCCD 1994, Article 1).

40 The SRCCL definition is intended to complement the more detailed UNCCD definition, expanding
41 the scope to all regions, not just drylands, providing an operational definition that emphasises the
42 relationship between land degradation and climate for use in this report. Through its attention to the
43 three aspects biological productivity, ecological integrity and value to humans, the SRCCL definition
44 is consistent with the Land Degradation Neutrality (LDN) concept, which aims to maintain or enhance
45 the land-based natural capital, and the ecosystem services that flow from it (Cowie et al. 2018).

1 In the SRCCL definition of land degradation, changes in land condition resulting solely from natural
2 processes (such as volcanic eruptions and tsunamis) are not considered land degradation, as these are
3 not direct or indirect human-induced processes. Climate variability exacerbated by human-induced
4 climate change can contribute to land degradation. Value to humans can be expressed in terms of
5 ecosystem services or Nature's Contribution to People.

6 The definition recognises the reality presented in the literature that land-use and land management
7 decisions often result in trade-offs between time, space, ecosystem services, and stakeholder groups
8 (e.g. Dallimer and Stringer 2018). The interpretation of a negative trend in land condition is somewhat
9 subjective, especially where there is a trade-off between ecological integrity and value to humans. The
10 definition also does not consider the magnitude of the negative trend or the possibility that a negative
11 trend in one criterion may be an acceptable trade-off for a positive trend in another criterion. For
12 example, reducing timber yields to safeguard biodiversity by leaving on site more wood that can
13 provide habitat, or vice versa, is a trade-off that needs to be evaluated based on context (i.e. the
14 broader landscape) and society's priorities. Reduction of biological productivity *or* ecological
15 integrity *or* value to humans *can* constitute degradation, but any one of these changes need not
16 necessarily be considered degradation. Thus, a land-use change that reduces ecological integrity and
17 enhances **sustainable** food production at a specific location is not necessarily degradation. Different
18 stakeholder groups with different world views value ecosystem services differently. As Warren (2002)
19 explained: land degradation is contextual. Further, a decline in biomass carbon stock does not always
20 signify degradation, such as when caused by periodic forest harvest. Even a decline in productivity
21 may not equate to land degradation, such as when a high intensity agricultural system is converted to
22 a lower input more sustainable production system.

23 In the SRCCL definition, degradation is indicated by a negative trend in land condition during the
24 period of interest, thus the baseline is the land condition at the start of this period. The concept of
25 baseline is theoretically important but often practically difficult to implement for conceptual and
26 methodological reasons (Herrick et al. 2019; Prince et al. 2018; see also Sections 4.3.1 and 4.4.1).
27 Especially in biomes characterised by seasonal and interannual variability, the baseline values of the
28 indicators to be assessed should be determined by averaging data over a number of years prior to the
29 commencement of the assessment period (Orr et al. 2017; see also 4.2.4).

30 Forest degradation is land degradation in forest remaining forest. In contrast, deforestation refers to
31 the conversion of forest to non-forest that involves a loss of tree cover and a change in land-use.
32 Internationally accepted definitions of forest (FAO 2015; UNFCCC 2013) include lands where tree
33 cover has been lost temporarily, due to disturbance or harvest, with an expectation of forest regrowth.
34 Such temporary loss of forest cover therefore is not deforestation.

35 **4.1.4 Land degradation in previous IPCC reports**

36 Several previous IPCC assessment reports include brief discussions of land degradation. In AR5
37 WGIII land degradation is one factor contributing to uncertainties of the mitigation potential of land-
38 based ecosystems, particularly in terms of fluxes of soil carbon (Smith et al., 2014, p. 817). In AR5
39 WGI, soil carbon was discussed comprehensively but not in the context of land degradation, except
40 forest degradation (Ciais et al. 2013) and permafrost degradation (Vaughan et al. 2013). Climate
41 change impacts were discussed comprehensively in AR5 WGII, but land degradation was not
42 prominent. Land use and land cover changes were treated comprehensively in terms of effects on the
43 terrestrial carbon stocks and flows (Settele et al. 2015) but links to land degradation were to a large
44 extent missing. Land degradation was discussed in relation to human security as one factor which in
45 combination with extreme weather events has been proposed to contribute to human migration (Adger
46 et al. 2014), an issue discussed more comprehensively in this chapter (see section 4.7.3). Drivers and
47 processes of degradation by which land-based carbon is released to the atmosphere and/or the long-

1 term reduction in the capacity of the land to remove atmospheric carbon and to store this in biomass
2 and soil carbon, have been discussed in the methodological reports of IPCC (IPCC 2006, 2014a) but
3 less so in the assessment reports.

4 The Special Report on Land Use, Land-Use Change and Forestry (SR-LULUCF) (Watson et al. 2000)
5 focused on the role of the biosphere in the global cycles of greenhouse gases (GHG). Land
6 degradation was not addressed in a comprehensive way. Soil erosion was discussed as a process by
7 which soil carbon is lost and the productivity of the land is reduced. Deposition of eroded soil carbon
8 in marine sediments was also mentioned as a possible mechanism for permanent sequestration of
9 terrestrial carbon (Watson et al. 2000) (p. 194). The possible impacts of climate change on land
10 productivity and degradation were not discussed comprehensively. Much of the report was about how
11 to account for sources and sinks of terrestrial carbon under the Kyoto Protocol.

12 The IPCC Special Report on Managing the Risks of Extreme Events and Disasters to Advance
13 Climate Change Adaptation (SREX) (IPCC 2012) did not provide a definition of land degradation.
14 Nevertheless, it addressed different aspects related to some types of land degradation in the context of
15 weather and climate extreme events. From this perspective, it provided key information on both
16 observed and projected changes in weather and climate (extremes) events that are relevant to extreme
17 impacts on socio-economic systems and on the physical components of the environment, notably on
18 permafrost in mountainous areas and coastal zones for different geographic regions, but little explicit
19 links to land degradation. The report also presented the concept of sustainable land management as an
20 effective risk reduction tool.

21 Land degradation has been treated in several previous IPCC reports but mainly as an aggregated
22 concept associated with emissions of GHG or as an issue that can be addressed through adaptation
23 and mitigation.

24 **4.1.5 Sustainable land management and sustainable forest management**

25 Sustainable land management (SLM) is defined as “the stewardship and use of land resources,
26 including soils, water, animals and plants, to meet changing human needs, while simultaneously
27 ensuring the long-term productive potential of these resources and the maintenance of their
28 environmental functions” (Adapted from World Overview of Conservation Approaches and
29 Technologies, WOCAT). Achieving the objective of ensuring that productive potential is maintained
30 in the long term will require implementation of adaptive management and “triple loop learning”, that
31 seeks to monitor outcomes, learn from experience and emerging new knowledge, modifying
32 management accordingly (Rist et al. 2013).

33 Sustainable Forest Management (SFM) is defined as “the stewardship and use of forests and forest
34 lands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity,
35 vitality and their potential to fulfill, now and in the future, relevant ecological, economic and social
36 functions, at local, national, and global levels, and that does not cause damage to other ecosystems”
37 (Forest Europe 2016; Mackey et al. 2015). This SFM definition was developed by the Ministerial
38 Conference on the Protection of Forests in Europe and has since been adopted by the Food and
39 Agriculture Organization. Forest management that fails to meet these sustainability criteria can
40 contribute to land degradation. Land degradation can be reversed through restoration and
41 rehabilitation, which are defined in the Glossary, where other terms that are used but not explicitly
42 defined in this section can also be found. While the definitions of SLM and SFM are very similar and
43 could be merged, both are included to maintain the subtle differences in the existing definitions.

44 Climate change impacts interact with land management to determine sustainable or degraded outcome
45 (Figure 4.1). Climate change can exacerbate many degradation processes (Table 4.1) and introduce
46 novel ones (e.g., permafrost thawing or biome shifts). To avoid, reduce or reverse degradation, land

1 management activities can be selected to mitigate the impact of, and adapt to, climate change. In some
2 cases, climate change impacts may result in increased productivity and carbon stocks, at least in the
3 short term. For example, longer growing seasons due to climate warming can lead to higher forest
4 productivity (Henttonen et al. 2017; Kauppi et al. 2014; Dragoni et al. 2011), but warming alone
5 many not increase productivity where other factors such a water supply are limiting (Hember et al.
6 2017).

7 The types and intensity of human land-use and climate change impacts on lands affect their carbon
8 stocks and their ability to operate as carbon sinks. In managed agricultural lands, degradation can
9 result in reductions of soil organic carbon stocks, which also adversely affects land productivity and
10 carbon sinks (See Figure 4.1).

11 The transition from natural to managed forest landscapes usually results in an initial reduction of
12 landscape-level carbon stocks. The magnitude of this reduction is a function of the differential in
13 frequency of stand replacing natural disturbances (e.g. wildfires) and harvest disturbances, as well as
14 the age-dependence of these disturbances (Harmon et al. 1990; Kurz et al. 1998a; Trofymow et al.
15 2008).

16 Sustainable forest management applied at the landscape scale to existing unmanaged forests can first
17 reduce average forest carbon stocks and subsequently increase the rate at which carbon dioxide is
18 removed from the atmosphere, because net ecosystem production of forest stands is highest in
19 intermediate stand ages (Kurz et al. 2013; Volkova et al. 2018; Tang et al. 2014). The net impact on
20 the atmosphere depends on the magnitude of the reduction in carbon stocks, the fate of the harvested
21 biomass (i.e. use in short or long-lived products and for bioenergy, and therefore displacement of
22 emissions associated with GHG-intensive building materials and fossil fuels), and the rate of
23 regrowth. Thus, the impacts of sustainable forest management on one indicator (e.g., past reduction
24 in C stocks in the forested landscape) can be negative, while those on another indicator (e.g., current
25 forest productivity and rate of CO₂ removal from the atmosphere, avoided fossil fuel emissions) can
26 be positive. Sustainably managed forest landscapes can have a lower biomass carbon density than
27 unmanaged forest, but the younger forests can have a higher growth rate, and therefore contribute
28 stronger carbon sinks, than older forests (Trofymow et al. 2008; Volkova et al. 2018; Poorter et al.
29 2016).

30

1
2 **Figure 4.1** Conceptual figure illustrating that climate change impacts interact with land management to
3 determine sustainable or degraded outcome. Climate change can exacerbate many degradation processes
4 (Table 4.1) and introduce novel ones (e.g., permafrost thawing or biome shifts), hence management needs
5 to respond to climate impacts in order to avoid, reduce or reverse degradation. The types and intensity of
6 human land-use and climate change impacts on lands affect their carbon stocks and their ability to
7 operate as carbon sinks. In managed agricultural lands, degradation typically results in reductions of soil
8 organic carbon stocks, which also adversely affects land productivity and carbon sinks. In forest land,
9 reduction in biomass carbon stocks alone is not necessarily an indication of a reduction in carbon sinks.
10 Sustainably managed forest landscapes can have a lower biomass carbon density but the younger forests
11 can have a higher growth rate, and therefore contribute stronger carbon sinks, than older forests. Ranges
12 of carbon sinks in forest and agricultural lands are overlapping. In some cases, climate change impacts
13 may result in increased productivity and carbon stocks, at least in the short term.

14 Selective logging and thinning can maintain and enhance forest productivity and achieve co-benefits
15 when conducted with due care for the residual stand and at intensity and frequency that does not
16 exceed the rate of regrowth (Romero and Putz 2018). In contrast, unsustainable logging practices can
17 lead to stand-level degradation. For example, degradation occurs when selective logging (high-
18 grading) removes valuable large-diameter trees, leaving behind damaged, diseased, non-commercial
19 or otherwise less productive trees, reducing carbon stocks and also adversely affecting subsequent
20 forest recovery (Belair and Ducey 2018; Nyland 1992).

21 Sustainable forest management is defined using several criteria (see above) and its implementation
22 will typically involve trade-offs among these criteria. The conversion of primary forests to sustainably
23 managed forest ecosystems increases relevant economic, social and other functions but often with
24 adverse impacts on biodiversity (Barlow et al. 2007). In regions with infrequent or no stand replacing

1 natural disturbances, the timber yield per hectare harvested in managed secondary forests is typically
2 lower than the yield per hectare from the first harvest in the primary forest (Romero and Putz 2018).

3 The sustainability of timber yield has been achieved in temperate and boreal forests where
4 intensification of management has resulted in increased growing stocks and increased harvest rates in
5 countries where forests had previously been overexploited (Henttonen et al. 2017; Kauppi et al. 2018).
6 However, intensification of management to increase forest productivity can be associated with
7 reductions in biodiversity. For example, when increased productivity is achieved by periodic thinning
8 and removal of trees that would otherwise die due to competition, thinning reduces the amount of
9 dead organic matter of snags and coarse woody debris that can provide habitat and this loss reduces
10 biodiversity (Spence 2001; Ehnström 2001) and forest carbon stocks (Russell et al. 2015; Kurz et al.
11 2013). Recognition of adverse biodiversity impacts of high yield forestry is leading to modified
12 management aimed at increasing habitat availability through, for example, variable retention logging
13 and continuous cover management (Roberts et al. 2016) and through the re-introduction of fire
14 disturbances in landscapes where fires have been suppressed (Allen et al. 2002). Biodiversity losses
15 are also observed during the transition from primary to managed forests in tropical regions (Barlow et
16 al. 2007) where tree species diversity can be very high, e.g. in the Amazon region about 16,000 tree
17 species are estimated to exist (ter Steege et al. 2013).

18 Forest certification schemes have been used to document SFM outcomes (Rametsteiner and Simula
19 2003) by assessing a set of criteria and indicators (e.g., Lindenmayer et al. 2000). While many of the
20 certified forests are found in temperate and boreal countries (Rametsteiner and Simula 2003;
21 MacDicken et al. 2015), examples from the tropics also show that SFM can improve outcomes. For
22 example, selective logging emits 6% of the tropical GHG annually and improved logging practices
23 can reduce emissions by 44 % while maintaining timber production (Ellis et al. 2019). In the Congo
24 Basin, implementing reduced impact logging (RIL-C) practices can cut emissions in half without
25 reducing the timber yield (Umunay et al. 2019). SFM adoption depends on the socio-economic and
26 political context and its improvement depends mainly on better reporting and verification (Siry et al.
27 2005).

28 The successful implementation of SFM requires well established and functional governance,
29 monitoring, and enforcement mechanisms to eliminate deforestation, illegal logging, arson, and other
30 activities that are inconsistent with SFM principles (Nasi et al. 2011). Moreover, following human and
31 natural disturbances forest regrowth must be ensured through reforestation, site rehabilitation
32 activities or natural regeneration. Failure of forests to regrow following disturbances will lead to
33 unsustainable outcomes and long-term reductions in forest area, forest cover, carbon density, forest
34 productivity and land-based carbon sinks (Nasi et al. 2011).

35 Achieving all of the criteria of the definitions of SLM and SFM is an aspirational goal that will be
36 made more challenging where climate change impacts, such as biome shifts and increased
37 disturbances, are predicted to adversely affect future biodiversity and contribute to forest degradation
38 (Warren et al. 2018). Land management to enhance land sinks will involve trade-offs that need to be
39 assessed within their spatial, temporal and societal context.

40 **4.1.6 The human dimension of land degradation and forest degradation**

41 Studies of land and forest degradation are often biased towards biophysical aspects both in terms of its
42 processes, such as erosion or nutrient depletion, and its observed physical manifestations, such as
43 gullying or low primary productivity. Land users' own perceptions and knowledge about land
44 conditions and degradation have often been neglected or ignored by both policy makers and scientists
45 (Reed et al. 2007; Forsyth 1996; Andersson et al. 2011). A growing body of work is nevertheless
46 beginning to focus on land degradation through the lens of local land users (Kessler and Stroosnijder
47 2006; Fairhead and Scoones 2005; Zimmerer 1993; Stocking et al. 2001) and the importance of local

1 and indigenous knowledge within land management is starting to be appreciated (Montanarella et al.
2 2018). Climate change impacts directly and indirectly the social reality, the land users, and the
3 ecosystem and vice versa. Land degradation can also have an impact on climate change (see Section
4 4.6).

5 The use and management of land is highly gendered and is expected to remain so for the foreseeable
6 future (Kristjanson et al. 2017). Women have often less formal access to land than men and less
7 influence over decisions about land, even if they carry out many of the land management tasks
8 (Jerneck 2018a; Elmhirst 2011; Toulmin 2009; Peters 2004; Agarwal 1997; Jerneck 2018b). Many
9 oft-cited sweeping statements about women's subordination in agriculture are difficult to substantiate,
10 yet it is clear that gender inequality persists (Doss et al. 2015). Even if women's access to land is
11 changing formally (Kumar and Quisumbing 2015), the practical outcome is often limited due to
12 several other factors related to both formal and informal institutional arrangements and values (Lavers
13 2017; Kristjanson et al. 2017; Djurfeldt et al. 2018). Women are also affected differently than men
14 when it comes to climate change, having lower adaptive capacities due to factors such as prevailing
15 land tenure frameworks, lower access to other capital assets and dominant cultural practices (Vincent
16 et al. 2014; Antwi-Agyei et al. 2015; Gabrielsson et al. 2013). This affects the options available to
17 women to respond to both land degradation and climate change. Indeed, access to land and other
18 assets (e.g., education and training) is key in shaping land-use and land management strategies (Liu et
19 al. 2018b; Lambin et al. 2001). Young people is another category that is often disadvantaged in terms
20 of access to resources and decision making power, even though they carry out much of the day-to-day
21 work (Wilson et al. 2017; Kosec et al. 2018; Naamwintome and Bagson 2013).

22 Land rights differ between places and are dependent on the political-economic and legal context
23 (Montanarella et al. 2018). This means there is no universally applicable best arrangement.
24 Agriculture in highly erosion prone regions requires site specific and long lasting soil and water
25 conservation measures, such as terraces (see 4.8.1), which may benefit from secure private land rights
26 (Tarfasa et al. 2018; Soule et al. 2000). Pastoral modes of production and community based forest
27 management systems are often dominated by communal land tenure arrangements, which may
28 conflict with agricultural/forestry modernization policies implying private property rights (Antwi-
29 Agyei et al. 2015; Benjaminsen and Lund 2003; Itkonen 2016; Owour et al. 2011; Gebara 2018)

30 Cultural ecosystem services, defined as the non-material benefits people obtain from ecosystems
31 through spiritual enrichment, cognitive development, reflection, recreation and aesthetic experiences
32 (Millennium Assessment 2005) are closely linked to land and ecosystems, although often
33 underrepresented in the literature on ecosystem services (Tengberg et al. 2012; Hernández-Morcillo
34 et al. 2013). Climate change interacting with land conditions can impact cultural aspects, such as
35 sense of place and sense of belonging (Olsson et al. 2014).

36 **4.2 Land degradation in the context of climate change**

37 Land degradation results from a complex chain of causes making the clear distinction between direct
38 and indirect drivers difficult. In the context of climate change, an additional complex aspect is brought
39 by the reciprocal effects that both processes have on each other (i.e. climate change influencing land
40 degradation and vice versa). In this chapter, we use the terms processes and drivers with the following
41 meanings:

42 **Processes of land degradation** are those direct mechanisms by which land is degraded and are
43 similar to the notion of "direct drivers" in the Millennium Ecosystem Assessment (MA, Millennium
44 Ecosystem Assessment, 2005) framework. In this report, a comprehensive list of land degradation
45 processes is presented in Table 4.1.

1 **Drivers of land degradation** are those indirect conditions which may drive processes of land
2 degradation and are similar to the notion of “indirect drivers” in the MA framework. Examples of
3 indirect drivers of land degradation are changes in land tenure or cash crop prices, which can trigger
4 land-use or management shifts that affect land degradation.

5 An exact demarcation between processes and drivers is not possible. Drought and fires are described
6 as drivers of land degradation in the next section but they can also be a process: for example, if
7 repeated fires deplete seed sources they can affect regeneration and succession of forest ecosystems.
8 The responses to land degradation follow the logic of the Land Degradation Neutrality concept:
9 avoiding, reducing and reversing land degradation (Orr et al. 2017b; Cowie et al. 2018).

10 In research on land degradation, climate and climate variability are often intrinsic factors. The role of
11 climate change, however, is less articulated. Depending on what conceptual framework is used,
12 climate change is understood either as a process or a driver of land degradation, and sometimes both.

13 **4.2.1 Processes of land degradation**

14 A large array of interactive physical, chemical, biological and human processes led to what we define
15 in this report as land degradation (Johnson and Lewis 2007). The biological productivity, ecological
16 integrity (which encompasses both functional and structural attributes of ecosystems) or the human
17 value (which includes any benefit that people get from the land) of a given territory can deteriorate as
18 the result of processes triggered at scales that range from a single furrow (e.g., water erosion under
19 cultivation) to the landscape level (e.g., salinisation through raising groundwater levels under
20 irrigation). While pressures leading to land degradation are often exerted on specific components of
21 the land systems (i.e., soils, water, biota), once degradation processes start, other components become
22 affected through cascading and interactive effects. For example, different pressures and degradation
23 processes can have convergent effects, as can be the case of overgrazing leading to wind erosion,
24 landscape drainage resulting in wetland drying, and warming causing more frequent burning; all of
25 which can independently lead to reductions of the soil organic matter pools as second order process.
26 Still, the reduction of organic matter pools is also a first order process triggered directly by the effects
27 of rising temperatures (Crowther et al., 2016) as well as other climate changes such as precipitation
28 shifts (Viscarra Rossel et al. 2014). Beyond this complexity, a practical assessment of the major land
29 degradation processes helps to reveal and categorise the multiple pathways in which climate change
30 exerts a degradation pressure (Table 4.1).

31 Conversion of freshwater wetlands to agricultural land has historically been a common way of
32 increasing the area of arable land. Despite the small areal extent (~1% of the earth’s surface (Hu et al.
33 2017; Dixon et al. 2016)), freshwater wetlands provide a very large number of ecosystem services,
34 such as groundwater replenishment, flood protection, and nutrient retention, and are biodiversity
35 hotspots (Reis et al. 2017; Darrah et al. 2019; Montanarella et al. 2018). The loss of wetlands since
36 1900 has been estimated at ~55% globally (Davidson 2014) (*low confidence*) and 35% since 1970
37 (Darrah et al. 2019) (*medium confidence*) which in many situations pose a problem for adaptation to
38 climate change. Drainage causes loss of wetlands, which can be further exacerbated by climate
39 change, and reduces the capacity to adapt to climate change (Barnett et al. 2015; Colloff et al. 2016;
40 Finlayson et al. 2017) (*high confidence*).

41 **4.2.1.1 Types of land degradation processes**

42 Land degradation processes can affect the soil, water or biotic components of the land or in their
43 respective interfaces (Table 4.1). Across land degradation processes, those affecting the soil have
44 received more attention. The most widespread and studied land degradation processes affecting soils
45 are water and wind erosion, which have accompanied agriculture since its onset and are still dominant
46 (Table 4.1). Degradation through erosion processes is not restricted to soil loss in detachment areas
47 but includes impacts on transport and deposition areas as well (less commonly, deposition areas can

1 have their soils improved by these inputs). Larger scale degradation processes related to the whole
2 continuum of soil erosion, transport and deposition include dune field expansion/displacement,
3 development of gully networks and the accumulation of sediments (siltation) of natural and artificial
4 water bodies (Poesen and Hooke 1997; Ravi et al. 2010). Long-distance sediment transport during
5 erosion events can have remote effects on land systems as documented for the fertilisation effect of
6 African dust on the Amazon (Yu et al. 2015).

7 Coastal erosion represents a special case among erosional, with reports linking it to climate change.
8 While human interventions in coastal areas (e.g., expansion of shrimp farms) and rivers (e.g.,
9 upstream dams cutting coastal sediment supply), and economic activities causing land subsidence
10 (Keogh and Törnqvist 2019; Allison et al. 2016) are dominant human drivers, storms and sea level
11 rise have already left a significant global imprint on coastal erosion (Mentaschi et al. 2018). Recent
12 projections that take into account geomorphological and socioecological feedbacks suggest that
13 coastal wetlands may not get reduced by sea level rise if their inland growth is accommodated with
14 proper management actions (Schuerch et al. 2018a).

15 Other physical degradation process in which no material detachment and transport are involved
16 include soil compaction, hardening, sealing and any other mechanism leading to the loss of porous
17 space crucial for holding and exchanging air and water (Hamza and Anderson 2005). A very extreme
18 case of degradation through pore volume loss, manifested at landscape or larger scales, is ground
19 subsidence. Typically caused by the lowering of groundwater or oil levels, subsidence involves a
20 sustained collapse of the ground surface, which can lead to other degradation processes such as
21 salinisation and permanent flooding. Chemical soil degradation processes include relatively simple
22 changes, like nutrient depletion resulting from the imbalance of nutrient extraction on harvested
23 products and fertilisation, and more complex ones, such as acidification and increasing metal toxicity.
24 Acidification in croplands is increasingly driven by excessive nitrogen fertilisation and to a lower
25 extent by the depletion of cation like calcium, potassium or magnesium through exports in harvested
26 biomass (Guo et al. 2010). One of the most relevant chemical degradation processes of soils in the
27 context of climate change is the depletion of its organic matter pool. Reduced in agricultural soils
28 through the increase of respiration rates by tillage and the decline of belowground plant biomass
29 inputs, soil organic matter pools have been diminished also by the direct effects of warming, not only
30 in cultivated land but also under natural vegetation (Bond-Lamberty et al. 2018). Debate persists,
31 however, on whether in more humid and carbon rich ecosystems the simultaneous stimulation of
32 decomposition and productivity may result in the lack of effects on soil carbon (Crowther et al. 2016;
33 van Gestel et al. 2018). In the case of forests, harvesting, particularly if it is exhaustive as in the case
34 of the use of residues for energy generation, can also lead to organic matter declines (Achat et al.
35 2015). Affected by many other degradation processes (e.g. wildfire increase, salinisation) and having
36 negative effects on other pathways of soil degradation (e.g. reduced nutrient availability, metal
37 toxicity). Soil organic matter can be considered a “hub” of degradation processes and a critical link
38 with the climate system (Minasny et al. 2017).

39 Land degradation processes can also start from alterations in the hydrological system that are
40 particularly important in the context of climate change. Salinisation, although perceived and reported
41 in soils, is typically triggered by water table-level rises driving salts to the surface under dry to sub-
42 humid climates (Schofield and Kirkby 2003). While salty soils occur naturally under these climates
43 (primary salinity), human interventions have expanded their distribution (secondary salinity with
44 irrigation without proper drainage being the predominant cause of salinisation (Rengasamy 2006).
45 Yet, it has also taken place under non-irrigated conditions where vegetation changes (particularly dry
46 forest clearing and cultivation) had reduced the magnitude and depth of soil water uptake, triggering
47 water table rises towards the surface. Changes in evapotranspiration and rainfall regimes can
48 exacerbate this process (Schofield and Kirkby 2003). Salinisation can also result from the intrusion of

1 sea water into coastal areas both as a result of sea level rise and ground subsidence (Colombani et al.
2 2016).

3 Recurring flood and waterlogging episodes (Bradshaw et al. 2007; Poff 2002), and the more chronic
4 expansion of wetlands over dryland ecosystems are mediated by the hydrological system, on
5 occasions aided by geomorphological shifts as well (Kirwan et al. 2011). This is also the case for the
6 drying of continental water bodies and wetlands, including the salinisation and drying of lakes and
7 inland seas (Anderson et al. 2003; Micklin 2010; Herbert et al. 2015). In the context of climate
8 change, the degradation of peatland ecosystems is particularly relevant given their very high carbon
9 storage and their sensitivity to changes in soils, hydrology and/or vegetation (Leifeld and Menichetti
10 2018). Drainage for land-use conversion together with peat mining are major drivers of peatland
11 degradation, yet other factors such as the extractive use of their natural vegetation and the interactive
12 effects of water table levels and fires (both sensitive to climate change) are important (Hergoualc'h et
13 al. 2017a; Lilleskov et al. 2019).

14 The biotic components of the land can also be the focus of degradation processes. Vegetation clearing
15 processes associated with land-use changes are not limited to deforestation but include other natural
16 and seminatural ecosystems such as grasslands (the most cultivated biome on Earth), as well as dry
17 steppes and shrublands, which give place to croplands, pastures, urbanisation or just barren land. This
18 clearing process is associated with net C losses from the vegetation and soil pool. Not all biotic
19 degradation processes involve biomass losses. Woody encroachment of open savannahs involve the
20 expansion of woody plant cover and/or density over herbaceous areas and often limits the secondary
21 productivity of rangelands (Asner et al. 2004, Anadon et al. 2014). These processes have been
22 accelerated since the mid-1800s over most continents (Van Auken 2009). Change in plant
23 composition of natural or semi-natural ecosystems without any significant vegetation structural
24 changes is another pathway of degradation affecting rangelands and forests. In rangelands, selective
25 grazing and its interaction with climate variability and/or fire can push ecosystems to new
26 compositions with lower forage value and higher proportion of invasive species (Illius and O'Connor
27 1999, Sasaki et al. 2007), in some cases with higher carbon sequestration potential, yet with very
28 complex interactions between vegetation and soil carbon shifts (Piñeiro et al. 2010). In forests,
29 extractive logging can be a pervasive cause of degradation leading to long-term impoverishment and
30 in extreme cases, a full loss of the forest cover through its interaction with other agents such as fires
31 (Foley et al. 2007) or progressive intensification of land use. Invasive alien species are another source
32 of biological degradation. Their arrival into cultivated systems is constantly reshaping crop production
33 strategies making agriculture unviable on occasions. In natural and seminatural systems such as
34 rangelands, invasive plant species not only threaten livestock production through diminished forage
35 quality, poisoning and other deleterious effects, but have cascading effects on other processes such as
36 altered fire regimes and water cycling (Brooks et al. 2004). In forests, invasions affect primary
37 productivity and nutrient availability, change fire regimes, and alter species composition, resulting in
38 long term impacts on carbon pools and fluxes (Peltzer et al. 2010).

39 Other biotic components of ecosystems have been shown as a focus of degradation processes.
40 Invertebrate invasions in continental waters can exacerbate other degradation processes such as
41 eutrophication, which is the over enrichment of nutrients leading to excessive algal growth (Walsh et
42 al. 2016a). Shifts in soil microbial and mesofaunal composition, which can be caused by pollution
43 with pesticides or nitrogen deposition but also by vegetation or disturbance regime shifts, alter many
44 soil functions including respiration rates and C release to the atmosphere (Hussain et al. 2009;
45 Crowther et al. 2015). The role of the soil biota modulating the effects of climate change on soil
46 carbon have been recently demonstrated (Ratcliffe et al. 2017), highlighting the importance of this
47 less known component of the biota as a focal point of land degradation. Of special relevance as both
48 indicators and agents of land degradation recovery are mycorrhiza, which are root associated fungal

1 organisms (Asmelash et al. 2016; Vasconcellos et al. 2016). In natural dry ecosystems, biological soil
2 crusts composed by a broad range of organisms including mosses are a particularly sensitive focus for
3 degradation (Field et al. 2010) with evidenced sensitivity to climate change (Reed et al. 2012).

4 **4.2.1.2 Land degradation processes and climate change**

5 While the subdivision of individual processes is challenged by their strong interconnectedness, it
6 provides a useful setting to identify the most important “focal points” of climate change pressures on
7 land degradation. Among land degradation processes those responding more directly to climate
8 change pressures include all types of erosion and soil organic matter declines (soil focus), salinisation,
9 sodification and permafrost thawing (soil/water focus), waterlogging of dry ecosystems and drying of
10 wet ecosystems (water focus), and a broad group of biological mediated processes like woody
11 encroachment, biological invasions, pest outbreaks (biotic focus), together with biological soil crust
12 destruction and increased burning (soil/biota focus) (Table 4.1). Processes like ground subsidence can
13 be affected by climate change indirectly through sea level rise (Keogh and Törnqvist 2019).

14 Even when climate change exerts a direct pressure on degradation processes, it can be a secondary
15 driver subordinated to other overwhelming human pressures. Important exceptions are three processes
16 in which climate change is a dominant global or regional pressure and the main driver of their current
17 acceleration. These are coastal erosion as affected by sea level rise and increased storm
18 frequency/intensity (*high agreement, medium evidence*) (Johnson et al. 2015; Alongi 2015; Harley et
19 al. 2017a; Nicholls et al. 2016), permafrost thawing responding to warming (*high agreement, robust
20 evidence*) (Liljedahl et al. 2016; Peng et al. 2016; Batir et al. 2017) and increased burning responding
21 to warming and altered precipitation regimes (*high agreement, robust evidence*) (Jolly et al. 2015;
22 Abatzoglou and Williams 2016; Taufik et al. 2017; Knorr et al. 2016). The previous assessment
23 highlights the fact that climate change not only exacerbates many of the well acknowledged ongoing
24 land degradation processes of managed ecosystems (i.e., croplands and pastures), but becomes a
25 dominant pressure that introduces novel degradation pathways in natural and seminatural ecosystems.
26 Climate change has influenced species invasions and the degradation that they cause by enhancing the
27 transport, colonisation, establishment, and ecological impact of the invasive species, but also by
28 impairing their control practices (*medium agreement, medium evidence*) (Hellmann et al. 2008).

1 **Table 4.1 Major land degradation processes and their connections with climate change.** For each process a “focal point” (soil, water, biota) on which degradation
 2 occurs first place is indicated, acknowledging that most processes propagate to other land components and cascade into or interact with some of the other processes
 3 listed below. The impact of climate change on each process is categorised based on the proximity (very direct = high, very indirect=low) and dominance
 4 (dominant=high, subordinate to other pressures = low) of effects. The major effects of climate change on each process are highlighted together with the
 5 predominant pressures from other drivers. Feedbacks of land degradation processes on climate change are categorized according to the intensity (very
 6 intense=high, subtle=low) of the chemical (greenhouse gases emissions or capture) or physical (energy and momentum exchange, aerosol emissions) effects.
 7 Warming effects are indicated in red and cooling effects in blue. Specific feedbacks on climate change are highlighted.

Processes	Focal point	Impacts of Climate Change		Feedbacks on Climate Change					
		proximity	dominance	intensity of chemical effects	intensity of physical effects	global extent	Specific Impacts		
Wind erosion	Soil	high	medium	Climate Change pressures Altered wind/drought patterns (<i>high confidence</i> on effect, <i>medium-low confidence</i> on trend) (1). Indirect effect through vegetation type and biomass production shifts	Other pressures Tillage, leaving low cover, overgrazing, deforestation/vegetation clearing, large plot sizes, vegetation and fire regime shifts	low	medium	high	Radiative cooling by dust release (<i>medium confidence</i>). Ocean and land fertilisation and C burial (<i>medium confidence</i>). Albedo increase. Dust effect as condensation nuclei (19).
Water erosion	Soil	high	medium	Increasing rainfall intensity (<i>high confidence</i> on effect and trend) (2). Indirect effects on fire frequency/intensity, permafrost thawing, biomass production.	Tillage, cultivation leaving low cover, overgrazing, deforestation/vegetation clearing, vegetation burning, poorly designed roads and paths.	medium	medium	high	Net C release. Net release is probably less than site-specific loss due to deposition and burial (<i>high confidence</i>). Albedo increase (20).
Coastal erosion	Soil/Water	high	high	Sea level rise, increasing intensity/frequency of storm surges (<i>high confidence</i> on effects and trends)(3)	Retention of sediments by upstream dams, Coastal aquaculture, Elimination of mangrove forests, Subsidence	high	low	low	Release of old buried C pools (<i>medium confidence</i>)(21).

Subsidence	Soil/Water	low	low	Indirect through increasing drought leading to higher ground water use. Indirect through enhanced decomposition (e.g. through drainage) in organic soils.	Groundwater depletion / overpumping. Peatland drainage.	low/high	low	low	Unimportant in the case of groundwater depletion. Very high net C release in the case of drained peatlands
Compaction/Hardening	Soil	low	low	Indirect through reduced organic matter content.	Land use conversion, machinery overuse, intensive grazing, poor tillage/grazing management (e.g. under wet or waterlogged conditions)	low	low	medium	Contradictory effects of reduced aeration on N ₂ O emissions
Nutrient depletion	Soil	low	low	Indirect (e.g. shifts in cropland distribution, BECCS)	Insufficient replenishment of harvested nutrients	low	low	medium	Net C release due shrinking SOC pools. Larger reliance on soil liming with associated CO ₂ releases.
Acidification/Overfertilisation	Soil	low	low	Indirect (e.g. shifts in cropland distribution, BECCS). Sulfidic wetland drying due to increased drought as special direct effect.	High N fertilisation. High cation depletion. Acid rain/deposition	medium	low	medium	N ₂ O release from overfertilised soils, increased by acidification. Inorganic C release from acidifying soils (<i>medium to high confidence</i>) (22).
Pollution	Soil/Biota	low	low	Indirect (e.g. increased pest and weed incidence)	Intensifying chemical control of weed and pests	low	low	medium	Unknown, probably unimportant.
Organic matter decline	Soil	high	medium	Warming accelerates soil respiration rates (<i>medium confidence</i> on effects and trends) (4). Indirect effects through changing quality of plant litter or fire/waterlogging regimes.	Tillage. reduced plant input to soil. Drainage of waterlogged soils. Influenced by most of the other soil degradation processes.	high	low	high	Net C release (<i>high confidence</i>)(23).
Metal toxicity	Soil	low	low	Indirect	High cation depletion, fertilisation, mining activities	low	low	low	unknown, probably unimportant.

Salinisation	Soil / Water	High	low	Sea level rise (<i>high confidence</i> on effects and trends) (5). Water balance shifts (<i>medium confidence</i> on effects and trends) (6). Indirect effects through irrigation expansion.	Irrigation without good drainage infrastructure. Deforestation and water table level raises under dryland agriculture	low	medium	medium	Reduced methane emissions with high sulfate load. Albedo increase.
Sodification (increased sodium and associated physical degradation in soils)	Soil / Water	High	low	Water balance shifts (<i>medium confidence</i> on effects and trends) (7). Indirect effects through irrigation expansion.	Poor water management	low	medium	low	Net C release due to soil structure and organic matter dispersion. Albedo increase.
Permafrost thawing	Soil / Water	High	high	Warming (<i>very high confidence</i> on effects and trends) (8), seasonality shifts and accelerated snow melt leading to higher erosivity.		high	low	high	Net C release. CH ₄ release (<i>high confidence</i>)(24).
Waterlogging of dry systems	Water	High	medium	Water balance shifts (<i>medium confidence</i> on effects and trends) (9). Indirect effects through vegetation shifts.	Deforestation. Irrigation without good drainage infrastructure	medium	medium	low	CH ₄ release. Albedo decrease
Drying of continental waters/wetland/lowlands	Water	High	medium	Increasing extent and duration of drought (<i>high confidence</i> on effects, <i>medium confidence</i> on trends) (10). Indirect effects through vegetation shifts.	Upstream surface and groundwater water consumption. Intentional drainage. Trampling/overgrazing.	medium	medium	medium	Net C release. N ₂ O release. Albedo increase
Flooding	Water	High	medium	Sea level raise, increasing intensity/frequency of storm surges, increasing rainfall intensity causing flash floods (<i>high confidence</i> on effects and trends)(11).	Land clearing. Increasing impervious surface. Transport infrastructure.	medium	medium	low	CH ₄ and N ₂ O release. Albedo decrease
Eutrophication of continental waters	Water/Biota	Low	low	Indirect through warming effects on N losses from the land or climate change effects on erosion rates. Interactive effects of warming and nutrient loads on algal blooms.	Excess fertilisation. Erosion. Poor management of livestock/human sewage.	medium	low	low	CH ₄ and N ₂ O release.

Woody encroachment	Biota	High	medium	Rainfall shifts (<i>medium confidence</i> on effects and trends), CO ₂ rise (<i>medium confidence</i> on effects, <i>very high confidence</i> on trends)(12).	Overgrazing. Altered fire regimes, fire suppression. Invasive alien species.	high	high	high	Net C storage. Albedo decrease
Species loss, compositional shifts	Biota	High	medium	Habitat loss as a result of climate shifts (<i>medium confidence</i> on effects and trends) (13).	Selective grazing and logging causing plant species loss, Pesticides causing soil microbial and soil faunal losses, Large animal extinctions, Interruption of disturbance regimes	low	low	medium	Unknown.
Soil microbial and mesofaunal shifts	Biota	High	low	Habitat loss as a result of climate shifts (<i>medium confidence</i> on effects and trends) (14).	Altered fire regimes, nitrogen deposition, pesticide pollution, vegetation shifts, disturbance regime shifts	low	low	medium	Unknown.
Biological soil crust destruction	Biota/Soil	High	medium	Warming. Changing rainfall regimes. (<i>medium confidence</i> on effects, high confidence and trends). Indirect through fire regime shifts and/or invasions (15).	Overgrazing and trampling. Land use conversion.	low	high	high	Radiative cooling through albedo rise and dust release (<i>high confidence</i>)(25).
Invasions	Biota	High	medium	Habitat gain as a result of climate shifts (<i>medium confidence</i> on effects and trends) (16).	Intentional and unintentional species introductions.	low	low	medium	Unknown.
Pest outbreaks	Biota	High	medium	Habitat gain and accelerated reproduction as a result of climate shifts (<i>medium confidence</i> on effects and trends) (17).	Large scale monocultures. Poor pest management practices.	medium	low	medium	Net C release.

Increased burning	Soil/Biota	High	high	Warming, drought, shifting precipitation regimes, also wet spells rising fuel load. (<i>high confidence</i> on effects and trends) (18).	Fire suppression policies increasing wildfire intensity. Increasing use of fire for rangeland management. Agriculture introducing fires in humid climates without previous fire history. Invasions.	high	medium	medium	Net C release. CO, CH ₄ , N ₂ O release. Albedo increase. (<i>high confidence</i>). Long term decline of NPP in non-adapted ecosystems (26).

1 4.2.2 Drivers of land degradation

2 Drivers of land degradation and land improvement are many and they interact in multiple ways.
 3 Figure 4.2, illustrates how some of the most important drivers interact with the land users. It is
 4 important to keep in mind that both natural and human factors can drive both degradation and
 5 improvement (Kiage 2013; Bisaro et al. 2014).

6

7 **Figure 4.2 Schematic representation of the interactions between the human and environmental**
 8 **components of the land system showing decision making and ecosystem services as the key linkages**
 9 **between the components (moderated by an effective system of local and scientific knowledge), and**
 10 **indicating how the rates of change and the way these linkages operate must be kept broadly in balance for**
 11 **functional coevolution of the components. Modified with permission from (Stafford Smith et al. 2007).**

12 Land degradation is driven by the entire spectrum of factors, from very short and intensive events
 13 such as individual rain storms of 10 minutes removing topsoil or initiating a gully or a landslide
 14 (Coppus and Imeson 2002; Morgan 2005b) to century scale slow depletion of nutrients or loss of soil
 15 particles (Johnson and Lewis 2007, p. 5-6). But instead of focusing on absolute temporal variations,
 16 the drivers of land degradation can be assessed in relation to the rates of possible recovery.
 17 Unfortunately, this is impractical to do in a spatially explicit way because rates of soil formation is
 18 difficult to measure due the slow rate, usually < 5mm/century (Delgado and Gómez 2016). Studies
 19 suggest that erosion rates of conventionally tilled agricultural fields exceed the rate at which soil is
 20 generated by one to two orders of magnitude (Montgomery 2007a).

21 The landscape effects of gully erosion from one short intensive rainstorm can persist for decades and
 22 centuries (Showers 2005). Intensive agriculture under the Roman Empire in occupied territories in
 23 France is still leaving its marks and can be considered an example of irreversible land degradation
 24 (Dupouey et al. 2002).

25 The climate change related drivers of land degradation are both gradual changes of temperature,
 26 precipitation, and wind as well as changes of the distribution and intensity of extreme events (Lin et
 27 al. 2017). Importantly, these drivers can act in two directions: land improvement and land

1 degradation. Increasing CO₂ levels in the atmosphere is a driver of land improvement even if the net
2 effect is modulated by other factors, such as the availability of nitrogen (Terrer et al. 2016) and water
3 (Gerten et al. 2014; Settele et al. 2015; Girardin et al. 2016).

4 The gradual and planetary changes that can cause land degradation/improvement have been studied by
5 global integrated models and Earth observation technologies. Studies of global land suitability for
6 agriculture suggest that climate change will increase the area suitable for agriculture by 2100 in the
7 Northern high latitudes by 16% (Ramankutty et al. 2002) or 5.6 million km² (Zabel et al. 2014), while
8 tropical regions will experience a loss (Ramankutty et al. 2002; Zabel et al. 2014).

9 Temporal and spatial patterns of tree mortality can be used as an indicator of climate change impacts
10 on terrestrial ecosystems. Episodic mortality of trees occur naturally even without climate change, but
11 more widespread spatio-temporal anomalies can be a sign of climate induced degradation (Allen et al.
12 2010). In the absence of systematic data on tree mortality, a comprehensive meta-analysis of 150
13 published articles suggests that increasing tree mortality around the world can be attributed to
14 increasing drought and heat stress in forests worldwide (Allen et al. 2010).

15 Other and more indirect drivers can be a wide range of factors such as demographic changes,
16 technological change, changes of consumption patterns and dietary preferences, political and
17 economic changes, and social changes (Mirzabaev et al. 2016). It is important to stress that there are
18 no simple or direct relationships between underlying drivers and land degradation, such as poverty or
19 high population density, that are necessarily causing land degradation (Lambin et al. 2001). However,
20 drivers of land degradation need to be studied in the context of spatial, temporal, economic,
21 environmental and cultural aspects (Warren 2002). Some analyzes suggest an overall negative
22 correlation between population density and land degradation (Bai et al. 2008) but we find many local
23 examples of both positive and negative relationships (Brandt et al. 2018a, 2017). Even if there are
24 correlations in one or the other direction, causality is not always the same.

25 Land degradation is inextricably linked to several climate variables, such as temperature,
26 precipitation, wind, and seasonality. This means that there are many ways in which climate change
27 and land degradation are linked. The linkages are better described as a web of causality than a set of
28 cause – effect relationships.

29 **4.2.3 Attribution in the case of land degradation**

30 The question here is whether or not climate change can be attributed to land degradation and vice
31 versa. Land degradation is a complex phenomenon often affected by multiple factors such as climatic
32 (rainfall, temperature, and wind), abiotic ecological factors (e.g. soil characteristics and topography),
33 type of land use (e.g. farming of various kinds, forestry, or protected area), and land management
34 practices (e.g. tilling, crop rotation, and logging/thinning). Therefore, attribution of land degradation
35 to climate change is extremely challenging. Because land degradation is highly dependent on land
36 management, it is even possible that climate impacts would trigger land management changes
37 reducing or reversing land degradation, sometimes called transformational adaptation (Kates et al.
38 2012). There is not much research on attributing land degradation explicitly to climate change, but
39 there is more on climate change as a threat multiplier for land degradation. However, it is in some
40 cases possible to infer climate change impacts on land degradation both theoretically and empirically.
41 Section 4.2.3.1 will outline the potential direct linkages of climate change on land degradation based
42 on current theoretical understanding of land degradation processes and drivers. Section 4.2.3.2 will
43 investigate possible indirect impacts on land degradation.

44 **4.2.3.1 Direct linkages with climate change**

45 The most important direct impacts of climate change on land degradation are the results of increasing
46 temperatures, changing rainfall patterns, and intensification of rainfall. These changes will in various

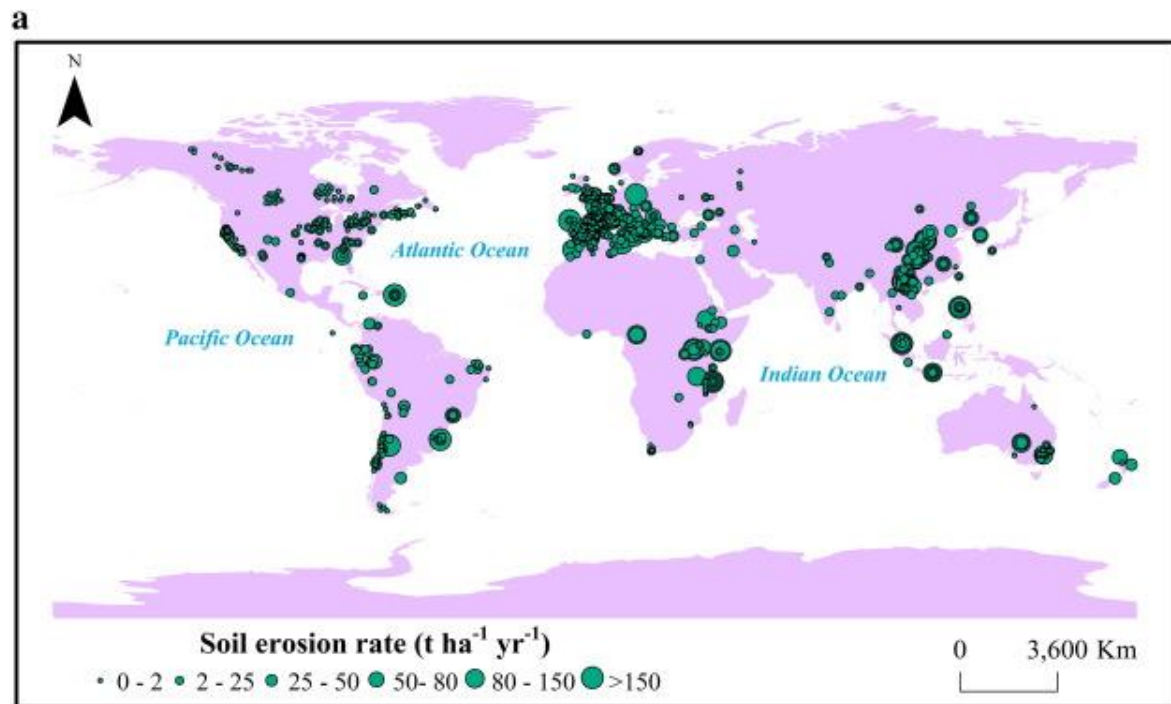

1 combinations cause changes in erosion rates and the processes driving both increases and decreases of
2 soil erosion. From an attribution point of view, it is important to note that projections of precipitation
3 are in general more uncertain than projections of temperature changes (Murphy et al. 2004; Fischer
4 and Knutti 2015; IPCC 2013a). Precipitation involves local processes of larger complexity than
5 temperature and projections are usually less robust than those for temperature (Giorgi and Lionello
6 2008; Pendergrass 2018).

7 Theoretically the intensification of the hydrological cycle as a result of human induced climate change
8 is well established (Guerreiro et al. 2018; Trenberth 1999; Pendergrass et al. 2017; Pendergrass and
9 Knutti 2018) and also empirically observed (Blenkinsop et al. 2018; Burt et al. 2016a; Liu et al. 2009;
10 Bindoff et al. 2013). AR5 WGI concluded that heavy precipitation events have increased in
11 frequency, intensity, and/or amount since 1950 (*likely*) and that further changes in this direction are
12 *likely to very likely* during the 21st century (IPCC 2013). The IPCC Special Report on 1.5°C
13 concluded that human-induced global warming has already caused an increase in the frequency,
14 intensity and/or amount of heavy precipitation events at the global scale (Hoegh-Guldberg et al.
15 2018). As an example, in central India, there has been a threefold increase in widespread extreme rain
16 events during 1950–2015 which has influenced several land degradation processes, not least soil
17 erosion (Burt et al. 2016b). In Europe and North America, where observation networks are dense and
18 having long time series, it is *likely* that the frequency or intensity of heavy rainfall have increased
19 (IPCC 2013b). It is also expected that seasonal shifts and cycles such as monsoons and ENSO (see
20 Glossary) will further increase the intensity of rainfall events (IPCC 2013).

21 When rainfall regimes change, it is expected to drive changes in vegetation cover and composition,
22 which may be a cause of land degradation in and of itself, as well as impacting other aspects of land
23 degradation. Vegetation cover, for example is a key factor in determining soil loss through both water
24 (Nearing et al. 2005) and wind erosion (Shao 2008). Changing rainfall regimes also affect below-
25 ground biological processes, such as fungi and bacteria (Meisner et al. 2018; Shuab et al. 2017;
26 Asmelash et al. 2016).

27 Changing snow accumulation and snow melt alter both volume and timing of hydrological flows in
28 and from mountain areas (Brahney et al. 2017; Lutz et al. 2014), with potentially large impacts on
29 downstream areas. Soil processes are also affected by changing snow conditions by affecting the
30 partitioning between evaporation and streamflow and between subsurface flow and surface runoff
31 (Barnhart et al. 2016). Rainfall intensity is a key climatic driver of soil erosion. Early modelling
32 studies and theory suggest that light rainfall events will decrease while heavy rainfall events increase
33 at about 7% per degree of warming (Liu et al. 2009; Trenberth 2011). Such changes result in increases
34 in the intensity of rainfall which increase the erosive power of rainfall (erosivity) and hence increase
35 the likelihood of water erosion. Increases in rainfall intensity can even exceed the rate of increase of
36 atmospheric moisture content (Liu et al. 2009; Trenberth 2011). Erosivity is highly correlated to the
37 product of total rainstorm energy and the maximum 30 minute rainfall intensity of the storm (Nearing
38 et al. 2004a) and increases of erosivity will exacerbate water erosion substantially (Nearing et al.
39 2004a). However, the effects will not be uniform but highly variable across regions (Almagro et al.
40 2017; Mondal et al. 2016). Several empirical studies around the world have shown the increasing
41 intensity of rainfall (IPCC 2013b; Ma et al. 2015, 2017) and also suggest that this will be accentuated
42 with future increasing warming (Cheng and AghaKouchak 2015; Burt et al. 2016b; O’Gorman 2015).

43 The very comprehensive database of direct measurements of water erosion presented by García-Ruiz
44 et al. (2015) contains 4377 entries (North America: 2776, Europe: 847, Asia: 259, Latin America:
45 237, Africa: 189, Australia & Pacific: 67), even though not all entries are complete (Figure 4.3).

1
2 **Figure 4.3. Map of observed soil erosion rates in database of 4377 entries by García-Ruiz et al., 2015).**
3 **The map was published by (Li and Fang 2016).**

4 An important finding from that database is that almost any erosion rate is possible under almost any
5 climatic condition (García-Ruiz et al. 2015). Even if the results show few clear relationships between
6 erosion and land conditions, the authors highlighted four observations: 1) the highest erosion rates
7 were found in relation to agricultural activities – even though moderate erosion rates were also found
8 in agricultural settings, 2) high erosion rates after forest fires were not observed (although the cases
9 were few), 3) land covered by shrubs showed generally low erosion rates, 4) pasture land showed
10 generally medium rates of erosion. Some important findings for the link between soil erosion and
11 climate change can be noted from erosion measurements: erosion rates tend to increase with
12 increasing mean annual rainfall, with a peak in the interval of 1000 to 1400 mm annual rainfall
13 (García-Ruiz et al. 2015) (*low confidence*). However, such relationships are overshadowed by the fact
14 that most rainfall events do not cause any erosion, instead erosion is caused by a few high intensity
15 rainfall events (Fischer et al. 2016; Zhu et al. 2019). Hence mean annual rainfall is not a good
16 predictor of erosion (Gonzalez-Hidalgo et al. 2012, 2009). In the context of climate change, it means
17 the tendency of rainfall patterns to change towards more intensive precipitation events is serious. Such
18 patterns have already been observed widely, even in cases where the total rainfall is decreasing
19 (Trenberth 2011). The findings generally confirm the strong consensus about the importance of
20 vegetation cover as a protection against soil erosion, emphasising how extremely important land
21 management is for controlling erosion.

22 In the Mediterranean region, the observed and expected decrease in annual rainfall due to climate
23 change is accompanied by an increase of rainfall intensity and hence erosivity (Capolongo et al.
24 2008). In tropical and sub-tropical regions, the on-site impacts of soil erosion dominate, and are
25 manifested in very high rates of soil loss, in some cases exceeding $100 \text{ t ha}^{-1} \text{ yr}^{-1}$ (Tadesse 2001;
26 García-Ruiz et al. 2015). In temperate regions, the off-site costs of soil erosion are often a greater
27 concern, for example siltation of dams and ponds, downslope damage to property, roads and other
28 infrastructure (Boardman 2010). In cases where water erosion occurs the down-stream effects, such as
29 siltation of dams, are often significant and severe in terms of environmental and economic damages

1 (Kidane and Alemu 2015; Reinwarth et al. 2019; Quiñonero-Rubio et al. 2016; Adeogun et al. 2018;
2 Ben Slimane et al. 2016).

3 The distribution of wet and dry spells also affects land degradation although uncertainties remain
4 depending on resolution of climate models used for prediction (Kendon et al. 2014). Changes in
5 timing of rainfall events may have significant impacts on processes of soil erosion through changes in
6 wetting and drying of soils (Lado et al. 2004).

7 Soil moisture content is affected by changes in evapotranspiration and evaporation which may
8 influence the partitioning of water into surface and subsurface runoff (Li and Fang 2016; Nearing et
9 al. 2004b). This partitioning of rainfall can have a decisive effect on erosion (Stocking et al. 2001).

10 Wind erosion is a serious problem in agricultural regions, not only in drylands (Wagner 2013). Near-
11 surface wind speeds over land areas have decreased in recent decades (McVicar and Roderick 2010),
12 partly as a result of changing surface roughness (Vautard et al. 2010). Theoretically (Bakun 1990;
13 Bakun et al. 2015) and empirically (Sydeman et al. 2014; England et al. 2014) mean winds along
14 coastal regions worldwide have increased with climate change (*medium evidence, high agreement*).
15 Other studies of wind and wind erosion have not detected any long-term trend suggesting that climate
16 change has altered wind patterns outside drylands in a way that can significantly affect the risk of
17 wind erosion (Pryor and Barthelmie 2010; Barring et al. 2003). Therefore, the findings regarding wind
18 erosion and climate change are inconclusive, partly due to inadequate measurements.

19 Global mean temperatures are rising worldwide, but particularly in the Arctic region (*high*
20 *confidence*) (IPCC 2018a). Heat stress from extreme temperatures and heatwaves (multiple days of
21 hot weather in a row) have increased markedly in some locations in the last three decades (*high*
22 *confidence*), and are *virtually certain* to continue during the 21st century (Olsson et al. 2014a). The
23 IPCC Special Report on Global Warming of 1.5°C concluded that human-induced global warming has
24 already caused more frequent heatwaves in most of land regions, and that climate models project
25 robust differences between present-day and global warming up to 1.5°C and between 1.5°C and 2°C
26 (Hoegh-Guldberg et al. 2018). Direct temperature effects on soils are of two kinds. Firstly, permafrost
27 thawing leads to soil degradation in boreal and high altitude regions (Yang et al. 2010; Jorgenson and
28 Osterkamp 2005). Secondly, warming alters the cycling of nitrogen (N) and carbon (C) in soils, partly
29 due to impacts on soil microbiota (Solly et al. 2017). There are many studies with particularly strong
30 experimental evidence, but a full understanding of cause and effect is contextual and elusive (Conant
31 et al. 2011a,b; Wu et al. 2011). This is discussed comprehensively in Chapter 2.

32 Climate change, including increasing atmospheric CO₂ levels, affects vegetation structure and
33 function and hence conditions for land degradation. Exactly how vegetation responds to changes
34 remains a research task. In a comparison of seven global vegetation models under four representative
35 concentration pathways Friend et al., (2014) found that all models predicted increasing vegetation
36 carbon storage, however with substantial variation between models. An important insight compared
37 with previous understanding is that structural dynamics of vegetation seems to play a more important
38 role for carbon storage than vegetation production (Friend et al. 2014). The magnitude of CO₂
39 fertilisation of vegetation growth, and hence conditions for land degradation is still uncertain (Holtum
40 and Winter 2010), particularly in tropical rainforests (Yang et al. 2016). For more discussion on this
41 topic, see Chapter 2 in this report.

42 In summary, rainfall changes attributed to human-induced climate change have already intensified
43 drivers of land degradation (*robust evidence, high agreement*) but attributing land degradation to
44 climate change is challenging because of the importance of land management (*medium evidence, high*
45 *agreement*). Changes in climate variability modes, such as in monsoons and ENSO events, can also
46 affect land degradation (*low evidence, low agreement*).

1 **4.2.3.2 Indirect and complex linkages with climate change**

2 Many important indirect linkages between land degradation and climate change occur via agriculture,
3 particularly through changing outbreaks of pests (Rosenzweig et al. 2001; Porter et al. 1991; Thomson
4 et al. 2010; Dhanush et al. 2015; Lamichhane et al. 2015), which is covered comprehensively in
5 Chapter 5. More negative impacts have been observed than positive ones (IPCC 2014b). After 2050
6 the risk of yield losses increase as a result of climate change in combination with other drivers
7 (*medium confidence*) and such risks will increase dramatically if global mean temperatures increase
8 by ~4°C (*high confidence*) (Porter et al. 2014). The reduction (or plateauing) in yields in major
9 production areas (Brisson et al. 2010; Lin and Huybers 2012; Grassini et al. 2013) may trigger
10 cropland expansion elsewhere, either into natural ecosystems, marginal arable lands or intensification
11 on already cultivated lands, with possible consequences for increasing land degradation.

12 Precipitation and temperature changes will trigger changes in land- and crop management, such as
13 changes in planting and harvest dates, type of crops, and type of cultivars, which may alter the
14 conditions for soil erosion (Li and Fang 2016).

15 Much research has tried to understand how plants are affected by a particular stressor, for example
16 drought, heat, or waterlogging, including effects on belowground processes. But less research has
17 tried to understand how plants are affected by several simultaneous stressors – which of course is
18 more realistic in the context of climate change (Mittler 2006; Kerns et al. 2016) and from a hazards
19 point of view (see 7.2.1). From an attribution point of view, such a complex web of causality is
20 problematic if attribution is only done through statistical significant correlation. It requires a
21 combination of statistical links and theoretically informed causation, preferably integrated into a
22 model. Some modelling studies have combined several stressors with geomorphologically explicit
23 mechanisms (using the WEPP model) and realistic land use scenarios, and found severe risks of
24 increasing erosion from climate change (Mullan et al. 2012; Mullan 2013). Other studies have
25 included various management options, such as changing planting and harvest dates (Zhang and
26 Nearing 2005; Parajuli et al. 2016; Routschek et al. 2014; Nunes and Nearing 2011), type of cultivars
27 (Garbrecht and Zhang 2015), and price of crops (Garbrecht et al. 2007; O’Neal et al. 2005) to
28 investigate the complexity of how new climate regimes may alter soil erosion rates.

29 In summary, climate change increases the risk of land degradation both in terms of likelihood and
30 consequence but the exact attribution to climate change is challenging due to several confounding
31 factors. But since climate change exacerbates most degradation processes it is clear that unless land
32 management is improved, climate change will result in increasing land degradation (*very high*
33 *confidence*).

34 **4.2.4 Approaches to assessing land degradation**

35 In a review of different approaches and attempts to map global land degradation, Gibbs and Salmon
36 (2015) identified four main approaches to map the global extent of degraded lands: expert opinions
37 (Oldeman and van Lynden 1998; Dregne 1998; Reed 2005; Bot et al. 2000), satellite observation of
38 vegetation greenness (e.g., remote sensing of NDVI (Normalized Difference Vegetation Index), EVI
39 (Enhanced Vegetation Index), PPI (Plant Phenology Index) (Yengoh et al. 2015; Bai et al. 2008c; Shi
40 et al. 2017a; Abdi et al. 2019; JRC 2018), biophysical models (biogeographical/ topological) (Cai et
41 al. 2011b; Hickler et al. 2005; Steinkamp and Hickler 2015; Stoorvogel et al. 2017) and inventories of
42 land use/condition. Together they provide a relatively complete evaluation, but none on its own
43 assesses the complexity of the process (Vogt et al. 2011; Gibbs and Salmon 2015). There is, however,
44 a robust consensus that remote sensing and field-based methods are critical to assess and monitor land
45 degradation, particularly over large areas (such as global, continental and sub-continental) although
46 there are still knowledge gaps to be filled (Wessels et al. 2007, 2004; Prince 2016; Ghazoul and
47 Chazdon 2017) as well as the problem of baseline (see 4.1.3).

1 Remote sensing can provide meaningful proxies of land degradation in terms of severity, temporal
2 development, and areal extent. These proxies of land degradation include several indexes that have
3 been used to assess land conditions and monitoring the changes of land condition, for example extent
4 of gullies, severe forms of rill and sheet erosion, and deflation. The presence of open-access, quality
5 controlled and continuously updated global databases of remote sensing data is invaluable, and is the
6 only method for consistent monitoring of large areas over several decades (Sedano et al. 2016; Brandt
7 et al. 2018b; Turner 2014). The NDVI, as a proxy for Net Primary Production (NPP, see glossary), is
8 one of the most commonly used methods to assess land degradation, since it indicates land cover, an
9 important factor for soil protection. Although NDVI is not a direct measure of vegetation biomass,
10 there is a close coupling between NDVI integrated over a season and in situ NPP (*high agreement,*
11 *robust evidence*) (see Higginbottom et al. 2014; Andela et al. 2013; Wessels et al. 2012).

12 Distinction between land degradation/improvement and the effects of climate variation is an important
13 and contentious issue (Murthy and Bagchi 2018; Ferner et al. 2018). There is no simple and
14 straightforward way to disentangle these two effects. The interaction of different determinants of
15 primary production is not well understood. A key barrier to this is a lack of understanding of the
16 inherent inter-annual variability of vegetation (Huxman et al. 2004; Knapp and Smith 2001; Ruppert
17 et al. 2012; Bai et al. 2008a; Jobbágy and Sala 2000). One possibility is to compare potential land
18 productivity modelled by vegetation models and actual productivity measured by remote sensing
19 (Seaquist et al. 2009; Hickler et al. 2005; van der Esch et al. 2017), but the difference in spatial
20 resolution, typically 0.5 degrees for vegetation models compared to 0.25–0.5 km for remote sensing
21 data, is hampering the approach. Moderate-resolution Imaging Spectroradiometer, or MODIS,
22 provides higher spatial resolution (up to 0.25 km), delivers data for the Enhanced Vegetation Index
23 (EVI) which is calculated similarly to NDVI and have showed robust approach to estimate spatial
24 patterns of global annual primary productivity (Shi et al. 2017b; Testa et al. 2018).

25 Another approach to disentangle the effects of climate and land use/management is to use the Rain
26 Use Efficiency (RUE), defined as the biomass production per unit of rainfall, as an indicator (Le
27 Houerou 1984; Prince et al. 1998; Fensholt et al. 2015). A variant of the RUE approach is the residual
28 trend (RESTREND) of a NDVI time-series, defined as the fraction of the difference between the
29 observed NDVI and the NDVI predicted from climate data (Yengoh et al. 2015; John et al. 2016).
30 These two metrics aim to estimate the NPP, rainfall and the time dimensions. They are simple
31 transforms of the same three variables: RUE shows the NPP relationship with rainfall for individual
32 years, while RESTREND is the interannual change of RUE; also, both consider that rainfall is the
33 only variable that affects biomass production. They are legitimate metrics when used appropriately,
34 but in many cases they involve oversimplifications and yield misleading results (Fensholt et al. 2015;
35 Prince et al. 1998).

36 Furthermore, increases in NPP do not always indicate improvement in land condition/reversal of land
37 degradation, since this does not account for changes in vegetation composition. It could, for example,
38 result from conversion of native forest to plantation, or due to bush encroachment, which many
39 consider to be a form of land degradation (Ward 2005). Also, NPP may be increased by irrigation,
40 which can enhance productivity in the short-medium term while increasing risk of soil salinisation in
41 the long term (Niedertscheider et al. 2016).

42 Recent progress and expanding time series of canopy characterisations based on passive microwave
43 satellite sensors have offered rapid progress in regional and global descriptions of forest degradation
44 and recovery trends (Tian et al. 2017). The most common proxy is VOD (vertical optical depth) and
45 has already been used to describe global forest/savannah carbon stock shifts over two decades,
46 highlighting strong continental contrasts (Liu et al. 2015a) demonstrating the value of this approach to
47 monitor forest degradation at large scales. Contrasting NDVI which is only sensitive to vegetation
48 “greenness”, from which primary production can be modelled, VOD is also sensitive to water in

1 woody parts of the vegetation and hence provides a view of vegetation dynamics that can be
2 complementary to NDVI. As well as the NDVI, VOD also needs to be corrected to take into account
3 the rainfall variation (Andela et al. 2013).

4 Even though remote sensing offers much potential, its application to land degradation and recovery
5 remains challenging as structural changes often occur at scales below the detection capabilities of
6 most remote sensing technologies. Additionally, if the remote sensing is based on vegetation indexes
7 data, other forms of land degradation, such as nutrient depletion, changes of soil physical or biological
8 properties, loss of values for humans, among others, cannot be inferred indirectly by remote sensing.
9 The combination of remotely sensed images and field based approach can give improved estimates of
10 carbon stocks and tree biodiversity (Imai et al. 2012; Fujiki et al. 2016).

11 Additionally, the majority of trend techniques employed would be capable of detecting only the most
12 severe of degradation processes, and would therefore not be useful as a degradation early-warning
13 system (Higginbottom et al. 2014; Wessels et al. 2012). However, additional analyses using higher
14 resolution imagery, such as the Landsat and SPOT satellites, would be well suited to provide further
15 localized information on trends observed (Higginbottom et al. 2014). New approaches to assess land
16 degradation using high spatial resolution are developing but the need for time series makes progress
17 slow. The use of synthetic aperture radar (SAR) data has been shown to be advantageous for the
18 estimation of soil surface characteristics, in particular surface roughness and soil moisture (Gao et al.
19 2017; Bousbih et al. 2017), and detecting and quantifying selective logging (Lei et al. 2018). It is still
20 necessary to maintain the efforts to fully assess land degradation using remote sensing.

21 Computer simulation models can be used alone or combined with the remote sensing observations to
22 assess land degradation. The RUSLE (Revised Universal Soil Loss Equation) can be used, to some
23 extent, to predict the long-term average annual soil loss by water erosion. RUSLE has been constantly
24 revisited to estimate soil loss based on the product of rainfall–runoff erosivity, soil erodibility, slope
25 length and steepness factor, conservation factor, and support practice parameter (Nampak et al. 2018).
26 Inherent limitations of RUSLE include data-sparse regions, inability to account for soil loss from
27 gully erosion or mass wasting events, and that it does not predict sediment pathways from hillslopes
28 to water bodies (Benavidez et al. 2018). Since RUSLE models only provide gross erosion, the
29 integration of a further module in the RUSLE scheme to estimate the sediment yield from the
30 modelled hillslopes is needed. The spatially distributed sediment delivery model WaTEM/SEDEM
31 has been widely tested in Europe (Borrelli et al. 2018). Wind erosion is another factor that needs to be
32 taken into account in the modelling of soil erosion (Webb et al. 2017a, 2016). Additional models need
33 to be developed to include the limitations of the RUSLE models.

34 Regarding the field based approach to assess land degradation, there are multiple indicators that
35 reflect functional ecosystem processes linked to ecosystem services and, thus, to the value for
36 humans. These indicators are a composite set of measurable attributes from different factors, such as
37 climate, soil, vegetation, biomass, management, among others, that can be used together or to develop
38 indexes to better assess land degradation (Allen et al. 2011; Kosmas et al. 2014).

39 Declines in vegetation cover, changes in vegetation structure, decline in mean species abundances,
40 decline in habitat diversity, changes in abundance of specific indicator species, reduced vegetation
41 health and productivity, and vegetation management intensity and use, are the most common
42 indicators in the vegetation condition of forest and woodlands (Stocking et al. 2001; Wiesmair et al.
43 2017; Ghazoul and Chazdon 2017; Alkemade et al. 2009).

44 Several indicators of the soil quality (soil organic matter, depth, structure, compaction, texture, pH,
45 C:N ratio, aggregate size distribution and stability, microbial respiration, soil organic carbon,
46 salinisation, among others) have been proposed (see also 2.2) (Schoenholtz et al. 2000). Among these,
47 soil organic matter (SOM) directly and indirectly drives the majority of soil functions. Decreases in

1 SOM can lead to a decrease in fertility and biodiversity, as well as a loss of soil structure, causing
2 reductions in water holding capacity, increased risk of erosion (both wind and water) and increased
3 bulk density and hence soil compaction (Allen et al. 2011; Certini 2005; Conant et al. 2011a). Thus,
4 indicators related with the quantity and quality of the SOM are necessary to identify land degradation
5 (Pulido et al. 2017; Dumanski and Pieri 2000). The composition of the microbial community is *very*
6 *likely* to be positive impacted by both climate change and land degradation processes (Evans and
7 Wallenstein 2014; Wu et al. 2015; Classen et al. 2015), thus changes in microbial community
8 composition can be very useful to rapidly reflect land degradation (e.g. forest degradation increased
9 the bacterial alpha-diversity indexes) (Flores-Rentería et al. 2016; Zhou et al. 2018). These indicators
10 might be used as a set of indicators site-dependent, and in a plant-soil system (Ehrenfeld et al. 2005).

11 Useful indicators of degradation and improvement include changes in ecological processes and
12 disturbance regimes that regulate the flow of energy and materials and that control ecosystem
13 dynamics under a climate change scenario. Proxies of dynamics include spatial and temporal turnover
14 of species and habitats within ecosystems (Ghazoul et al. 2015; Bahamondez and Thompson 2016).
15 Indicators in agricultural lands include crop yield decreases and difficulty in maintaining yields
16 (Stocking et al. 2001). Indicators of landscape degradation/improvement in fragmented forest
17 landscapes include the extent, size, and distribution of remaining forest fragments, an increase in edge
18 habitat, and loss of connectivity and ecological memory (Zahawi et al. 2015; Pardini et al. 2010).

19 In summary, as land degradation is such a complex and global process there is no single method by
20 which land degradation can be estimated objectively and consistently over large areas (*very high*
21 *confidence*). However, many approaches exist that can be used to assess different aspects of land
22 degradation or provide proxies of land degradation. Remote sensing, complemented by other kinds of
23 data (i.e., field observations, inventories, expert opinions), is the only method that can generate
24 geographically explicit and globally consistent data over time scales relevant for land degradation
25 (several decades).

26 **4.3 Status and current trends of land degradation**

27 The scientific literature on land degradation often excludes forest degradation, yet here we attempt to
28 assess both issues. Because of the different bodies of scientific literature, we assess land degradation
29 and forest degradation under different sub-headings, and where possible draw integrated conclusions.

30 **4.3.1 Land degradation**

31 There are no reliable global maps of the extent and severity of land degradation (Gibbs and Salmon
32 2015; Prince et al. 2018; van der Esch et al. 2017), despite the fact that land degradation is a severe
33 problem (Turner et al. 2016). The reasons are both conceptual, i.e., how is land degradation defined,
34 using what baseline (Herrick et al. 2019) or over what time period, and methodological, i.e. how can it
35 be measured (Prince et al. 2018). Although there is a strong consensus that land degradation is a
36 reduction in productivity of the land or soil, there are diverging views regarding the spatial and
37 temporal scales at which land degradation occurs (Warren 2002), and how this can be quantified and
38 mapped. Proceeding from the definition in this report, there are also diverging views concerning
39 ecological integrity and the value to humans. A comprehensive treatment of the conceptual discussion
40 about land degradation is provided by the recent report on land degradation from the
41 Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services, IPBES
42 (Montanarella et al. 2018).

43 A review of different attempts to map global land degradation, based on expert opinion, satellite
44 observations, biophysical models and a data base of abandoned agricultural lands, suggested that

1 between <10 M km² to 60 M km² (corresponding to 8–45% of the ice-free land area) have been
2 degraded globally (Gibbs and Salmon, 2015) (*very low confidence*).

3 One often used global assessment of land degradation used trends in NDVI as a proxy for land
4 degradation and improvement during the period 1983 to 2006 (Bai et al. 2008b,c) with an update to
5 2011 (Bai et al. 2015). These studies, based on very coarse resolution satellite data (8 km NOAA
6 AVHRR), indicated that between 22% and 24% of the global ice-free land area was subject to a
7 downward trend, while about 16% showed an increasing trend. The study also suggested, contrary to
8 earlier assessments (Middleton and Thomas 1997), that drylands were not among the most affected
9 regions. Another study using a similar approach for the period 1981-2006 suggested that about 29%
10 of the global land area is subject to ‘land degradation hotspots’, i.e. areas with acute land degradation
11 in need of particular attention. These hotspot areas were distributed over all agro-ecological regions
12 and land cover types. Two different studies have tried to link land degradation, identified by NDVI as
13 a proxy, and number of people affected: Le et al. (2016) estimated that at least 3.2 billion people were
14 affected, while Barbier and Hochard (2016, 2018) estimated that 1.33 billion people were affected, of
15 which 95% were living in developing countries.

16 Yet another study, using a similar approach and type of remote sensing data, compared NDVI trends
17 with biomass trends calculated by a global vegetation model over the period 1982-2010 and found
18 that 17-36% of the land areas showed a negative NDVI trend while a positive or neutral trend was
19 predicted in modelled vegetation (Schut et al. 2015). The World Atlas of Desertification (3rd edition)
20 includes a global map of land productivity change over the period 1999 to 2013, which is one useful
21 proxy for land degradation (Cherlet et al. 2018). Over that period about 20% of the global ice-free
22 land area shows signs of declining or unstable productivity, whereas about 20% shows increasing
23 productivity. The same report also summarized the productivity trends by land categories and found
24 that most forest land showed increasing trends in productivity while rangelands had more declining
25 trends than increasing trends (Fig 4.4). These productivity assessments, however, do not distinguish
26 between trends due to climate change and trends due to other factors. A recent analysis of “greening”
27 of the world using MODIS time series of NDVI 2000 – 2017, shows a striking increase in the
28 greening over China and India. In China the greening is seen over both forested areas, 42%, and
29 cropland areas, in which 32% is increasing (see Section 4.9.3). In India, the greening is almost
30 entirely associated with cropland (82%) (Chen et al. 2019).

31 All the studies of vegetation trends referred to above show that there are regionally-differentiated
32 trends of either decreasing or increasing vegetation. When comparing vegetation trends with trends in
33 climatic variables, Schut et al. (2015) found very few areas (1-2%) where an increase in vegetation
34 trend was independent of the climate drivers, and that study suggested that positive vegetation trends
35 are primarily caused by climatic factors.

36

7 In an attempt to go beyond the mapping of global vegetation trends for assessing land degradation,
 8 Borelli et al. (2017) used a soil erosion model (RUSLE) and suggested that soil erosion is mainly
 9 caused in areas of crop land expansion, particularly in sub-Saharan Africa, South America and
 10 Southeast Asia. The method is controversial for both conceptual reasons (i.e., the ability of the model
 11 to capture the most important erosion processes) and data limitations (i.e., the availability of relevant
 12 data at regional to global scales), and its validity for assessing erosion over large areas has been
 13 questioned by several studies (Baveye 2017; Evans and Boardman 2016a,b; Labrière et al. 2015).

14 An alternative to using remote sensing for assessing the state of land degradation is to compile field
 15 based data from around the globe (Turner et al. 2016). In addition to the problems of definitions and
 16 baselines, this approach is also hampered by the lack of standardized methods used in the field. An
 17 assessment of the global severity of soil erosion in agriculture, based on 1,673 measurements around
 18 the world (compiled from 201 peer reviewed articles), indicated that the global net median rate of soil
 19 formation (i.e., formation minus erosion) is about 0.004 mm yr^{-1} ($\sim 0.05 \text{ t ha}^{-1}\text{yr}^{-1}$) compared with the
 20 median net rate of soil loss in agricultural fields, 1.52 mm yr^{-1} ($\sim 18 \text{ t ha}^{-1}\text{yr}^{-1}$) in tilled fields and
 21 0.065 mm yr^{-1} ($\sim 0.8 \text{ t ha}^{-1}\text{yr}^{-1}$) in no-till fields (Montgomery 2007a). This means that the rate of soil
 22 erosion from agricultural fields is in between 380 (conventional tilling) and 16 times (no-till) the
 23 natural rate of soil formation (*medium agreement, limited evidence*). These approximate figures are
 24 supported by another large meta-study including over 4000 sites around the world (see Figure 4.4)
 25 where the average soil loss from agricultural plots was $\sim 21 \text{ t ha}^{-1}\text{yr}^{-1}$ (García-Ruiz et al. 2015).
 26 Climate change, mainly through the intensification of rainfall, will further increase these rates unless
 27 land management is improved (*high agreement, medium evidence*).

1 Soils contain about 1500 Gt of organic carbon (median across 28 different estimates presented by
2 (Scharlemann et al. 2014)), which is about 1.8 times more carbon than in the atmosphere (Ciais et al.
3 2013) and 2.3 – 3.3 times more than what is held in the terrestrial vegetation of the world (Ciais et al.
4 2013). Hence, land degradation including land conversion leading to soil carbon losses has the
5 potential to impact the atmospheric concentration of CO₂ substantially. When natural ecosystems are
6 cultivated they lose soil carbon that accumulated over long time periods. The loss rate depends on the
7 type of natural vegetation and how the soil is managed. Estimates of the magnitude of loss vary but
8 figures between 20% and 59% have been reported in several meta studies (Poeplau and Don 2015;
9 Wei et al. 2015; Li et al. 2012; Murty et al. 2002; Guo and Gifford 2002). The amount of soil carbon
10 lost explicitly due to land degradation after conversion is hard to assess due to large variation in local
11 conditions and management, see also Chapter 2.

12 From a climate change perspective, land degradation plays an important role in the dynamics of
13 nitrous oxide (N₂O) and methane (CH₄). N₂O is produced by microbial activity in the soil and the
14 dynamics are related to both management practices and weather conditions while CH₄ dynamics are
15 primarily determined by the amount of soil carbon and to what extent the soil is subject to water
16 logging (Palm et al. 2014), see also Chapter 2.

17 Several attempts have been made to map the human footprint on the planet (Čuček et al. 2012; Venter
18 et al. 2016) but they in some cases confuse human impact on the planet with degradation. From our
19 definition it is clear that human impact (or pressure) is not synonymous with degradation but
20 information on the human footprint provides a useful mapping of potential non-climatic drivers of
21 degradation.

22 In summary, there are no uncontested maps of the location, extent and severity of land degradation.
23 Proxy estimates based on remote sensing of vegetation dynamics provide one important information
24 source, but attribution of the observed changes in productivity to climate change, human activities, or
25 other drivers is hard. Nevertheless, the different attempts to map the extent of global land degradation
26 using remotely sensed proxies show some convergence and suggest that about a quarter of the ice free
27 land area is subject to some form of land degradation (*limited evidence, medium agreement*) affecting
28 about 3.2 billion people (*low confidence*). Attempts to estimate the severity of land degradation
29 through soil erosion estimates suggest that soil erosion is a serious form of land degradation in
30 croplands closely associated with unsustainable land management in combination with climatic
31 parameters, some of which are subject to climate change (*limited evidence, high agreement*). Climate
32 change is one among several causal factors in the status and current trends of land degradation
33 (*limited evidence, high agreement*).

34 **4.3.2 Forest degradation**

35 Quantifying degradation in forests has also proven difficult. Indicators that remote sensing or
36 inventory methods can measure more easily than reductions in biological productivity, losses of
37 ecological integrity or value to humans include reductions in canopy cover or carbon stocks.
38 However, the causes of reductions in canopy cover or carbon stocks can be many (Curtis et al. 2018),
39 including natural disturbances (e.g., fires, insects and other forest pests), direct human activities (e.g.,
40 harvest, forest management) and indirect human impacts (such as climate change) and these may not
41 reduce long-term biological productivity. In many boreal, some temperate and other forest types
42 natural disturbances are common, and consequently these disturbance-adapted forest types are
43 comprised of a mosaic of stands of different ages and stages of stand recovery following natural
44 disturbances. In those managed forests where natural disturbances are uncommon or suppressed,
45 harvesting is the primary determinant of forest age-class distributions.

46 Quantifying forest degradation as a reduction in productivity, carbon stocks or canopy cover also
47 requires that an initial condition (or baseline) is established against which this reduction is assessed

1 (see Section 4.1.4). In forest types with rare stand-replacing disturbances, the concept of “intact” or
2 “primary” forest has been used to define the initial condition (Potapov et al. 2008) but applying a
3 single metric can be problematic (Bernier et al. 2017). Moreover, forest types with frequent stand-
4 replacing disturbances, such as wildfires, or with natural disturbances that reduce carbon stocks, such
5 as some insect outbreaks, experience over time a natural variability of carbon stocks or canopy
6 density making it more difficult to define the appropriate baseline carbon density or canopy cover
7 against which to assess degradation. In these systems, forest degradation cannot be assessed at the
8 stand level, but requires a landscape-level assessment that takes into consideration the stand age-class
9 distribution of the landscape, which reflects natural and human disturbance regimes over past decades
10 to centuries and also considers post-disturbance regrowth (van Wagner 1978; Volkova et al. 2018;
11 Lorimer and White 2003).

12 The lack of a consistent definition of forest degradation also affects the ability to establish estimates
13 of the rates or impacts of forest degradation because the drivers of degradation are not clearly defined
14 (Sasaki and Putz 2009). Moreover, the literature at times confounds estimates of forest degradation
15 and deforestation (i.e. the conversion of forest to non-forest land uses). Deforestation is a change in
16 land use, while forest degradation is not, although severe forest degradation can ultimately lead to
17 deforestation.

18 Based on empirical data provided by 46 countries, the drivers for deforestation (due to commercial
19 agriculture) and forest degradation (due to timber extraction and logging) are similar in Africa, Asia
20 and Latin America (Hosonuma et al. 2012). More recently, global forest disturbance over the period
21 2001 – 2015 was attributed to commodity driven deforestation ($27 \pm 5\%$), forestry ($26 \pm 4\%$), shifting
22 agriculture ($24 \pm 3\%$) and wildfire ($23 \pm 4\%$). The remaining $0.6 \pm 0.3\%$ was attributed to the
23 expansion of urban centers (Curtis et al. 2018).

24 The trends of productivity shown by several remote sensing studies (see previous section) are largely
25 consistent with mapping of forest cover and change using a 34 year time series of coarse resolution
26 satellite data (NOAA AVHRR) (Song et al. 2018). This study, based on a thematic classification of
27 satellite data, suggests that (i) global tree canopy cover increased by 2.24 million km² between 1982
28 and 2016 (corresponding to +7.1%) but with regional differences that contribute a net loss in the
29 tropics and a net gain at higher latitudes, and (ii) the fraction of bare ground decreased by 1.16 million
30 km² (corresponding to -3.1%), mainly in agricultural regions of Asia (Song et al. 2018), see Figure
31 4.5. Other tree or land cover datasets show opposite global net trends (Li et al. 2018b), but high
32 agreement in terms of net losses in the tropics and large net gains in the temperate and boreal zones
33 (Li et al. 2018b; Song et al. 2018; Hansen et al. 2013). Differences across global estimates are further
34 discussed in Chapter 1 (1.1.2.3) and Chapter 2.

35 The changes detected from 1982 to 2016 were primarily linked to direct human action, such as land-
36 use changes (about 60% of the observed changes), but also to indirect effects, such as human induced
37 climate change (about 40% of the observed changes) (Song et al. 2018), a finding also supported by a
38 more recent study (Chen et al. 2019). The climate induced effects were clearly discernible in some
39 regions, such as forest decline in the US Northwest due to increasing pest infestation and increasing
40 fire frequency (Lesk et al. 2017; Abatzoglou and Williams 2016; Seidl et al. 2017), warming induced
41 vegetation increase in the Arctic region, general greening in the Sahel probably as a result of
42 increasing rainfall and atmospheric CO₂, and advancing treelines in mountain regions (Song et al.
43 2018).

44 Keenan et al.(Keenan et al. 2015) and Sloan and Sayer (2015) studied the 2015 Forest Resources
45 Assessment (FRA) of the FAO (FAO 2016) and found that the total forest area from 1990 to 2015
46 declined by 3%, an estimate that is supported by a global remote sensing assessment of forest area
47 change that found a 2.8% decline between 1990-2010 (D’Annunzio et al. 2017; Lindquist and
48 D’Annunzio 2016). The trend in deforestation is, however, contradicting between these two global

1 assessments with FAO (2016) suggesting deforestation is slowing down while the remote sensing
 2 assessments finds it to be accelerating (D'Annunzio et al. 2017). Recent estimates (Song et al. 2018)
 3 owing to semantic and methodological differences (see Chapter 1, section 1.1.2.3) suggest global tree
 4 cover to have increased over the period 1982-2016, which contradicts the forest area dynamics
 5 assessed by FAO (2016, Lindquist and D'Annunzio 2016). The loss rate in tropical forest areas from
 6 2010 to 2015 is 55 000 km² yr⁻¹. According to the FRA the global natural forest area also declined
 7 from 39.61 M km² to 37.21 M km² during the period 1990 to 2015 (Keenan et al. 2015).

8

13 Since 1850, deforestation globally contributed 77% of the emissions from land-use and land-cover
 14 change (LULCC) while degradation contributed 10% (with the remainder originating from non-forest
 15 land uses) (Houghton and Nassikas 2018). That study also showed large temporal and regional
 16 differences with northern mid-latitude forests currently contributing carbon sinks due to increasing
 17 forest area and forest management. However, the contribution to carbon emissions of degradation as
 18 percentage of total forest emissions (degradation and deforestation) are uncertain, with estimates
 19 varying from 25% (Pearson et al. 2017) to nearly 70% of carbon losses (Baccini et al. 2017). The 25%
 20 estimate refers to an analysis of 74 developing countries within tropical and subtropical regions
 21 covering 22 million km² for the period 2005-2010 while the 70% estimate refers to an analysis of the
 22 tropics for the period 2003-2014, but by and large the scope of these studies is the same. Pearson et al.
 23 (2017) estimated annual gross emissions of 2.1 Gt CO₂, of which 53% were derived from timber
 24 harvest, 30% from wood fuel harvest and 17% from forest fire. Estimating gross emissions only,
 25 creates a distorted representation of human impacts on the land sector carbon cycle. While forest
 26 harvest for timber and fuel wood and land-use change (deforestation) contribute to gross emissions, to
 27 quantify impacts on the atmosphere it is necessary to estimate net emissions, i.e. the balance of gross
 28 emissions and gross removals of carbon from the atmosphere through forest regrowth (Chazdon et al.
 29 2016a; Poorter et al. 2016; Sanquetta et al. 2018).

1 Current efforts to reduce atmospheric CO₂ concentrations can be supported by reductions in forest-
2 related carbon emissions and increases in sinks, which requires that the net impact of forest
3 management on the atmosphere be evaluated (Griscom et al. 2017). Forest management and the use
4 of wood products in GHG mitigation strategies result in changes in forest ecosystem C stocks,
5 changes in harvested wood product C stocks, and potential changes in emissions resulting from the
6 use of wood products and forest biomass that substitute for other emissions-intensive materials such
7 as concrete, steel and fossil fuels (Kurz et al. 2016; Lemprière et al. 2013; Nabuurs et al. 2007). The
8 net impact of these changes on GHG emissions and removals, relative to a scenario without forest
9 mitigation actions needs to be quantified, (e.g. Werner et al. 2010; Smyth et al. 2014; Xu et al. 2018).
10 Therefore, reductions in forest ecosystem C stocks alone are an incomplete estimator of the impacts of
11 forest management on the atmosphere (Nabuurs et al. 2007; Lemprière et al. 2013; Kurz et al. 2016;
12 Chen et al. 2018b). The impacts of forest management and the carbon storage in long-lived products
13 and landfills vary greatly by region, however, because of the typically much shorter life-span of wood
14 products produced from tropical regions compared to temperate and boreal regions (Earles et al. 2012;
15 Lewis et al. 2019; Jordan et al. 2018) (see also section 4.8.4).

16 Assessments of forest degradation based on remote sensing of changes in canopy density or land
17 cover, (e.g., (Hansen et al. 2013; Pearson et al. 2017) quantify changes in aboveground biomass C
18 stocks and require additional assumptions or model-based analyses to also quantify the impacts on
19 other ecosystem carbon pools including belowground biomass, litter, woody debris and soil carbon.
20 Depending on the type of disturbance, changes in aboveground biomass may lead to decreases or
21 increases in other carbon pools, for example, windthrow and insect induced tree mortality may result
22 in losses in aboveground biomass that are (initially) off-set by corresponding increases in dead
23 organic matter carbon pools (Yamanoi et al. 2015; Kurz et al. 2008), while deforestation will reduce
24 the total ecosystem carbon pool (Houghton et al. 2012).

25 A global study of current vegetation carbon stocks (450 Gt C), relative to a hypothetical condition
26 without land-use (916 Gt C), attributed 42-47% of carbon stock reductions to land management
27 effects without land-use change, while the remaining 53-58% of carbon stock reductions were
28 attributed to deforestation and other land-use changes (Erb et al. 2018). While carbon stocks in
29 European forests are lower than hypothetical values in the complete absence of human land use, forest
30 area and carbon stocks have been increasing over recent decades (McGrath et al. 2015; Kauppi et al.
31 2018). Studies of Gingrich et al. (2015) on the long-term trends in land-use over nine European
32 countries (Albania, Austria, Denmark, Germany, Italy, the Netherlands, Romania, Sweden and the
33 United Kingdom) also show an increase in forest land and reduction in cropland and grazing land
34 from the 19th century to the early 20th century. However, the extent to which human activities have
35 affected the productive capacity of forest lands is poorly understood. Biomass Production Efficiency
36 (BPE), i.e. the fraction of photosynthetic production used for biomass production, was significantly
37 higher in managed forests (0.53) compared to natural forests (0.41) (and it was also higher in
38 managed (0.44) compared to natural (0.63) grasslands) (Capioli et al. 2015). Managing lands for
39 production may involve trade-offs. For example, a larger proportion of Net Primary Production in
40 managed forests is allocated to biomass carbon storage, but lower allocation to fine roots is
41 hypothesised to reduce soil C stocks in the long-term (Noormets et al. 2015). Annual volume
42 increment in Finnish forests has more than doubled over the last century, due to increased growing
43 stock, improved forest management and environmental changes (Henttonen et al. 2017).

44 As economies evolve, the patterns of land-use and C stock changes associated with human expansion
45 into forested areas often include a period of rapid decline of forest area and carbon stocks, recognition
46 of the need for forest conservation and rehabilitation, and a transition to more sustainable land
47 management that is often associated with increasing carbon stocks, (e.g. Birdsey et al. 2006).
48 Developed and developing countries around the world are in various stages of forest transition

1 (Kauppi et al. 2018; Meyfroidt and Lambin 2011). Thus, opportunities exist for sustainable forest
2 management to contribute to atmospheric carbon targets through reduction of deforestation and
3 degradation, forest conservation, forest restoration, intensification of management, and enhancements
4 of carbon stocks in forests and harvested wood products (Griscom et al. 2017) (*medium evidence*,
5 *medium agreement*).

6 **4.4 Projections of land degradation in a changing climate**

7 Land degradation will be affected by climate change in both direct and indirect ways, and land
8 degradation will to some extent also feed-back into the climate system. The direct impacts are those in
9 which climate and land interact directly in time and space. Examples of direct impacts are when
10 increasing rainfall intensity exacerbates soil erosion, or when prolonged droughts reduce the
11 vegetation cover of the soil making it more prone to erosion and nutrient depletion. The indirect
12 impacts are those where climate change impacts and land degradation are separated in time and/or
13 space. Examples of such impacts are when declining agricultural productivity due to climate change
14 drives an intensification of agriculture elsewhere, which may cause land degradation. Land
15 degradation, if sufficiently widespread, may also feed back into the climate system by reinforcing
16 ongoing climate change.

17 Although climate change is exacerbating many land degradation processes (*high to very high*
18 *confidence*), prediction of future land degradation is challenging because land management practices
19 determine to a very large extent the state of the land. Scenarios of climate change in combination with
20 land degradation models can provide useful knowledge on what kind and extent of land management
21 will be necessary to avoid, reduce and reverse land degradation.

22 **4.4.1 Direct impacts on land degradation**

23 There are two main levels of uncertainty in assessing the risks of future climate change induced land
24 degradation. The first level, where uncertainties are comparatively low, is the changes of the
25 degrading agent, such as erosive power of precipitation, heat stress from increasing temperature
26 extremes (HÜVE et al. 2011), water stress from droughts, and high surface wind speed. The second
27 level of uncertainties, and where the uncertainties are much larger, relates to the above and
28 belowground ecological changes as a result of changes in climate, such as rainfall, temperature, and
29 increasing level of CO₂. Vegetation cover is crucial to protect against erosion (Mullan et al. 2012;
30 García-Ruiz et al. 2015).

31 Changes in rainfall patterns, such as distribution in time and space, and intensification of rainfall
32 events will increase the risk of land degradation, both in terms of likelihood and consequences (*high*
33 *agreement, medium evidence*). Climate induced vegetation changes will increase the risk of land
34 degradation in some areas (where vegetation cover will decline) (*medium confidence*). Landslides are
35 a form of land degradation that is induced by extreme rainfall events. There is a strong theoretical
36 reason for increasing landslide activity due to intensification of rainfall, but the empirical evidence is
37 so far lacking that climate change has contributed to landslides (Crozier 2010; Huggel et al. 2012;
38 Gariano and Guzzetti 2016), human disturbance may be a more important future trigger than climate
39 change (Froude and Petley 2018).

40 Erosion of coastal areas as a result of sea level rise will increase worldwide (*very high confidence*). In
41 cyclone prone areas (such as the Caribbean, Southeast Asia, and the Bay of Bengal) the combination
42 of sea level rise and more intense cyclones (Walsh et al. 2016b), and in some areas also land
43 subsidence (Yang et al. 2019; Shirzaei and Bürgmann 2018; Wang et al. 2018; Fuangswasdi et al.
44 2019; Keogh and Törnqvist 2019), will pose a serious risk to people and livelihoods (*very high*
45 *confidence*), in some cases even exceeding limits to adaption, see further section 4.8.4.1, 4.9.6, 4.9.8.

1 **4.4.1.1 Changes in water erosion risk due to precipitation changes**

2 The hydrological cycle is intensifying with increasing warming of the atmosphere. The intensification
3 means that the number of heavy rainfall events is increasing while the total number of rainfall events
4 tends to decrease (Trenberth 2011; Li and Fang 2016; Kendon et al. 2014; Guerreiro et al. 2018; Burt
5 et al. 2016a; Westra et al. 2014; Pendergrass and Knutti 2018) (*robust evidence, high agreement*).
6 Modelling of changes in land degradation as a result of climate change alone is hard because of the
7 importance of local contextual factors. As shown above, actual erosion rate is extremely dependent on
8 local conditions, primarily vegetation cover and topography (García-Ruiz et al. 2015). Nevertheless,
9 modelling of soil erosion risks has advanced substantially in recent decades and such studies are
10 indicative of future changes in the risk of soil erosion while actual erosion rates will still primarily be
11 determined by land management. In a review article, Li & Fang (Li and Fang 2016) summarised 205
12 representative modelling studies around the world where erosion models had been used in
13 combination with down-scaled climate models to assess future (between 2030 to 2100) erosion rates.
14 The meta-study by Li & Fang considered, where possible, climate change in terms of temperature
15 increase and changing rainfall regimes and their impacts on vegetation and soils. Almost all of the
16 sites had current soil loss rates above 1 t ha^{-1} (assumed to be the upper limit for acceptable soil erosion
17 in Europe) and 136 out of 205 studies predicted increased soil erosion rates. The percentage increase
18 in erosion rates varied between 1.2% to as much as over 1600%, whereas 49 out of 205 studies
19 projected more than 50% increase. Projected soil erosion rates varied substantially between studies
20 because the important of local factors, hence climate change impacts on soil erosion should preferably
21 be assessed at the local to regional scale, rather than the global (Li and Fang 2016).

22 Mesoscale convective systems (MCS), typically thunder storms, have increased markedly in recent 3-
23 4 decades in the USA and Australia and they are projected to increase substantially (Prein et al. 2017).
24 Using a climate model with the ability to represent MCS, Prein and colleagues were able to predict
25 future increases in frequency, intensity, and size of such weather systems. Findings include the 30%
26 decrease in number of MCS of $<40\text{ mm h}^{-1}$, but a sharp increase of 380% in the number of extreme
27 precipitation events of $>90\text{ mm h}^{-1}$ over the North American continent. The combined effect of
28 increasing precipitation intensity and increasing size of the weather systems implies that the total
29 amount of precipitation from these weather systems is expected to increase by up to 80% (Prein et al.
30 2017), which will substantially increase the risk of land degradation in terms of landslides, extreme
31 erosion events, flashfloods etc.

32 The potential impacts of climate change on soil erosion can be assessed by modelling the projected
33 changes in particular variables of climate change known to cause erosion, such as erosivity of rainfall.
34 A study of the conterminous United States based on three climate models and three scenarios (A2,
35 A1B, and B1) found that rainfall erosivity will increase in all scenarios, even if there are large spatial
36 differences – strong increase in NE and NW, and either weak or inconsistent trends in the SW and
37 mid-West (Segura et al. 2014).

38 In a study of how climate change will impact future soil erosion processes in the Himalayas, Gupta
39 and Kumar (2017) estimated that soil erosion will increase by about 27% in the near term (2020s) and
40 22% in the medium term (2080s), with little difference between scenarios. A study from Northern
41 Thailand estimated that erosivity will increase by 5% in the near term (2020s) and 14% in the medium
42 term (2080s), which would result in a similar increase of soil erosion, all other factors being constant
43 (Plangoen and Babel 2014). Observed rainfall erosivity has increased significantly in the lower Niger
44 Basin (Nigeria) and are predicted to increase further based on statistical downscaling of four General
45 Circulation Models (GCM) scenarios, with an estimated increase of 14%, 19% and 24% for the
46 2030s, 2050s, and 2070s respectively (Amanambu et al. 2019).

47 Many studies from around the world where statistical downscaling of GCM results have been used in
48 combination with process based erosion models show a consistent trend of increasing soil erosion

1 Using a comparative approach Serpa et al. (2015) studied two Mediterranean catchments (one dry and
2 one humid) using a spatially explicit hydrological model (SWAT) in combination with land use and
3 climate scenarios for 2071-2100. Climate change projections showed, on the one hand, decreased
4 rainfall and streamflow for both catchments whereas sediment export decreased only for the humid
5 catchment; projected land use change, from traditional to more profitable, on the other hand resulted
6 in increase in streamflow. The combined effect of climate and land use change resulted in reduced
7 sediment export for the humid catchment (-29% for A1B; -22% for B1) and increased sediment export
8 for the dry catchment (+222% for A1B; +5% for B1). Similar methods have been used elsewhere, also
9 showing the dominant effect of land use/land cover for runoff and soil erosion (Neupane and Kumar
10 2015).

11 A study of future erosion rates in Northern Ireland, using a spatially explicit erosion model in
12 combination with downscaled climate projections (with and without sub-daily rainfall intensity
13 changes), showed that erosion rates without land management changes would decrease by 2020s,
14 2050s and 2100s irrespective of changes in intensity, mainly as a result of a general decline in rainfall
15 (Mullan et al. 2012). When land management scenarios were added to the modelling, the erosion rates
16 started to vary dramatically for all three time periods, ranging from a decrease of 100% for no-till land
17 use, to an increase of 3621% for row crops under annual tillage and sub-days intensity changes
18 (Mullan et al. 2012). Again, it shows how crucial land management is for addressing soil erosion, and
19 the important role of rainfall intensity changes.

20 There is a large body of literature based on modelling future land degradation due to soil erosion
21 concluding that in spite of the increasing trend of erosive power of rainfall (*medium evidence, high*
22 *agreement*) land degradation is primarily determined by land management (*very high confidence*).

23 **4.4.1.2 Climate induced vegetation changes, implications for land degradation**

24 The spatial mosaic of vegetation is determined by three factors: the ability of species to reach a
25 particular location, how species tolerate the environmental conditions at that location (e.g.
26 temperature, precipitation, wind, the topographic and soil conditions), and the interaction between
27 species (including above/below ground species (Settele et al. 2015). Climate change is projected to
28 alter the conditions and hence impact the spatial mosaic of vegetation, which can be considered a
29 form of land degradation. Warren et al. (2018) estimated that only about 33% of globally important
30 biodiversity conservation areas will remain intact if global mean temperature increases to 4.5°C, while
31 twice that area (67%) will remain intact if warming is restricted to 2°C. According to AR5, the
32 clearest link between climate change and ecosystem change is when temperature is the primary driver,
33 with changes of Arctic tundra as a response to significant warming as the best example (Settele et al.
34 2015). Even though distinguishing climate induced changes from land use changes is challenging,
35 Boit et al. (2016) suggest that 5-6% of biomes in South America will undergo biome shifts until 2100,
36 regardless of scenario, attributed to climate change. The projected biome shifts are primarily forests
37 shifting to shrubland and dry forests becoming fragmented and isolated from more humid forests
38 (Boit et al. 2016). Boreal forests are subject to unprecedented warming in terms of speed and
39 amplitude (IPCC 2013b), with significant impacts on their regional distribution (Juday et al. 2015).
40 Globally, tree lines are generally expanding northward and to higher elevations, or remaining stable,
41 while a reduction in tree line was rarely observed and only where disturbances occurred (Harsch et al.
42 2009) There is *limited evidence* of a slow northward migration of the boreal forest in eastern North
43 America (Gamache and Payette 2005). The thawing of permafrost may increase drought induced tree
44 mortality throughout the circumboreal zone (Gauthier et al. 2015).

45 Forests are a prime regulator of hydrological cycling, both fluxes of atmospheric moisture and
46 precipitation, hence climate and forests are inextricably linked (Ellison et al. 2017; Keys et al. 2017).
47 Forest management influences the storage and flow of water in forested watersheds, particularly
48 harvesting, thinning and construction of roads increase the likelihood of floods as an outcome of

1 extreme climate events (Eisenbies et al. 2007). Water balance of at least partly forested landscapes is
2 to a large extent controlled by forest ecosystems (Sheil and Murdiyarso 2009; Pokam et al. 2014).
3 This includes surface runoff, as determined by evaporation and transpiration and soil conditions, and
4 water flow routing (Eisenbies et al. 2007). Water use efficiency (i.e., the ratio of water loss to biomass
5 gain) is increasing with increased CO₂ levels (Keenan et al. 2013), hence transpiration is predicted to
6 decrease which in turn will increase surface runoff (Schlesinger and Jasechko 2014). However, the
7 interaction of several processes makes predictions challenging (Frank et al. 2015; Trahan and
8 Schubert 2016). Surface runoff is an important agent in soil erosion.

9 Generally, removal of trees through harvesting or forest death (Anderegg et al. 2012) will reduce
10 transpiration and hence increase the runoff during the growing season. Management induced soil
11 disturbance (such as skid trails and roads) will affect water flow routing to rivers and streams (Zhang
12 et al. 2017; Luo et al. 2018; Eisenbies et al. 2007).

13 Climate change affects forests in both positive and negative ways (Trumbore et al. 2015; Price et al.
14 2013) and there will be regional and temporal differences in vegetation responses (Hember et al.
15 2017; Midgley and Bond 2015). Several climate change related drivers interact in complex ways, such
16 as warming, changes in precipitation and water balance, CO₂ fertilisation, and nutrient cycling, which
17 makes projections of future net impacts challenging (see 2.3.1.2) (Kurz et al. 2013; Price et al. 2013).
18 In high latitudes, a warmer climate will extend the growing seasons which however, could be
19 constrained by summer drought (Holmberg et al. 2019) while increasing levels of atmospheric CO₂
20 will increase water use efficiency but not necessarily tree growth (Giguère-Croteau et al. 2019).
21 Improving one growth limiting factor will only enhance tree growth if other factors are not limiting
22 (Norby et al. 2010; Trahan and Schubert 2016; Xie et al. 2016; Frank et al. 2015). Increasing forest
23 productivity has been observed in most of Fennoscandia (Kauppi et al. 2014; Henttonen et al. 2017),
24 Siberia and the northern reaches of North America as a response to a warming trend (Gauthier et al.
25 2015) but increased warming may also decrease forest productivity and increase risk of tree mortality
26 and natural disturbances (Price et al. 2013; Girardin et al. 2016; Beck et al. 2011; Hember et al. 2016;
27 Allen et al. 2011). The climatic conditions in high latitudes are changing at a magnitude faster than
28 the ability of forests to adapt with detrimental, yet unpredictable, consequences (Gauthier et al. 2015).

29 Negative impacts dominate, however, and have already been documented (Lewis et al. 2004; Bonan et
30 al. 2008; Beck et al. 2011) and are predicted to increase (Miles et al. 2004 ; Allen et al. 2010;
31 Gauthier et al. 2015; Girardin et al. 2016; Trumbore et al. 2015). Several authors have emphasized a
32 concern that tree mortality (forest dieback) will increase due to climate induced physiological stress as
33 well as interactions between physiological stress and other stressors, such as insect pests, diseases,
34 and wildfires (Anderegg et al. 2012; Sturrock et al. 2011; Bentz et al. 2010; McDowell et al. 2011).
35 Extreme events such as extreme heat and drought, storms, and floods also pose increased threats to
36 forests in both high and low latitude forests (Lindner et al. 2010; Mokria et al. 2015). However,
37 comparing observed forest dieback with modelled climate induced damages did not show a general
38 link between climate change and forest dieback (Steinkamp and Hickler 2015). Forests are subject to
39 increasing frequency and intensity of wildfires which is projected to increase substantially with
40 continued climate change (see also Cross-Chapter Box 3: Fire and climate change, Chapter 2) (Price
41 et al. 2013). In the tropics, interaction between climate change, CO₂ and fire could lead to abrupt
42 shifts between woodland and grassland dominated states in the future (Shanahan et al. 2016).

43 Within the tropics, much research has been devoted to understanding how climate change may alter
44 regional suitability of various crops. For example coffee is expected to be highly sensitive to both
45 temperature and precipitation changes, both in terms of growth and yield and in terms of increasing
46 problems of pests (Ovalle-Rivera et al. 2015). Some studies conclude that the global area of coffee
47 production will decrease by 50% (Bunn et al. 2015). Due to increased heat stress, the suitability of
48 Arabica coffee is expected to deteriorate in Mesoamerica, while it can improve in high altitude areas

1 in South America. The general pattern is that the climatic suitability for Arabica coffee will
2 deteriorate at low altitudes of the tropics as well as at the higher latitudes (Ovalle-Rivera et al. 2015).
3 This means that climate change in and of itself can render unsustainable previously sustainable land
4 use and land management practices and vice versa (Laderach et al. 2011).

5 Rangelands are projected to change in complex ways due to climate change. Increasing levels of
6 atmospheric CO₂ stimulate directly plant growth and can potentially compensate negative effects from
7 drying by increasing rain use efficiency. But the positive effect of increasing CO₂ will be mediated by
8 other environmental conditions, primarily water availability but also nutrient cycling, fire regimes and
9 invasive species. Studies over the North American rangelands suggest, for example, that warmer and
10 dryer climatic conditions will reduce NPP in the southern Great Plains, the Southwest, and northern
11 Mexico, but warmer and wetter conditions will increase NPP in the northern Plains and southern
12 Canada (Polley et al. 2013).

13 **4.4.1.3 Coastal erosion**

14 Coastal erosion is expected to increase dramatically by sea level rise and in some areas in
15 combination with increasing intensity of cyclones (highlighted in Section 4.9.6). Cyclone induced
16 coastal erosion). Coastal regions are also characterised by high population density, particularly in Asia
17 (Bangladesh, China, India, Indonesia, Vietnam), whereas the highest population increase in coastal
18 regions is projected in Africa (East Africa, Egypt, and West Africa) (Neumann et al. 2015). For
19 coastal regions worldwide, and particularly in developing countries with high population density in
20 low-lying coastal areas, limiting the warming to 1.5°C to 2.0 °C will have major socio-economic
21 benefits compared with higher temperature scenarios (IPCC 2018a; Nicholls et al. 2018). For more in-
22 depth discussions on coastal process, please refer to Chapter 4 of the upcoming IPCC Special Report
23 on The Ocean and Cryosphere in a Changing Climate (IPCC SROCC).

24 Despite the uncertainty related to the responses of the large ice sheets of Greenland and west
25 Antarctica, climate change-induced sea level rise is largely accepted and represents one of the biggest
26 threats faced by coastal communities and ecosystems (Nicholls et al. 2011; Cazenave and Cozannet
27 2014; DeConto and Pollard 2016; Mengel et al. 2016). With significant socio-economic effects, the
28 physical impacts of projected sea level rise, notably coastal erosion, have received considerable
29 scientific attention (Nicholls et al. 2011; Rahmstorf 2010; Hauer et al. 2016).

30 Rates of coastal erosion or recession will increase due to rising sea levels and in some regions also in
31 combination with increasing oceans waves (Day and Hodges 2018; Thomson and Rogers 2014;
32 McInnes et al. 2011; Mori et al. 2010), lack or absence of sea-ice (Savard et al. 2009; Thomson and
33 Rogers 2014) and thawing of permafrost (Hoegh-Guldberg et al. 2018), and changing cyclone paths
34 (Tamarin-Brodsky and Kaspi 2017; Lin and Emanuel 2016a). The respective role of the different
35 climate factors in the coastal erosion process will vary spatially. Some studies have shown that the
36 role of sea level rise on the coastal erosion process can be less important than other climate factors,
37 like wave heights, changes in the frequency of the storms, and the cryogenic processes (Ruggiero
38 2013; Savard et al. 2009). Therefore, in order to have a complete picture of the potential effects of sea
39 level rise on rates of coastal erosion, it is crucial to consider the combined effects of the
40 aforementioned climate controls and the geomorphology of the coast under study.

41 Coastal wetlands around the world are sensitive to sea-level rise. Projections of the impacts on global
42 coastlines are inconclusive, with some projections suggesting that 20% to 90% (depending on sea-
43 level rise scenario) of present day wetlands will disappear during the 21st century (Spencer et al.
44 2016). Another study, which included natural feed-back processes and management responses
45 suggested that coastal wetlands may actually increase (Schuerch et al. 2018b).

1 Low-lying coastal areas in the tropics are particularly subject to the combined effect of sea-level rise
2 and increasing intensity of tropical cyclones, conditions which in many cases pose limits to
3 adaptation, see section 4.8.5.1.

4 Many large coastal deltas are subject to the additional stress of shrinking deltas as a consequence of
5 the combined effect of reduced sediment loads from rivers due to damming and water use, and land
6 subsidence resulting from extraction of ground water or natural gas, and aquaculture (Higgins et al.
7 2013; Tessler et al. 2016; Minderhoud et al. 2017; Tessler et al. 2015; Brown and Nicholls 2015;
8 Szabo et al. 2016; Yang et al. 2019; Shirzaei and Bürgmann 2018; Wang et al. 2018; Fuangswasdi et
9 al. 2019). In some cases the rate of subsidence can outpace the rate of sea level rise by one order of
10 magnitude (Minderhoud et al. 2017) or even two (Higgins et al. 2013). Recent findings from the
11 Mississippi Delta raises the risk of a systematic underestimation of the rate of land subsidence in
12 coastal deltas (Keogh and Törnqvist 2019)

13 In sum, from a land degradation point of view, low lying coastal areas are particularly exposed to the
14 nexus of climate change and increasing concentration of people (Elliott et al. 2014) (*robust evidence,*
15 *high agreement*) and the situation will become particularly acute in delta areas shrinking from both
16 reduced sediment loads and land subsidence (*robust evidence, high agreement*).

17 **4.4.2 Indirect impacts on land degradation**

18 Indirect impacts of climate change on land degradation are difficult to quantify because of the many
19 conflating factors. The causes of land-use change are complex, combining physical, biological and
20 socioeconomic drivers (Lambin et al. 2001; Lambin and Meyfroidt 2011). One such driver of land-use
21 change is the degradation of agricultural land, which can result in a negative cycle of natural land
22 being converted to agricultural land to sustain production levels. The intensive management of
23 agricultural land can lead to a loss of soil function, negatively impacting the many ecosystem services
24 provided by soils including maintenance of water quality and soil carbon sequestration (Smith et al.
25 2016a). The degradation of soil quality due to cropping is of particular concern in tropical regions,
26 where it results in a loss of productive potential of the land, affecting regional food security and
27 driving conversion of non-agricultural land, such as forestry, to agriculture (Lambin et al. 2003;
28 Drescher et al. 2016; Van der Laan et al. 2017). Climate change will exacerbate these negative cycles
29 unless sustainable land managed practices are implemented.

30 Climate change impacts on agricultural productivity (see Chapter 5) will have implications for the
31 intensity of land use and hence exacerbate the risk of increasing land degradation. There will be both
32 localised effects (i.e., climate change impacts on productivity affecting land use in the same region)
33 and teleconnections (i.e., climate change impacts and land-use change are spatially and temporally
34 separate) (Wicke et al. 2012; Pielke et al. 2007). If global temperature increases beyond 3°C it will
35 have negative yield impacts on all crops (Porter et al. 2014) which, in combination with a doubling of
36 demands by 2050 (Tilman et al. 2011), and increasing competition for land from the expansion of
37 negative emissions technologies (IPCC 2018a; Schleussner et al. 2016), will exert strong pressure on
38 agricultural lands and food security.

39 In sum, reduced productivity of most agricultural crops will drive land-use changes worldwide (*robust*
40 *evidence, medium agreement*), but predictions of how this will impact land degradation is challenging
41 because of several conflating factors. Social change, such as widespread changes in dietary
42 preferences will have a huge impact on agriculture and hence land degradation (*medium evidence,*
43 *high agreement*).

4.5 Impacts of bioenergy and technologies for CO₂ removal (CDR) on land degradation

4.5.1 Potential scale of bioenergy and land-based CDR

In addition to the traditional land use drivers (e.g. population growth, agricultural expansion, forest management), a new driver will interact to increase competition for land throughout this century: the potential large-scale implementation of land-based technologies for CO₂ removal (CDR). Land-based CDR include afforestation and reforestation, bioenergy with carbon capture and storage (BECCS), soil carbon management, biochar and enhanced weathering (Smith et al., 2015; Smith 2016)

Most scenarios, including two of the four pathways in the IPCC Special Report on 1.5°C (IPCC 2018a), compatible with stabilisation at 2°C involve substantial areas devoted to land-based CDR, specifically afforestation/ reforestation and BECCS (Schleussner et al. 2016; Smith et al. 2016b; Mander et al. 2017). Even larger land areas are required in most scenarios aimed at keeping average global temperature increases to below 1.5 °C, and scenarios that avoid BECCS also require large areas of energy crops in many cases (IPCC 2018b), although some options with strict demand-side management avoid this need (Grubler et al. 2018). Consequently, the addition of carbon capture and storage (CCS) systems to bioenergy facilities enhances mitigation benefits because it increases the carbon retention time and reduces emissions relative to bioenergy facilities without CCS. The IPCC SR15 states that “When considering pathways limiting warming to 1.5°C with no or limited overshoot, the full set of scenarios shows a conversion of 0.5 – 11 M km² of pasture into 0 – 6 M km² for energy crops, a 2 M km² reduction to 9.5 M km² increase forest, and a 4 M km² decrease to a 2.5 M km² increase in non-pasture agricultural land for food and feed crops by 2050 relative to 2010.” (Rogelj et al., 2018, p. 145). For comparison, the global cropland area in 2010 was 15.9 M km² (Table 1.1), and (Woods et al. 2015) estimate the area of abandoned and degraded land potentially available for energy crops (or afforestation/reforestation) exceeds 5 M km². However, the area of available land has long been debated, as much marginal land is subject customary land tenure and used informally often by impoverished communities (Baka 2013, 2014; Haberl et al. 2013; Young 1999). Thus, as noted in the SR15, “The implementation of land-based mitigation options would require overcoming socio-economic, institutional, technological, financing and environmental barriers that differ across regions” (IPCC, 2018a, p. 18).

The wide range of estimates reflects the large differences among the pathways, availability of land in various productivity classes, types of NET implemented, uncertainties in computer models, and social and economic barriers to implementation (Fuss et al. 2018; Nemet et al. 2018; Minx et al. 2018).

4.5.2 Risks of land degradation from expansion of bioenergy and land-based CDR

The large-scale implementation of high intensity dedicated energy crops, and harvest of crop and forest residues for bioenergy, could contribute to increases in the area of degraded lands: intensive land management can result in nutrient depletion, over fertilisation and soil acidification, salinisation (from irrigation without adequate drainage), wet ecosystems drying (from increased evapotranspiration), as well as novel erosion and compaction processes (from high impact biomass harvesting disturbances) and other land degradation processes described in Section 4.2.1.

Global integrated assessment models used in the analyses of mitigation pathways vary in their approaches to modelling CDR (Bauer et al. 2018) and the outputs have large uncertainties due to their limited capability to consider site-specific details (Krause et al. 2018). Spatial resolutions vary from 11 world regions to 0.25 degrees gridcells (Bauer et al. 2018). While model projections identify potential areas for CDR implementation (Heck et al. 2018), the interaction with climate change induced biome shifts, available land and its vulnerability to degradation are unknown. The crop/forest

1 types and management practices that will be implemented are also unknown, and will be influenced
2 by local incentives and regulations. While it is therefore currently not possible to project the area at
3 risk of degradation from the implementation of land-based CDR, there is a clear risk that expansion of
4 energy crops at the scale anticipated could put significant strain on land systems, biosphere integrity,
5 freshwater supply and biogeochemical flows (Heck et al. 2018). Similarly, extraction of biomass for
6 energy from existing forests, particularly where stumps are utilized, can impact soil health (de Jong et
7 al. 2017). Reforestation and afforestation present a lower risk of land degradation and may in fact
8 reverse degradation (see Section 4.5.3) although potential adverse hydrological and biodiversity
9 impacts will need to be managed (Caldwell et al. 2018; Brinkman et al. 2017). Soil carbon
10 management can deliver negative emissions while reducing or reversing land degradation. Chapter 6
11 discusses the significance of context and management in determining environmental impacts of
12 implementation of land-based options.

13 **4.5.3 Potential contributions of land-based CDR to reducing and reversing land** 14 **degradation**

15 Although large-scale implementation of land-based CDR has significant potential risks, the need for
16 negative emissions and the anticipated investments to implement such technologies can also create
17 significant opportunities. Investments into land-based CDR can contribute to halting and reversing
18 land degradation, to the restoration or rehabilitation of degraded and marginal lands (Chazdon and
19 Uriarte 2016; Fritsche et al. 2017) and can contribute to the goals of land degradation neutrality (Orr
20 et al. 2017a).

21 Estimates of the global area of degraded land range from less than 10 to 60 M km² (Gibbs and
22 Salmon 2015), see also section 4.3.1. Additionally, large areas are classified as marginal lands and
23 may be suitable for the implementation of bioenergy and land-based CDR (Woods et al. 2015). The
24 yield per hectare of marginal and degraded lands is lower than on fertile lands, and if CDR will be
25 implemented on marginal and degraded lands this will increase the area demand and costs per unit
26 area of achieving negative emissions (Fritsche et al. 2017). Selection of lands suitable for CDR must
27 be considered carefully to reduce conflicts with existing users, to assess the possible trade-offs in
28 biodiversity contributions of the original and the CDR land uses, to quantify the impacts on water
29 budgets, and to ensure sustainability of the CDR land use.

30 Land use and land condition prior to the implementation of CDR affect the climate change benefits
31 (Harper et al. 2018). Afforestation/ reforestation on degraded lands can increase C stocks in
32 vegetation and soil, increase carbon sinks (Amichev et al. 2012), and deliver co-benefits for
33 biodiversity and ecosystem services particularly if a diversity of local species are used. Afforestation
34 and reforestation on native grasslands can reduce soil carbon stocks, although the loss is typically
35 more than compensated by increases in biomass and dead organic matter C stocks (Bárcena et al.
36 2014; Li et al. 2012; Ovalle-Rivera et al. 2015; Shi et al. 2013), and may impact biodiversity (Li et al.
37 2012) (see also 4.4.1: Large scale forest cover expansion, what can be learned in context of the
38 SRCCL).

39 Strategic incorporation of energy crops into agricultural production systems, applying an integrated
40 landscape management approach, can provide co-benefits for management of land degradation and
41 other environmental objectives. For example, buffers of Miscanthus and other grasses can enhance
42 soil carbon and reduce water pollution (Cacho et al. 2018; Odgaard et al. 2019), and strip-planting of
43 short rotation tree crops can reduce the water table where crops are affected by dryland salinity
44 (Robinson et al. 2006). Shifting to perennial grain crops has the potential to combine food production
45 with carbon sequestration at a higher rate than with annual grain crops and avoid the trade-off
46 between food production and climate change mitigation (Crews, Carton, & Olsson, 2018; de Oliveira,
47 Brunsell, Sutherlin, Crews, & DeHaan, 2018; Ryan et al., 2018, see also 4.9.2).

1 Changes in land cover can affect surface reflectance, water balances and emissions of volatile organic
2 compounds and thus the non-GHG impacts on the climate system from afforestation/reforestation or
3 planting energy crops (Anderson et al. 2011; Bala et al. 2007; Betts 2000; Betts et al. 2007), (see
4 Section 4.6 for further details). Some of these impacts reinforce the GHG mitigation benefits, while
5 others off-set the benefits, with strong local (slope, aspect) and regional (boreal vs. tropical biomes)
6 differences in the outcomes (Li et al. 2015). Adverse effects on albedo from afforestation with
7 evergreen conifers in boreal zones can be reduced through planting of broadleaf deciduous species
8 (Astrup et al. 2018; Cai et al. 2011a; Anderson et al. 2011).

9 Combining CDR technologies may prove synergistic. Two soil management techniques with an
10 explicit focus on increasing the soil carbon content rather than promoting soil conservation more
11 broadly have been suggested: Addition of biochar to agricultural soils (see 4.9.5) and addition of
12 ground silicate minerals to soils in order to take up atmospheric CO₂ through chemical weathering
13 (Taylor et al. 2017; Haque et al. 2019; Beerling 2017; Strefler et al. 2018). The addition of biochar is
14 comparatively well understood and also field tested at large scale, see section 4.9.5 for a
15 comprehensive discussion. The addition of silicate minerals to soils is still highly uncertain in terms
16 of its potential (from 95 GtCO₂ yr⁻¹ (Strefler et al. 2018) to only 2-4 GtCO₂ yr⁻¹ (Fuss et al. 2018)) and
17 costs (Schlesinger and Amundson 2018).

18 Effectively addressing land degradation through implementation of bioenergy and land-based CDR
19 will require site-specific local knowledge, matching of species with the local land, water balance,
20 nutrient and climatic conditions, and ongoing monitoring and, where necessary, adaptation of land
21 management to ensure sustainability under global change (Fritsche et al. 2017). Effective land
22 governance mechanisms including integrated land-use planning, along with strong sustainability
23 standards could support deployment of energy crops and afforestation/reforestation at appropriate
24 scales and geographical contexts (Fritsche et al. 2017). Capacity-building and technology transfer
25 through the international cooperation mechanisms of the Paris Agreement could support such efforts.
26 Modelling to inform policy development is most useful when undertaken with close interaction
27 between model developers and other stakeholders including policymakers to ensure that models
28 account for real world constraints (Dooley and Kartha 2018).

29 International initiatives to restore lands, such as the Bonn Challenge (Verdone and Seidl 2017) and
30 the New York Declaration on Forests (Chazdon et al. 2017), and interventions undertaken for Land
31 Degradation Neutrality and implementation of NDCs (see Glossary) can contribute to NET objectives.
32 Such synergies may increase the financial resources available to meet multiple objectives (see section
33 4.8.4).

34 **4.5.4 Traditional biomass provision and land degradation**

35 Traditional biomass (fuelwood, charcoal, agricultural residues, animal dung) used for cooking and
36 heating by some 2.8 billion people (38% of global population) in non-OECD countries accounts for
37 more than half of all bioenergy used worldwide (IEA 2017; REN21 2018; see Cross-Chapter Box 7
38 on Bioenergy, Chapter 6). Cooking with traditional biomass has multiple negative impacts on human
39 health, particularly for women, children and youth (Machisa et al. 2013; Sinha and Ray 2015; Price
40 2017; Mendum and Njenga 2018; Adefuye et al. 2007) and on household productivity including high
41 workloads for women and youth (Mendum and Njenga 2018; Brunner et al. 2018; Hou et al. 2018;
42 Njenga et al. 2019). Traditional biomass is land-intensive due to reliance on open fires, inefficient
43 stoves and overharvesting of woodfuel, contributing to land degradation, losses in biodiversity and
44 reduced ecosystem services (IEA 2017; Bailis et al. 2015; Masera et al. 2015; Specht et al. 2015;
45 Fritsche et al. 2017; Fuso Nerini et al. 2017). Traditional woodfuels account for 1.9-2.3% of global
46 GHG emissions, particularly in “hotspots” of land degradation and fuelwood depletion in eastern
47 Africa and South Asia, such that one-third of traditional woodfuels globally are harvested

1 unsustainably (Bailis et al. 2015). Scenarios to significantly reduce reliance on traditional biomass in
2 developing countries present multiple co-benefits (*high evidence, high agreement*), including reduced
3 emissions of black carbon, a short-lived climate forcer that also causes respiratory disease (Shindell et
4 al. 2012).

5 A shift from traditional to modern bioenergy, especially in the African context, contributes to
6 improved livelihoods and can reduce land degradation and impacts on ecosystem services (Smeets et
7 al. 2012; Gasparatos et al. 2018; Mudombi et al. 2018). In Sub-Saharan Africa, most countries
8 mention woodfuel in their Nationally Determined Contribution (NDC) but fail to identify
9 transformational processes to make fuelwood a sustainable energy source compatible with improved
10 forest management (Amugune et al. 2017). In some regions, especially in South and Southeast Asia, a
11 scarcity of woody biomass may lead to excessive removal and use of agricultural wastes and residues,
12 which contributes to poor soil quality and land degradation (Blanco-Canqui and Lal 2009; Mateos et
13 al. 2017).

14 In sub-Saharan Africa, forest degradation is widely associated with charcoal production although in
15 some tropical areas rapid re-growth can offset forest losses (Hoffmann et al. 2017; McNicol et al.
16 2018). Overharvesting of wood for charcoal contributes to the high rate of deforestation in sub-
17 Saharan Africa, which is five times the world average, due in part to corruption and weak governance
18 systems (Sulaiman et al. 2017). Charcoal may also be a by-product of forest clearing for agriculture,
19 with charcoal sale providing immediate income when the land is cleared for food crops (Kiruki et al.
20 2017; Ndegwa et al. 2016). Besides loss of forest carbon stock, a further concern for climate change is
21 methane and black carbon emissions from fuelwood burning and traditional charcoal-making
22 processes (Bond et al. 2013; Patange et al. 2015; Sparrevik et al. 2015).

23 A fundamental difficulty in reducing environmental impacts associated with charcoal lies in the small-
24 scale nature of much charcoal production in sub-Saharan Africa leading to challenges in regulating its
25 production and trade, which is often informal, and in some cases illegal, but nevertheless widespread
26 since charcoal is the most important urban cooking fuel (Zulu 2010; Zulu and Richardson 2013; Smith
27 et al. 2015; World Bank 2009) (World Bank, 2009). Urbanisation combined with population growth
28 has led to continuously increasing charcoal production. Low efficiency of traditional charcoal
29 production results in a four-fold increase in raw woody biomass required and thus much greater
30 biomass harvest (Hojas-Gascon et al. 2016; Smeets et al. 2012). With continuing urbanisation
31 anticipated, increased charcoal production and use will probably contribute to increasing land
32 pressures and increased land degradation, especially in sub-Saharan Africa (*medium evidence, high
33 agreement*).

34 Although it could be possible to source this biomass more sustainably, the ecosystem and health
35 impacts of this increased demand for cooking fuel would be reduced through use of other renewable
36 fuels or in some cases, non-renewable fuels (LPG), as well as through improved efficiency in end-use
37 and through better resource and supply chain management (Santos et al. 2017; Smeets et al. 2012;
38 Hoffmann et al. 2017). Integrated response options such as agro-forestry (see Chapter 6) and good
39 governance mechanisms for forest and agricultural management (see Chapter 7) can support the
40 transition to sustainable energy for households and reduce the environmental impacts of traditional
41 biomass.

42 **4.6 Impacts of land degradation on climate**

43 While Chapter 2 has its focus on land cover changes and their impacts on the climate system, this
44 chapter focuses on the influences of individual land degradation processes on climate (see cross
45 chapter Table 4.1) which may or may not take place in association to land cover changes. The effects

1 of land degradation on CO₂ and other greenhouse gases as well as those on surface albedo and other
2 physical controls of the global radiative balance are discussed.

3 **4.6.1 Impacts on greenhouse gases**

4 Land degradation processes with direct impact on soil and terrestrial biota have great relevance in
5 terms of CO₂ exchange with the atmosphere given the magnitude and activity of these reservoirs in
6 the global C cycle. As the most widespread form of soil degradation, erosion detaches the surface soil
7 material which typically hosts the highest organic C stocks, favoring the mineralisation and release as
8 CO₂, yet complementary processes such as C burial may compensate this effect, making soil erosion a
9 long-term C sink (*low agreement, limited evidence*), (Wang et al. 2017b), but see also (Chappell et al.
10 2016). Precise estimation of the CO₂ released from eroded lands is challenged by the fact that only a
11 fraction of the detached C is eventually lost to the atmosphere. It is important to acknowledge that a
12 substantial fraction of the eroded material may preserve its organic C load in field conditions.
13 Moreover, C sequestration may be favored through the burial of both the deposited material and the
14 surface of its hosting soil at the deposition location (Quinton et al. 2010). The cascading effects of
15 erosion on other environmental processes at the affected sites can often cause net CO₂ emissions
16 through their indirect influence on soil fertility and the balance of organic C inputs and outputs,
17 interacting with other non-erosive soil degradation processes such as nutrient depletion, compaction
18 and salinisation, which can lead to the same net C effects (see Table 4.1) (van de Koppel et al. 1997).

19 As natural and human-induced erosion can result in net C storage in very stable buried pools at the
20 deposition locations, degradation in those locations has a high C-release potential. Coastal ecosystems
21 such as mangrove forests, marshes and seagrasses are a typical deposition locations and their
22 degradation or replacement with other vegetation is resulting in a substantial C release (0.15 to 1.02
23 Gt C yr⁻¹) (Pendleton et al. 2012), which highlights the need for a spatially-integrated assessment of
24 land degradation impacts on climate that considers in-situ but also ex-situ emissions.

25 Cultivation and agricultural management of cultivated land are relevant in terms of global CO₂ land-
26 atmosphere exchange (see also 4.8.1). Besides the initial pulse of CO₂ emissions associated with the
27 onset of cultivation and associated vegetation clearing (see Chapter 2), agricultural management
28 practices can increase or reduce C losses to the atmosphere. Although global croplands are considered
29 to be at relatively neutral stage in the current decade (Houghton et al. 2012), this results from a highly
30 uncertain balance between coexisting net losses and gains. Degradation losses of soil and biomass
31 carbon appear to be compensated by gains from soil protection and restoration practices such as cover
32 crops, conservation tillage and nutrient replenishment favoring organic matter build-up. Cover crops,
33 increasingly used to improve soils, have the potential to sequester 0.12 Gt C yr⁻¹ on global croplands
34 with a saturation time of more than 150 years (Poeplau and Don 2015). No-till practices (i.e. tillage
35 elimination favoring crop residue retention in the soil surface) which were implemented to protect
36 soils from erosion and reduce land preparation times, were also seen with optimism as a C
37 sequestration option, which today is considered more modest globally and, in some systems, even less
38 certain (VandenBygaart 2016; Cheesman et al. 2016; Powlson et al. 2014). Among soil fertility
39 restoration practices, lime application for acidity correction, increasingly important in tropical
40 regions, can generate a significant net CO₂ source in some soils (Bernoux et al. 2003, Alemu et al
41 2017).

42 Land degradation processes in seminatural ecosystems driven by unsustainable uses of their
43 vegetation through logging or grazing lead to reduced plant cover and biomass stocks, causing net C
44 releases from soils and plant stocks. Degradation by logging activities is particularly important in
45 developing tropical and subtropical regions, involving C releases that exceed by far the biomass of
46 harvested products, including additional vegetation and soil sources that are estimated to reach 0.6 Gt
47 C yr⁻¹ (Pearson et al. 2014, 2017). Excessive grazing pressures pose a more complex picture with

1 variable magnitudes and even signs of C exchanges. A general trend of higher C losses in humid
2 overgrazed rangelands suggests a high potential for C sequestration following the rehabilitation of
3 those systems (Conant and Paustian 2002) with a global potential sequestration of 0.045 Gt C yr⁻¹. A
4 special case of degradation in rangelands are those processes leading to the woody encroachment of
5 grass-dominated systems, which can be responsible of declining animal production but high C
6 sequestration rates (Asner et al. 2003, Maestre et al. 2009).

7 Fire regime shifts in wild and seminatural ecosystems can become a degradation process in itself, with
8 high impact on net C emission and with underlying interactive human and natural drivers such as
9 burning policies (Van Wilgen et al. 2004), biological invasions (Brooks et al. 2009), and plant
10 pest/disease spread (Kulakowski et al. 2003). Some of these interactive processes affecting
11 unmanaged forests have resulted in massive C release, highlighting how degradation feedbacks on
12 climate are not restricted to intensively used land but can affect wild ecosystems as well (Kurz et al.
13 2008).

14 Agricultural land and wetlands represent the dominant source of non-CO₂ greenhouse gases (Chen et
15 al. 2018d). In agricultural land, the expansion of rice cultivation (increasing CH₄ sources), ruminant
16 stocks and manure disposal (increasing CH₄, N₂O and NH₃ fluxes) and nitrogen over-fertilisation
17 combined with soil acidification (increasing N₂O fluxes) are introducing the major impacts (*medium*
18 *agreement, medium evidence*) and their associated emissions appear to be exacerbated by global
19 warming (*medium agreement and medium evidence*) (Oertel et al. 2016).

20 As the major sources of global N₂O emissions, over-fertilisation and manure disposal are not only
21 increasing in-situ sources but also stimulating those along the pathway of dissolved inorganic nitrogen
22 transport all the way from draining waters to the ocean (*high agreement, medium evidence*). Current
23 budgets of anthropogenically fixed nitrogen on the Earth System (Tian et al. 2015; Schaefer et al.
24 2016; Wang et al. 2017a) suggest that N₂O release from terrestrial soils and wetlands accounts for 10-
25 15% of the inputs, yet many further release fluxes along the hydrological pathway remain uncertain,
26 with emissions from oceanic “dead-zones” being a major aspect of concern (Schlesinger 2009;
27 Rabalais et al. 2014).

28 Environmental degradation processes focused on the hydrological system, which are typically
29 manifested at the landscape scale, include both drying (as in drained wetlands or lowlands) and
30 wetting trends (as in waterlogged and flooded plains). Drying of wetlands reduces CH₄ emissions
31 (Turetsky et al. 2014) but favors pulses of organic matter mineralization linked to high N₂O release
32 (Morse and Bernhardt 2013; Norton et al. 2011). The net warming balance of these two effects is not
33 resolved and may be strongly variable across different types of wetlands. In the case of flooding of
34 non-wetland soils, a suppression of CO₂ release is typically over compensated in terms of net
35 greenhouse impact by enhanced CH₄ fluxes, that stem from the lack of aeration but are aided by the
36 direct effect of extreme wetting on the solubilisation and transport of organic substrates (McNicol and
37 Silver 2014). Both wetlands rewetting/restoration and artificial creation can increase CH₄ release
38 (Altor and Mitsch 2006; Fenner et al. 2011). Permafrost thawing is another major source of CH₄
39 release with substantial long-term contributions to the atmosphere that are starting to get globally
40 quantified (Christensen et al. 2004; Schuur et al. 2015; Walter Anthony et al. 2016).

41 **4.6.2 Physical impacts**

42 Among the physical effects of land degradation, surface albedo changes are those with the most
43 evident impact on the net global radiative balance and net climate warming/cooling. Degradation
44 processes affecting wild and semi-natural ecosystems such as fire regime changes, woody
45 encroachment, logging and overgrazing can trigger strong albedo changes before significant
46 biogeochemical shifts take place, in most cases these two types of effects have opposite signs in terms

1 of net radiative forcing, making their joint assessment critical for understanding climate feedbacks
2 (Bright et al. 2015).

3 In the case of forest degradation or deforestation, the albedo impacts are highly dependent on the
4 latitudinal/climatic belt to which they belong. In boreal forests the removal or degradation of the tree
5 cover increases albedo (net cooling effect)(*medium evidence, high agreement*) as the reflective snow
6 cover becomes exposed, which can exceed the net radiative effect of the associated C release to the
7 atmosphere (Davin et al. 2010; Pinty et al. 2011). On the other hand, progressive greening of boreal
8 and temperate forests has contributed to net albedo declines (*medium agreement, medium evidence*)
9 (Planque et al. 2017; Li et al. 2018a). In the northern treeless vegetation belt (tundra), shrub
10 encroachment leads to the opposite effect as the emergence of plant structures above the snow cover
11 level reduce winter-time albedo (Sturm 2005).

12 The extent to which albedo shifts can compensate carbon storage shifts at the global level has not
13 been estimated. A significant but partial compensation takes place in temperate and subtropical dry
14 ecosystems in which radiation levels are higher and C stocks smaller compared to their more humid
15 counterparts (*medium agreement, medium evidence*). In cleared dry woodlands half of the net global
16 warming effect of net C release has been compensated by albedo increase (Houspanossian et al.
17 2013), whereas in afforested dry rangelands albedo declines cancelled one fifth of the net C
18 sequestration (Rotenberg and Yakir 2010). Other important cases in which albedo effects impose a
19 partial compensation of C exchanges are the vegetation shifts associated to wild fires, as shown for
20 the savannahs, shrublands and grasslands of sub-Saharan Africa (Dintwe et al. 2017). Besides the net
21 global effects discussed above, albedo shifts can play a significant role on local climate (*high*
22 *agreement, medium evidence*), as exemplified by the effect of no-till agriculture reducing local heat
23 extremes in European landscapes (Davin et al. 2014) and the effects of woody encroachment causing
24 precipitation rises in the North American Great Plains (Ge and Zou 2013). Modeling efforts that
25 integrate ground data from deforested areas worldwide accounting for both physical and
26 biogeochemical effects, indicate that massive global deforestation would have a net warming impact
27 (Lawrence and Vandecar 2015) at both local and global levels with highlight non-linear effects of
28 forest loss on climate variables.

29 Beyond the albedo effects presented above, other physical impacts of land degradation on the
30 atmosphere can contribute to global and regional climate change. Of particular continental to global
31 relevance are the net cooling effects of dust emissions (*low agreement, medium evidence*) (Lau and
32 Kim 2007), but see also (Huang et al. 2014). Anthropogenic emission of mineral particles from
33 degrading land appear to have a similar radiative impact than all other anthropogenic aerosols
34 (Sokolik and Toon 1996). Dust emissions may explain regional climate anomalies through reinforcing
35 feedbacks, as suggested for the amplification of the intensity, extent and duration of the low
36 precipitation anomaly of the North American “Dust Bowl” in the 1930s (Cook et al. 2009). Another
37 source of physical effects on climate are surface roughness changes which, by affecting atmospheric
38 drag, can alter cloud formation and precipitation (*low agreement, low evidence*), as suggested by
39 modeling studies showing how the massive deployment of solar panels in the Sahara could increase
40 rainfall in the Sahel (Li et al. 2018c) or how woody encroachment in the Arctic tundra could reduce
41 cloudiness and raise temperature (Cho et al. 2018). The complex physical effects of deforestation, as
42 explored through modeling, converge into general net regional precipitation declines, tropical
43 temperature increases and boreal temperature declines, while net global effects are less certain
44 (Perugini et al. 2017). Integrating all the physical effects of land degradation and its recovery or
45 reversal is still challenge, yet modeling attempts suggest that over the last three decades the slow but
46 persistent net global greening caused by the average increase of leaf area in the land has caused a net
47 cooling of the Earth, mainly through the raise of evapotranspiration (Zeng et al. 2017) (*low*
48 *confidence*).

4.7 Impacts of climate-related land degradation on poverty and livelihoods

Unravelling the impacts of climate-related land degradation on poverty and livelihoods is highly challenging. This complexity is due to the interplay of multiple social, political, cultural, and economic factors, such as markets, technology, inequality, population growth, (Barbier and Hochard 2018) each of which interact and shape the ways in which social-ecological systems respond (Morton 2007). We find *limited evidence* attributing the impacts of climate-related land degradation to poverty and livelihoods, with climate often not distinguished from any other driver of land degradation. Climate is nevertheless frequently noted as a risk multiplier for both land degradation and poverty (*high agreement, robust evidence*) and is one of many stressors people live with, respond to and adapt to in their daily lives (Reid and Vogel 2006). Climate change is considered to exacerbate land degradation and potentially accelerate it due to heat stress, drought, changes to evapotranspiration rates and biodiversity, as well as a result of changes to environmental conditions that allow new pests and diseases to thrive (Reed and Stringer 2016b). In general terms, the climate (and climate change) can increase human and ecological communities' sensitivity to land degradation. Land degradation then leaves livelihoods more sensitive to the impacts of climate change and extreme climatic events (*high agreement, robust evidence*). If human and ecological communities exposed to climate change and land degradation are sensitive and cannot adapt, they can be considered vulnerable to it; if they are sensitive and can adapt, they can be considered resilient (Reed and Stringer 2016b). The impacts of land degradation will vary under a changing climate both spatially and temporally, leading some communities and ecosystems to be more vulnerable or more resilient than others under different scenarios. Even within communities, groups such as women and the youth are often more vulnerable than others.

4.7.1 Relationships between land degradation, climate change and poverty

This section sets out the relationships between land degradation and poverty, and climate change and poverty, leading to inferences about the 3-way links between them. Poverty is multidimensional and includes a lack of access to the whole range of capital assets that can be used to pursue a livelihood. Livelihoods constitute the capabilities, assets, and activities that are necessary to make a living (Chambers and Conway 1992; Olsson et al. 2014b).

The literature shows *high agreement* in terms of speculation that there are potential links between land degradation and poverty. However, studies have not provided robust quantitative assessments of the extent and incidence of poverty within land degradation affected populations (Barbier and Hochard 2016). Some researchers, e.g. Nachtergaele et al. (2011) estimate that 1.5 billion people were dependent upon degraded land to support their livelihoods in 2007, while >42 % of the world's poor population inhabit degraded areas. However, there is overall *low confidence* in the evidence base, a lack of studies that look beyond the past and present, and the literature calls for more in-depth research to be undertaken on these issues (Gerber et al. 2014). Recent work by Barbier and Hochard (Barbier and Hochard 2018) points to biophysical constraints such as poor soils and limited rainfall which interact to limit land productivity, suggesting that those farming in climatically less favourable agricultural areas are challenged by poverty. Studies such as those by (Coomes et al. 2011), focusing on an area in the Amazon, highlight the importance of the initial conditions of land holding in the dominant (shifting) cultivation system in terms of long-term effects on household poverty and future forest cover, showing initial land tenure and socio-economic aspects can make some areas less favourable too.

Much of the qualitative literature is focused on understanding the livelihood and poverty impacts of degradation through a focus on subsistence agriculture, where farms are small, under traditional or

1 informal tenure and where exposure to environmental (including climate) risks is high (Morton 2007).
2 In these situations, the poor lack access to assets (financial, social, human, natural and physical) and
3 in the absence of appropriate institutional supports and social protection, this leaves them sensitive
4 and unable to adapt, so a vicious cycle of poverty and degradation can ensue. To further illustrate the
5 complexity, livelihood assessments often focus on a single snapshot in time, livelihoods are dynamic
6 and people alter their livelihood activities and strategies depending the on internal and external
7 stressors to which they are responding (O'Brien et al. 2004). When certain livelihood activities and
8 strategies become no longer tenable as a result of land degradation (and may push people into
9 poverty), it can have further effects on issues such as migration (Lee 2009), as people adapt by
10 moving (see Section 4.7.3); and may result in conflict (see Section 4.7.3), as different groups within
11 society compete for scarce resources, sometimes through non-peaceful actions. Both migration and
12 conflict can lead to land use changes elsewhere that further fuel climate change through increased
13 emissions.

14 Similar challenges as for understanding land degradation-poverty linkages are experienced in
15 unravelling the relationship between climate change and poverty. A particular issue in examining
16 climate change-poverty links relates to the common use of aggregate economic statistics like GDP, as
17 the assets and income of the poor constitute such as minor proportion of national wealth (Hallegatte et
18 al. 2018). Aggregate quantitative measures also fail to capture the distributions of costs and benefits
19 from climate change. Furthermore, people fall into and out of poverty, with climate change being one
20 of many factors affecting these dynamics, through its impacts on livelihoods. Much of the literature
21 on climate change and poverty tends to look backward rather than forward (Skoufias et al. 2011),
22 providing a snap-shot of current or past relationships, (for example, (Dell et al. 2009) who examine
23 the relationship between temperature and income (GDP) using cross-sectional data from countries in
24 the Americas). Yet, simulations of future climate change impacts on income or poverty are largely
25 lacking.

26 Noting the *limited evidence* that exists that explicitly focuses on the relationship between land
27 degradation, climate change and poverty, Barbier and Hochard (2018b) suggest that those people
28 living in less favoured agricultural areas face a poverty-environment trap that can result in increased
29 land degradation under climate change conditions. The emergent relationships between land
30 degradation, climate change and poverty are shown in Figure 4.6 (see also Figure 6.1).

31

1
2 **Figure 4.6 Schematic representation of links between climate change, land management and socio-**
3 **economic conditions.**

4 The poor have access to few productive assets, so land, and the natural resource base more widely,
5 plays a key role in supporting the livelihoods of the poor. It is however, hard to make generalisations
6 about how important income derived from the natural resource base is for rural livelihoods in the
7 developing world (Angelsen et al. 2014) with studies focusing on forest resources having shown that
8 approximately one quarter of the total rural household income in developing countries stems from
9 forests, with forest-based income shares being tentatively higher for low-income households (Vedeld
10 et al. 2007; Angelsen et al. 2014). Different groups use land in different ways within their overall
11 livelihood portfolios and are therefore at different levels of exposure and sensitivity to climate shocks
12 and stresses. The literature nevertheless displays *high evidence* and *high agreement* that those
13 populations whose livelihoods are more sensitive to climate change and land degradation are often
14 more dependent on environmental assets, and these people are often the poorest members of society.
15 There is further *high evidence and high agreement* that both climate change and land degradation can
16 affect livelihoods and poverty through their threat multiplier effect. Research in Bellona, in the
17 Solomon Islands in the south Pacific (Reenberg et al. 2008) examined event-driven impacts on
18 livelihoods, taking into account weather events as one of many drivers of land degradation and links
19 to broader land-use and land cover changes that have taken place. Geographical locations
20 experiencing land degradation are often the same locations that are directly affected by poverty, and
21 are also affected by extreme events linked to climate change and variability.

22 Much of the assessment presented above has considered place-based analyses examining the
23 relationships between poverty, land degradation and climate change in the locations in which these
24 outcomes have occurred. Altieri and Nicholls (2017) note that due to the globalised nature of markets
25 and consumption systems, the impacts of changes in crop yields linked to climate-related land
26 degradation (manifest as lower yields) will be far reaching, beyond the sites and livelihoods
27 experiencing degradation. Despite these teleconnections, farmers living in poverty in developing
28 countries will be especially vulnerable due to their exposure, dependence on the environment for
29 income and limited options to engage in other ways to make a living (Rosenzweig and Hillel 1998). In
30 identifying ways in which these interlinkages can be addressed, (Scherr 2000) observes that key
31 actions that can jointly address poverty and environmental improvement often seek to increase access

1 to natural resources, enhance the productivity of the natural resource assets of the poor, and to engage
2 stakeholders in addressing public natural resource management issues. In this regard, it is increasingly
3 recognised that those suffering from and being vulnerable to land degradation and poverty need to
4 have a voice and play a role in the development of solutions, especially where the natural resources
5 and livelihood activities they depend on are further threatened by climate change.

6 **4.7.2 Impacts of climate related land degradation on food security**

7 How and where we grow food compared to where and when we need to consume it is at the crux of
8 issues surrounding land degradation, climate change and food security, especially because more than
9 75% of the global land surface (excluding Antarctica) faces rain-fed crop production constraints
10 (Fischer et al. 2009), see also Chapter 5. Taken separately, knowledge on land degradation processes
11 and human-induced climate change has attained a great level of maturity. However, their combined
12 effects on food security, notably food supply, remain underappreciated (Webb et al. 2017b), and
13 quantitative information is lacking. Just a few studies have shown how the interactive effects of the
14 aforementioned challenging, interrelated phenomena can impact crop productivity and hence food
15 security and quality (Karami et al. 2009; Allen et al. 2001; Högy and Fangmeier 2008) (*low evidence*).
16 Along with socio-economic drivers climate change accelerates land degradation due to its influence
17 on land-use systems (Millennium Assessment 2005; UNCCD 2017), potentially leading to a decline
18 in agri-food system productivity, particularly on the supply side. Increases in temperature and changes
19 in precipitation patterns are expected to have impacts on soil quality, including nutrient availability
20 and assimilation (St.Clair and Lynch 2010). Those climate-related changes are expected to have net
21 negative impacts on agricultural productivity, particularly in tropical regions, though the magnitude of
22 impacts depends on the models used. Anticipated supply side issues linked to land and climate relate
23 to biocapacity factors (including e.g. whether there is enough water to support agriculture); production
24 factors (e.g. chemical pollution of soil and water resources or lack of soil nutrients) and distribution
25 issues (e.g. decreased availability of and/or accessibility to the necessary diversity of quality food
26 where and when it is needed) (Stringer et al. 2011). Climate sensitive transport infrastructure is also
27 problematic for food security (Islam et al. 2017), and can lead to increased food waste, while poor
28 siting of roads and transport links can lead to soil erosion and forest loss (Xiao et al. 2017), further
29 feeding back into climate change.

30 Over the past decades, crop models have been useful tools for assessing and understanding climate
31 change impacts on crop productivity and food security (White et al. 2011; Rosenzweig et al. 2014).
32 Yet, the interactive effects of soil parameters and climate change on crop yields and food security
33 remain limited, with *low evidence* of how they play out in different economic and climate settings
34 (e.g. Sundström et al. 2014). Similarly, there have been few meta-analyses focusing on the adaptive
35 capacity of land-use practices such as conservation agriculture in light of climate stress (see e.g.
36 Steward et al. 2018), as well as *low evidence* quantifying the role of wild foods and forests (and by
37 extension forest degradation) in both the global food basket and in supporting household scale food
38 security (Bharucha and Pretty 2010; Hickey et al. 2016)

39 To be sustainable, any initiative aiming at addressing food security – encompassing supply, diversity
40 and quality - must take into consideration the interactive effects between climate and land degradation
41 in a context of other socio-economic stressors. Such socio-economic factors are especially important
42 if we look at demand side issues too, which include lack of purchasing power, large scale speculation
43 on global food markets leading to exponential price rises (Tadesse et al. 2014), competition in
44 appropriation of supplies and changes to per capita food consumption (Stringer et al. 2011; see also
45 Chapter 5). Lack of food security, combined with lack of livelihood options, is often an important
46 manifestation of vulnerability, and can act as a key trigger for people to migrate. In this way,
47 migration becomes an adaptation strategy.

4.7.3 Impacts of climate-related land degradation on migration and conflict

Land degradation may trigger competition for scarce natural resources potentially leading to migration and/or conflict, though even with *medium evidence* there is *low agreement* in the literature. Linkages between land degradation and migration occur within a larger context of multi-scale interaction of environmental and non-environmental drivers and processes, including resettlement projects, searches for education and/or income, land shortages, political turmoil, and family-related reasons (McLeman 2017; Hermans and Ide 2019). The complex contribution of climate to migration and conflict hampers retrieving any level of confidence on climate-migration and climate-conflict linkages, therefore constituting a major knowledge gap (Cramer et al. 2014; Hoegh-Guldberg et al. 2018).

There is *low evidence* on the causal linkages between climate change, land degradation processes (other than desertification) and migration. Existing studies on land degradation and migration – particularly in drylands – largely focus on the effect of rainfall variability and drought and shows how migration serves as adaptation strategy (Piguet et al. 2018; McLeman 2017; chapter 3). For example, in the Ethiopian highlands severe topsoil erosion and forest degradation is a major environmental stressor which is amplified by re-occurring droughts, with migration being an important household adaptation strategy (Morrissey 2013). In the humid tropics, land degradation, mainly as a consequence of deforestation, has been a reported reason for people leaving their homes during the Amazonian colonisation (Hecht 1983) but was also observed more recently, for example in Guatemala, where soil degradation was one of the most frequently cited migration pushes (López-Carr 2012) and Kenya, where households respond to low soil quality by sending temporary migrants for additional income generation (Gray 2011). In contrast, in the Andean highlands and the Pacific coastal plain, migration increased with land quality, probably because revenues from additional agricultural production was invested in costly forms of migration (Gray and Bilsborrow 2013). These mixed results illustrate the complex, non-linear relationship of land degradation-migration linkages and suggest explaining land degradation-migration linkages requires considering a broad socio-ecological embedding (McLeman 2017).

In addition to people moving away from an area due to “lost” livelihood activities, climate related land degradation can also reduce the availability of livelihood safety nets – environmental assets that people use during times of shocks or stress. For example, Barbier (2000) notes that wetlands in north-east Nigeria around Hadejia–Jama’are floodplain provide dry season pastures for seminomadic herders, agricultural surpluses for Kano and Borno states, groundwater recharge of the Chad formation aquifer and ‘insurance’ resources in times of drought. The floodplain also supports many migratory bird species. As climate change and land degradation combine, delivery of these multiple services can be undermined, particularly as droughts become more widespread, reducing the utility of this wetland environment as a safety net for people and wildlife alike.

Early studies conducted in Africa hint at a significant causal link between land degradation and violent conflict (Homer-Dixon et al. 1993). For example, Percival and Homer-Dixon (1995) identified land degradation as one of the drivers of the crisis in Rwanda in the early 1990s which allowed radical forces to stoke ethnic rivalries. With respect to the Darfur conflict, some scholars and UNEP concluded that land degradation, together with other environmental stressors, constitute a major security threat for the Sudanese people (Byers and Dragojlovic 2004; Sachs 2007; UNEP 2007). Recent studies show *low agreement*, suggesting that climate change can increase the likelihood of civil violence if certain economic, political and social factors, including low development and weak governance mechanisms, are present (Scheffran et al. 2012; Benjaminsen et al. 2012). In contrast, Raleigh (Raleigh and Urdal 2007) found in a global study that land degradation is a weak predictor for armed conflict. As such, studies addressing possible linkages between climate change – a key driver of land degradation – and the risks of conflict have yielded contradictory results and it remains largely

1 unclear whether land degradation resulting from climate change leads to conflict or cooperation
2 (Salehyan 2008; Solomon et al. 2018).

3 Land degradation-conflict linkages can be bi-directional. Research suggests that households
4 experiencing natural resource degradation often engage in migration for securing livelihoods
5 (Kreamer 2012), which potentially triggers land degradation at the destination leading to conflict there
6 (Kassa et al. 2017). While this indeed holds true for some cases it may not for others given the
7 complexity of processes, contexts and drivers. Where conflict and violence do ensue, it is often as a
8 result of a lack of appreciation for the cultural practices of others.

9 **4.8 Addressing land degradation in the context of climate change**

10 Land degradation in the form of soil carbon loss is estimated to have been ongoing for at least 12,000
11 years, but increased exponentially in the last 200 years (Sanderman et al. 2017). Before the advent of
12 modern sources of nutrients, it was imperative for farmers to maintain and improve soil fertility
13 through the prevention of runoff and erosion, and management of nutrients through vegetation
14 residues and manure. Many ancient farming systems were sustainable for hundreds and even
15 thousands of years, such as raised field agriculture in Mexico (Crews and Gliessman 1991), tropical
16 forest gardens in SE Asia and Central America (Ross 2011; Torquebiau 1992; Turner and Sabloff
17 2012), terraced agriculture in East Africa, Central America, Southeast Asia and the Mediterranean
18 basin (Turner and Sabloff 2012; Preti and Romano 2014; Widgren and Sutton 2004; Håkansson and
19 Widgren 2007; Davies and Moore 2016; Davies 2015), and integrated rice-fish cultivation in East
20 Asia (Frei and Becker 2005).

21 Such long-term sustainable farming systems evolved in very different times and geographical
22 contexts, but they share many common features, such as: the combination of species and structural
23 diversity in time, and space (horizontally and vertically) in order to optimise the use of available land;
24 recycling of nutrients through biodiversity of plants, animals, and microbes; harnessing the full range
25 of site-specific micro-environments (e.g. wet and dry soils); biological interdependencies which helps
26 suppression of pests; reliance on mainly local resources; reliance on local varieties of crops and
27 sometimes incorporation of wild plants and animals; the systems are often labour and knowledge
28 intensive (Rudel et al. 2016; Beets 1990; Netting 1993; Altieri and Koohafkan 2008). Such farming
29 systems have stood the test of time and can provide important knowledge for adapting farming
30 systems to climate change (Koohafkan and Altieri 2011).

31 In modern agriculture the importance of maintaining the biological productivity and ecological
32 integrity of farm land has not been a necessity in the same way as in pre-modern agriculture because
33 nutrients and water have been supplied externally. The extreme land degradation in the US Midwest
34 during the Dust Bowl period in the 1930s became an important wake-up call for agriculture and
35 agricultural research and development, from which we can still learn much in order to adapt to
36 ongoing and future climate change (McLeman et al. 2014; Baveye et al. 2011; McLeman and Smit
37 2006).

38 Sustainable Land Management (SLM) is a unifying framework for addressing land degradation and
39 can be defined as the stewardship and use of land resources, including soils, water, animals and
40 plants, to meet changing human needs, while simultaneously ensuring the long-term productive
41 potential of these resources and the maintenance of their environmental functions. 'It is a
42 comprehensive approach comprising technologies combined with social, economic and political
43 enabling conditions (Nkonya et al. 2011). It is important to stress that farming systems are informed
44 by both scientific and local/traditional knowledge. The power of SLM in small-scale diverse farming
45 was demonstrated effectively in Nicaragua after the severe cyclone Mitch in 1998 (Holt-Giménez
46 2002). Pairwise analysis of 880 fields with and without implementation of SLM practices showed that

1 the SLM fields systematically fared better than the fields without SLM in terms of more topsoil
 2 remaining, higher field moisture, more vegetation, less erosion and lower economic losses after the
 3 cyclone. Furthermore the difference between fields with and without SLM increased with increasing
 4 levels of storm intensity, increasing slope gradient, and increasing age of SLM (Holt-Giménez 2002).

5 When addressing land degradation through SLM and other approaches it is important to consider
 6 feedbacks that impact climate change. Table 4.2 shows some of the most important land degradation
 7 issues, their potential solutions, and their impacts on climate change. This table provides a link
 8 between the comprehensive lists of land degradation processes (Table 4.1) and land management
 9 solutions (Table 4.2).

Table 4.2 (Cross-chapter Ch 3 and Ch 4) Interaction of human and climate drivers can exacerbate desertification and land degradation

Climate change exacerbates the rate and magnitude of several ongoing land degradation and desertification processes. Human drivers of land degradation and desertification include expanding agriculture, agricultural practices and forest management. In turn land degradation and desertification are also drivers of climate change through the emission of greenhouse gases, reduced rates of carbon uptake and reduced capacity of ecosystems to act as carbon sinks into the future.

Human driver	Climate driver
Grazing pressure 	Warming trend 
Agriculture practices 	Extreme temperatures 
Expansion of agriculture 	Drying trend 
Forest clearing 	Extreme rainfall 
Wood fuel 	Shifting rains 
	Intensifying cyclones 
	Sea level rise 

Issue/syndrome	Impact on climate change	Human driver	Climate driver	Land management options	References
Erosion of agricultural soils	Emission: CO ₂ , N ₂ O			Increase soil organic matter, no till, perennial crops, erosion control, agro forestry, dietary change	{3.2.4, 3.5.1, 3.6.2, 3.8.1, 4.9.1, 4.9.5, 4.10.2, 4.10.5}
Deforestation	Emission of CO ₂			Forest protection, sustainable forest management and dietary change	{4.2.5, 4.6, 4.9.3, 4.9.4, 4.10.3}
Forest degradation	Emission of CO ₂ Reduced carbon sink			Forest protection, sustainable forest management	{4.2.5, 4.6, 4.9.3, 4.9.4, 4.10.3}
Overgrazing	Emission: CO ₂ , CH ₄ Increasing albedo			Controlled grazing, rangeland management	{3.2.4.2, 3.5.1, 3.7.1, 3.8.1, 4.9.1.4}
Firewood and charcoal production	Emission: CO ₂ , CH ₄ Increasing albedo			Clean cooking (health co-benefits, particularly for women and children)	{3.7.3, 4.6.4, 4.9.3, 4.9.4}
Increasing fire frequency and intensity	Emission: CO ₂ , CH ₄ , N ₂ O Emission: aerosols, increasing albedo			Fuel management, fire management	{3.2.4, 3.7.1, 4.2.5, 4.9.3, Cross chapter box 3}
Degradation of tropical peat soils	Emission: CO ₂ , CH ₄			Peatland restoration, erosion control, regulating the use of peat soils	{4.10.4}
Thawing of perma-frost	Emission: CO ₂ , CH ₄			relocation of settlement and infrastructure	{4.9.5.1}
Coastal erosion	Emission: CO ₂ , CH ₄			Wetland and coastal restoration, mangrove conservation, long term land use planning	{4.10.6, 4.10.7, 4.10.8}
Sand and dust storms, wind erosion	Emission: aerosols			Vegetation management, afforestation, windbreaks	{3.4.1, 3.5.1, 3.7.1, 3.8.1, 3.8.2}
Bush encroachment	Capturing: CO ₂ , Decreasing albedo			Grazing land management, fire management	{3.7.1.3, 3.8.3.2}

13 **4.8.1 Actions on the ground to address land degradation**

14 Concrete actions on the ground to address land degradation are primarily focused on soil and water
 15 conservation. In the context of adaptation to climate change, actions relevant for addressing land
 16 degradation are sometimes framed as ecosystem based adaptation (EBA) (Scarano 2017) or Nature
 17 Based Solutions (NBS) (Nesshöver et al. 2017), and in an agricultural context, agroecology (see

1 glossary) provides an important frame. The site-specific biophysical and social conditions, including
2 local and indigenous knowledge, are important for successful implementation of concrete actions.

3 Responses to land degradation generally take the form of agronomic measures (methods related to
4 managing the vegetation cover), soil management (methods related to tillage, nutrient supply), and
5 mechanical methods (methods resulting in durable changes to the landscape) (Morgan 2005a).
6 Measures may be combined to reinforce benefits to land quality, as well as improving carbon
7 sequestration that supports climate change mitigation. Some measures offer adaptation options and
8 other co-benefits, such as agroforestry involving planting fruit trees that can support food security in
9 the face of climate change impacts (Reed and Stringer 2016a) or application of compost or biochar
10 that enhances soil water holding capacity, so increases resilience to drought.

11 There are important differences in terms of labour and capital requirements for different technologies,
12 and also implications for land tenure arrangements. Agronomic measures and soil management
13 require generally little extra capital input and comprise activities repeated annually, so have no
14 particular implication for land tenure arrangements. Mechanical methods require substantial upfront
15 investments in terms of capital and labour, resulting in long lasting structural change requiring more
16 secure land tenure arrangements (Mekuriaw et al. 2018). Agroforestry is a particularly important
17 strategy for SLM in the context of climate change because the large potential to sequester carbon in
18 plants and soil and enhance resilience of agricultural systems (Zomer et al. 2016).

19 Implementation of sustainable land management practices has been shown to increase the productivity
20 of land (Branca et al. 2013) and to provide good economic returns on investment in many different
21 settings around the world (Mirzabaev et al. 2015). Giger et al (2018) showed in a meta study of 363
22 projects over the period 1990 to 2012 that 73% of the projects were perceived to have a positive or at
23 least neutral cost/benefit ratio in the short term, and 97% were perceived to have a positive or very
24 positive cost/benefit ratio in the long term (*robust evidence, high agreement*). Despite the positive
25 effects, uptake is far from universal. Local factors, both biophysical conditions (e.g. soils, drainage,
26 and topography) and socio-economic conditions (e.g. land tenure, economic status, and land
27 fragmentation) play decisive roles in the interest in, capacity to undertake, and successful
28 implementation of sustainable land management practices (Teshome et al. 2016; Vogl et al. 2017;
29 Tesfaye et al. 2016; Cerdà et al. 2018; Adimassu et al. 2016). From a landscape perspective,
30 sustainable land management can generate benefits, including adaptation to and mitigation of climate
31 change, for entire watersheds, but challenges remain regarding coordinated and consistent
32 implementation (Kerr et al. 2016; Wang et al. 2016a). (*medium evidence, medium agreement*)

33 **4.8.1.1 Agronomic and soil management measures**

34 Rebuilding soil carbon is an important goal of SLM, particularly in the context of climate change
35 (Rumpel et al. 2018). The two most important reasons why agricultural soils have lost 20-60% of the
36 soil carbon they contained under natural ecosystem conditions are the frequent disturbance through
37 tillage and harvesting and the change from deep rooted perennial plants to shallow rooted annual
38 plants (Crews and Rumsey 2017). Practices that build soil carbon are those that increase organic
39 matter input to soil, or reduce decomposition of soil organic matter.

40 Agronomic practices can alter the carbon balance significantly, by increasing organic inputs from
41 litter and roots into the soil. Practices include retention of residues, use of locally-adapted varieties,
42 inter-cropping, crop rotations, and green manure crops that replace the bare field fallow during winter
43 and are eventually ploughed before sowing next main crop (Henry et al., 2018). Cover crops (green
44 manure crops and catch crops that are grown between the main cropping seasons) can increase soil
45 carbon stock by between 0.22 and 0.4 t C ha⁻¹yr⁻¹ (Poepflau and Don 2015; Kaye and Quemada 2017).

46 Reduced tillage (or no-tillage) is an important strategy for reducing soil erosion and nutrient loss by
47 wind and water (Van Pelt et al. 2017; Panagos et al. 2015; Borrelli et al. 2016). But the evidence that

1 no-till agriculture also sequesters carbon is not compelling (VandenBygaart 2016). Soil sampling of
2 only the upper 30 cm can give biased results suggesting that soils under no-till practices have higher
3 carbon content than soils under conventional tillage (Baker et al. 2007; Ogle et al. 2012; Fargione et
4 al. 2018; VandenBygaart 2016).

5 Changing from annual to perennial crops can increase soil carbon content (Culman et al. 2013; Sainju
6 et al. 2017). A perennial grain crop (intermediate wheatgrass) was on average over four years a net
7 carbon sink of about 13.5 t CO₂ ha⁻¹yr⁻¹ (de Oliveira et al. 2018). Sprunger et al. (2018) compared an
8 annual winter wheat crop with a perennial grain crop (intermediate wheatgrass) and found that the
9 perennial grain root biomass was 15 times larger than winter wheat, however, there was no significant
10 difference in soil carbon pools after the four-year experiment. Exactly how much, and over what time
11 period, carbon can be sequestered through changing from annual to perennial crops depends on the
12 degree of soil carbon depletion and other local biophysical factors (see also section 4.9.2).

13 Integrated soil fertility management is a sustainable approach to nutrient management that uses a
14 combination of chemical and organic amendments (manure, compost, biosolids, biochar), rhizobial
15 nitrogen fixation, and liming materials to address soil chemical constraints (Henry et al., 2018). In
16 pasture systems, management of grazing pressure, fertilisation, diverse species including legumes and
17 perennial grasses can reduce erosion and enhance soil carbon (Conant et al. 2017).

18 **4.8.1.2 Mechanical soil and water conservation**

19 In hilly and mountainous terrain terracing is an ancient but still practiced soil conservation method
20 worldwide (Preti and Romano 2014) in climatic zones from arid to humid tropics (Balbo 2017). By
21 reducing the slope gradient of hillsides, terraces provide flat surfaces and deep, loose soils that
22 increase infiltration, reduce erosion and thus sediment transport. They also decrease the hydrological
23 connectivity and thus reduce hillside runoff (Preti et al. 2018; Wei et al. 2016; Arnáez et al. 2015;
24 Chen et al. 2017). In terms of climate change, terraces are a form of adaptation which helps both in
25 cases where rainfall is increasing or intensifying (by reducing slope gradient and the hydrological
26 connectivity), and where rainfall is decreasing (by increasing infiltration and reducing runoff) (*robust
27 evidence, high agreement*). There are several challenges, however, to continued maintenance and
28 construction of new terraces, such as the high costs in terms of labour and/or capital (Arnáez et al.
29 2015) and disappearing local knowledge for maintaining and constructing new terraces (Chen et al.
30 2017). The propensity of farmers to invest in mechanical soil conservation methods varies with land
31 tenure, farmers with secure tenure arrangements are more willing to invest in durable practices such
32 as terraces (Lovo 2016; Sklenicka et al. 2015; Haregeweyn et al. 2015). Where the slope is less
33 severe, erosion can be controlled by contour banks, and the keyline approach (Duncan 2016; Stevens
34 et al. 2015) to soil and water conservation.

35 **4.8.1.3 Agroforestry**

36 Agroforestry is defined as a collective name for land-use systems in which woody perennials (trees,
37 shrubs, etc.) are grown in association with herbaceous plants (crops, pastures) and/or livestock in a
38 spatial arrangement, a rotation, or both, and in which there are both ecological and economic
39 interactions between the tree and non-tree components of the system (Young, 1995, p. 11). At least
40 since the 1980s agroforestry has been widely touted as an ideal land management practice in areas
41 vulnerable to climate variations and subject to soil erosion. Agroforestry holds the promise of
42 improving of soil and climatic conditions while generating income from wood energy, timber, and
43 non-timber products – sometimes presented as a synergy of adaptation and mitigation of climate
44 change (Mbow et al. 2014).

45 There is strong scientific consensus that a combination of forestry with agricultural crops and/or
46 livestock, agroforestry systems can provide additional ecosystem services when compared with
47 monoculture crop systems (Waldron et al. 2017; Sonwa et al. 2011a, 2014, 2017; Charles et al. 2013).
48 Agroforestry can enable sustainable intensification by allowing continuous production on the same

1 unit of land with higher productivity without the need to use shifting agriculture systems to maintain
2 crop yields (Nath et al. 2016). This is especially relevant where there is a regional requirement to find
3 a balance between the demand for increased agricultural production and the protection of adjacent
4 natural ecosystems such as primary and secondary forests (Mbow et al. 2014). For example, the use of
5 agroforestry for perennial crops such as coffee and cocoa are increasingly promoted as offering a
6 route to sustainable farming with important climate change adaptation and mitigation co-benefits
7 (Sonwa et al. 2001; Kroeger et al. 2017). Reported co-benefits of agroforestry in cocoa production
8 include increased carbon sequestration in soils and biomass, improved water and nutrient use
9 efficiency and the creation of a favourable micro-climate for crop production (Sonwa et al. 2017; Chia
10 et al. 2016). Importantly, the maintenance of soil fertility using agroforestry has the potential to
11 reduce the practice of shifting-agriculture (of cocoa) which results in deforestation (Gockowski and
12 Sonwa 2011). However, positive interactions within these systems can be ecosystem and/or species
13 specific, but co-benefits such as increased resilience to extreme climate events, or improved soil
14 fertility are not always observed (Blaser et al. 2017; Abdulai et al. 2018). These contrasting outcomes
15 indicate the importance of field scale research programs to inform agroforestry system design, species
16 selection and management practices (Sonwa et al. 2014) .

17 Despite the many proven benefits, adoption of agroforestry has been low and slow (Toth et al. 2017;
18 National Research Centre for Agroforestry et al. 1999; Pattanayak et al. 2003; Jerneck and Olsson
19 2014). There are several reasons for the slow uptake, but the perception of risks and the time lag
20 between adoption and realisation of benefits are often important (Pattanayak et al. 2003; Mercer 2004;
21 Jerneck and Olsson 2013).

22 An important question for agroforestry is whether it supports poverty alleviation, or if it favours
23 comparatively affluent households. Experiences from India suggest that the overall adoption is (s)low
24 and differential between rich and poor households. Brockington et al. (2016), studied agroforestry
25 adoption over many years in South India, they found that overall only 18% of the households adopted
26 agroforestry but among the relatively rich households who adopted agroforestry, 97% of them were
27 still practicing it after 6-8 years and some had expanded their operations. Similar results were
28 obtained in Western Kenya, that food secure households were much more willing to adopt
29 agroforestry than food insecure households (Jerneck and Olsson 2013, 2014). Other experiences from
30 sub-Saharan Africa illustrate the difficulties (such as local institutional support) of having a continued
31 engagement of communities in agroforestry (Noordin et al. 2001; Matata et al. 2013; Meijer et al.
32 2015).

33 ***4.8.1.4 Crop-livestock interaction as an approach to manage land degradation***

34 The integration of crop and livestock production into “mixed farming” for smallholders in developing
35 countries became an influential model, particularly for Africa, in the early 1990s (Pritchard et al.
36 1992; McIntire et al. 1992). Crop-livestock integration under this model was seen as founded on three
37 pillars; improved use of manure for crop fertility management; expanded use of animal traction
38 (draught animals); and promotion of cultivated fodder crops. For Asia, emphasis was placed on
39 draught power for land preparation, manure for soil fertility enhancement, and fodder production as
40 an entry point for cultivation of legumes (Devendra and Thomas 2002). Mixed farming was seen as an
41 evolutionary process to expand food production in the face of population increase, promote
42 improvements in income and welfare, and protect the environment. The process could be further
43 facilitated and steered by research, extension and policy (Pritchard et al. 1992; McIntire et al. 1992;
44 Devendra 2002) (Pritchard et al., 1992; McIntire et al. 1992; Devendra 1992).

45 Scoones and Wolmer (2002) place this model in historical context, including concern about
46 population pressure on resources and the view that mobile pastoralism was environmentally
47 damaging. The latter view had already been critiqued by developing understandings of pastoralism,
48 mobility and communal tenure of grazing lands (for example (Behnke 1994; Ellis 1994)). They set out

1 a much more differentiated picture of crop livestock interactions, which can take place either within a
2 single farm household, or between crop and livestock producers, in which case they will be mediated
3 by formal and informal institutions governing the allocation of land, labour and capital, with the
4 interactions evolving through multiple place-specific pathways (Ramisch et al. 2002; Scoones and
5 Wolmer 2002). Promoting a diversity of approaches to crop-livestock interactions does not imply that
6 the integrated model necessarily leads to land degradation, but increases the space for institutional
7 support to local innovation (Scoones and Wolmer 2002).

8 However, specific managerial and technological practices that link crop and livestock production will
9 remain an important part of the repertoire of on-farm adaptation and mitigation. Howden and
10 coauthors (Howden et al. 2007) note the importance of innovation within existing integrated systems
11 including use of adapted forage crops. Rivera-Ferre et al. (2016) list as adaptation strategies with
12 high potential for grazing systems, mixed crop-livestock systems or both: crop-livestock integration in
13 general; soil management including composting; enclosure and corralling of animal; improved storage
14 of feed. Most of these are seen as having significant co-benefits for mitigation, and improved
15 management of manure is seen as a mitigation measure with adaptation co-benefits.

16 **4.8.2 Local and indigenous knowledge for addressing land degradation**

17 In practice, responses are anchored both in scientific research, as well as local, indigenous and
18 traditional knowledge and know-how. For example, studies in the Philippines Camacho et al. (2016)
19 examine how traditional integrated watershed management by indigenous people sustain regulating
20 services vital to agricultural productivity, while delivering co-benefits in the form of biodiversity and
21 ecosystem resilience at a landscape scale. Although responses can be site specific and sustainable at a
22 local scale, the multi-scale interplay of drivers and pressures can nevertheless cause practices that
23 have been sustainable for centuries to become less so. Siahaya et al (2016) explore the traditional
24 knowledge that has informed rice cultivation in the uplands of East Borneo, grounded in sophisticated
25 shifting cultivation methods (gilir balik) which have been passed on for generations (more than 200
26 years) in order to maintain local food production. Gilir balik involves temporary cultivation of plots,
27 after which, abandonment takes place as the land user moves to another plot, leaving the natural
28 (forest) vegetation to return. This approach is considered sustainable if it has the support of other
29 subsistence strategies, adapts to and integrates with the local context, and if the carrying capacity of
30 the system is not surpassed (Siahaya et al. 2016). Often gilir balik cultivation involves intercropping
31 of rice with bananas, cassava and other food crops. Once the abandoned plot has been left to recover
32 such that soil fertility is restored, clearance takes place again and the plot is reused for cultivation.
33 Rice cultivation in this way plays an important role in forest management, with several different types
34 of succession forest being found in the study area of Siahaya et al (2016). Nevertheless, interplay of
35 these practices with other pressures (large-scale land acquisitions for oil palm plantation, logging and
36 mining), risk their future sustainability. Use of fire is critical in processes of land clearance, so there
37 are also trade-offs for climate change mitigation which have been sparsely assessed.

38 Interest appears to be growing in understanding how indigenous and local knowledge inform land
39 users' responses to degradation, as scientists engage farmers as experts in processes of knowledge co-
40 production and co-innovation (Oliver et al. 2012; Bitzer and Bijman 2015). This can help to
41 introduce, implement, adapt and promote the use of locally appropriate responses (Schwilch et al.
42 2011). Indeed, studies strongly agree on the importance of engaging local populations in both
43 sustainable land and forest management. Meta-analyses in tropical regions that examined both forests
44 in protected areas and community managed forests suggest that deforestation rates are lower, with less
45 variation in deforestation rates presenting in community managed forests compared to protected
46 forests (Porter-Bolland et al. 2012). This suggests that consideration of the social and economic needs
47 of local human populations is vital in preventing forest degradation (Ward et al. 2018). However,
48 while disciplines such as ethnopedology seek to record and understand how local people perceive,

1 classify and use soil, and draw on that information to inform its management (Barrera-Bassols and
2 Zinck 2003), links with climate change and its impacts (perceived and actual) are not generally
3 considered.

4 **4.8.3 Reducing deforestation and forest degradation and increasing afforestation**

5 Improved stewardship of forests through reduction or avoidance of deforestation and forest
6 degradation, and enhancement of forest carbon stocks can all contribute to land-based natural climate
7 solutions (Angelsen et al. 2018; Sonwa et al. 2011b; Griscom et al. 2017). While estimates of annual
8 emissions from tropical deforestation and forest degradation range widely from 0.5 to 3.5 Gt C yr⁻¹
9 (Baccini et al. 2017; Houghton et al. 2012; Mitchard 2018, see also Chapter 2), they all indicate the
10 large potential to reduce annual emissions from deforestation and forest degradation. Recent estimates
11 of forest extent for Africa in 1900 may result in downward adjustments of historic deforestation and
12 degradation emission estimates (Aleman et al. 2018). Emissions from forest degradation in non-
13 Annex I countries have declined marginally from 1.1 GtCO₂ yr⁻¹ in 2001-2010 to 1 GtCO₂ yr⁻¹ in
14 2011-2015, but the relative emissions from degradation compared to deforestation have increased
15 from a quarter to a third (Federici et al. 2015). Forest sector activities in developing countries were
16 estimated to represent a technical mitigation potential in 2030 of 9 Gt CO₂ (Miles et al. 2015). This
17 was partitioned into reduction of deforestation (3.5 Gt CO₂), reduction in degradation and forest
18 management (1.7 Gt CO₂) and afforestation and reforestation (3.8 GtCO₂). The economic mitigation
19 potential will be lower than the technical potential (Miles et al. 2015).

20 Natural regeneration of second-growth forests enhances carbon sinks in the global carbon budget
21 (Chazdon and Uriarte 2016). In Latin America, Chazdon et al. (2016) estimated that in 2008, second-
22 growth forests (1 to 60 years old) covered 2.4 M km² of land (28.1% of the total study area). Over 40
23 years, these lands can potentially accumulate 8.5 Gt C in aboveground biomass via low-cost natural
24 regeneration or assisted regeneration, corresponding to a total CO₂ sequestration of 31.1 Gt CO₂
25 (Chazdon et al. 2016b). While aboveground biomass carbon stocks are estimated to be declining in
26 the tropics, they are increasing globally due to increasing stocks in temperate and boreal forests (Liu
27 et al. 2015b), consistent with the observations of a global land sector carbon sink (Le Quéré et al.
28 2013; Keenan et al. 2017; Pan et al. 2011).

29 Moving from technical mitigation potentials (Miles et al. 2015) to real reduction of emissions from
30 deforestation and forest degradation required transformational changes (Korhonen-Kurki et al. 2018).
31 This transformation can be facilitated by two enabling conditions: the presence of already initiated
32 policy change; or the scarcity of forest resources combined with an absence of any effective forestry
33 framework and policies. These authors and others (Angelsen et al. 2018) found that the presence of
34 powerful transformational coalitions of domestic pro-REDD+ political actors combined with strong
35 ownership and leadership, regulations and law enforcement, and performance-based funding, can
36 provide a strong incentive for achieving REDD+ goals.

37 Implementing schemes such as REDD+ and various projects related to the voluntary carbon market is
38 often regarded as a no-regrets investment (Seymour and Angelsen 2012) but the social and ecological
39 implications (including those identified in the Cancun Safeguards) must be carefully considered for
40 REDD+ projects to be socially and ecologically sustainable (Jagger et al. 2015). In 2018, 34 countries
41 have submitted a REDD+ forest reference level and/or forest reference emission level to the
42 UNFCCC. Of these REDD+ reference levels, 95% included the activity "reducing deforestation"
43 while 34% included the activity "reducing forest degradation" (FAO 2018). Five countries submitted
44 REDD+ results in the technical annex to their Biannual Update Report (BUR) totalling an emission
45 reduction of 6.3 Gt CO₂ between 2006 and 2015 (FAO 2018).

46 Afforestation is another mitigation activity that increases carbon sequestration (see also Cross-Chapter
47 Box 2: Implications of large-scale reforestation and afforestation, Chapter 1). Yet, it requires careful

1 consideration about where to plant trees to achieve potential climatic benefits given an altering of
2 local albedo and turbulent energy fluxes and increasing night-time land surface temperatures (Peng et
3 al., 2014). A recent hydro-climatic modelling effort has shown that forest cover can account for about
4 40% of the observed decrease in annual runoff (Buendia et al. 2016). A meta-analysis of afforestation
5 in Northern Europe (Bárcena and co-authors 2014) concluded that significant soil organic carbon
6 sequestration in Northern Europe occurs after afforestation of croplands but not grasslands. Additional
7 sequestration occurs in forest floors and biomass carbon stocks. Successful programmes of large scale
8 afforestation activities in South Korea and China are discussed in-depth a special case study (Section
9 4.9.3).

10 The potential outcome of efforts to reduce emissions from deforestation and degradation in Indonesia
11 through a 2011 moratorium on concessions to convert primary forests to either timber or palm oil uses
12 was evaluated against rates of emissions over the period 2000 to 2010. The study concluded that less
13 than 7% of emissions would have been avoided had the moratorium been implemented in 2000
14 because it only curtailed emissions due to a subset of drivers of deforestation and degradation (Busch
15 et al. 2015).

16 In terms of ecological integrity of tropical forests, the policy focus on carbon storage and tree cover
17 can be problematic if it leaves out other aspects of forests ecosystems, such as biodiversity – and
18 particularly fauna (Panfil and Harvey 2016; Peres et al. 2016; Hinsley et al. 2015). Other concerns of
19 forest based projects under the voluntary carbon market are potential negative socio-economic side
20 effects (Edstedt and Carton 2018a; Carton and Andersson 2017; Osborne 2011; Scheidel and Work
21 2018; Richards and Lyons 2016; Borrás and Franco 2018; Paladino and Fiske 2017) and leakage
22 (particularly at the subnational scale), i.e. when interventions to reduce deforestation or degradation at
23 one site displace pressures and increase emissions elsewhere (Atmadja and Verchot 2012; Phelps et
24 al. 2010; Lund et al. 2017; Balooni and Lund 2014).

25 Maintaining and increasing forest area, in particular of native forests rather than monoculture and
26 short-rotation plantations, contributes to the maintenance of global forest carbon stocks (Lewis et al.
27 2019) (*robust evidence, high agreement*).

28 **4.8.4 Sustainable forest management and CO₂ removal technologies**

29 While reducing deforestation and forest degradation may help directly meet mitigation goals,
30 sustainable forest management aimed at providing timber, fiber, biomass and non-timber resources
31 can provide long-term livelihood for communities, can reduce the risk of forest conversion to non-
32 forest uses (settlement, crops, etc.), and can maintain land productivity, thus reducing the risks of land
33 degradation (Putz et al. 2012; Gideon Neba et al. 2014; Sufo Kankeu et al. 2016; Nitcheu Tchiadje et
34 al. 2016; Rossi et al. 2017).

35 Developing sustainable forest management strategies aimed at contributing towards negative
36 emissions throughout this century requires an understanding of forest management impacts on
37 ecosystem carbon stocks (including soils), carbon sinks, carbon fluxes in harvested wood, carbon
38 storage in harvested wood products including landfills and the emission reductions achieved through
39 the use of wood products and bioenergy (Nabuurs et al. 2007; Lemprière et al. 2013; Kurz et al. 2016;
40 Law et al. 2018; Nabuurs et al. 2017). Transitions from natural to managed forest landscapes can
41 involve a reduction in forest carbon stocks, the magnitude of which depends on the initial landscape
42 conditions, the harvest rotation length relative to the frequency and intensity of natural disturbances
43 and on the age-dependence of managed and natural disturbances (Harmon et al. 1990; Kurz et al.
44 1998a). Initial landscape conditions, in particular the age-class distribution and therefore C stocks of
45 the landscape strongly affect the mitigation potential of forest management options (Ter-Mikaelian et
46 al. 2013; Kilpeläinen et al. 2017). Landscapes with predominantly mature forests may experience
47 larger reductions in carbon stocks during the transition to managed landscapes (Harmon et al. 1990;

1 Kurz et al. 1998b; Lewis et al. 2019) while in landscapes with predominantly young or recently
2 disturbed forests sustainable forest management can enhance carbon stocks (Henttonen et al. 2017).

3 Forest growth rates, net primary productivity, and net ecosystem productivity are age-dependent with
4 maximum rates of carbon removal from the atmosphere occurring in young to medium aged forests
5 and declining thereafter (Tang et al. 2014). In boreal forest ecosystem, estimation of carbon stocks
6 and carbon fluxes indicate that old growth stands are typically small carbon sinks or carbon sources
7 (Gao et al. 2018; Taylor et al. 2014; Hadden and Grelle 2016). In tropical forests, carbon uptake rates
8 in the first 20 years of forest recovery were 11 times higher than uptake rates in old-growth forests
9 (Poorter et al. 2016). Age-dependent increases in forest carbon stocks and declines in forest carbon
10 sinks mean that landscapes with older forests have accumulated more carbon but their sink strength is
11 diminishing, while landscapes with younger forests contain less carbon but they are removing CO₂
12 from the atmosphere at a much higher rate (Volkova et al. 2017; Poorter et al. 2016). The rates of
13 carbon removal are not just age-related but also controlled by many biophysical factors and human
14 activities (Bernal et al. 2018) and in ecosystems with uneven-aged, multispecies forests the
15 relationships between carbon stocks and sinks are more difficult and expensive to quantify.

16 Whether or not forest harvest and use of biomass is contributing to net reductions of atmospheric
17 carbon depends on carbon losses during and following harvest, rates of forest regrowth, and the use of
18 the harvested wood and the carbon retention in long-lived or short-lived products as well as the
19 emission reductions achieved through the substitution of emissions-intensive products with wood
20 products (Lemprière et al. 2013; Lundmark et al. 2014; Xu et al. 2018b; Olguin et al. 2018; Dugan
21 et al. 2018; Chen et al. 2018b; Pingoud et al. 2018; Seidl et al. 2007). Studies that ignore changes in
22 forest carbon stocks (such as some life cycle analyses that assume no impacts of harvest on forest
23 carbon stocks), ignore changes in wood product pools (Mackey et al. 2013) or assume long-term
24 steady state (Pingoud et al. 2018), or ignore changes in emissions from substitution benefits (Mackey
25 et al. 2013; Lewis et al. 2019) will arrive at diverging conclusions about the benefits of sustainable
26 forest management. Moreover, assessments of climate benefits of any mitigation action must also
27 consider the time dynamics of atmospheric impacts as some actions will have immediate benefits (e.g.
28 avoided deforestation) while others may not achieve net atmospheric benefits for decades or centuries.
29 For example, the climate benefits of woody biomass use for bioenergy depend on several factors such
30 as the source and alternate fate of the biomass, the energy type it substitutes and the rates of regrowth
31 of the harvested forest (Laganière et al. 2017; Ter-Mikaelian et al. 2014; Smyth et al. 2017).
32 Conversion of primary forests in regions of very low stand replacing disturbances to short-rotation
33 plantations where the harvested wood is used for short-lived products with low displacement factors
34 will increase emissions. In general, greater mitigation benefits are achieved if harvested wood
35 products are used for products with long carbon retention time and high displacement factors.

36 With increasing forest age, carbon sinks in forests will diminish until harvest or natural disturbances
37 such as wildfire remove biomass carbon or release it to the atmosphere (Seidl et al. 2017). While
38 individual trees can accumulate carbon for centuries (Köhl et al. 2017), stand level carbon
39 accumulation rates depend on both tree growth and tree mortality rates (Hember et al. 2016; Lewis et
40 al. 2004). Sustainable forest management, including harvest and forest regeneration, can help
41 maintain active carbon sinks by maintaining a forest age-class distribution that includes a share of
42 young, actively growing stands (Volkova et al. 2018; Nabuurs et al. 2017). The use of the harvested
43 carbon in either long-lived wood products (e.g. for construction), short-lived wood products (e.g.,
44 pulp and paper), or biofuels affects the net carbon balance of the forest sector (Lemprière et al. 2013;
45 Matthews et al. 2018). The use of these wood products can further contribute to GHG emission
46 reduction goals by avoiding the emissions from the products with higher embodied emissions that
47 have been displaced (Nabuurs et al. 2007; Lemprière et al. 2013). In 2007 the IPCC concluded that
48 “[i]n the long term, a sustainable forest management strategy aimed at maintaining or increasing

1 forest carbon stocks, while producing an annual sustained yield of timber, fibre or energy from the
2 forest, will generate the largest sustained mitigation benefit” (Nabuurs et al. 2007).—The apparent
3 trade-offs between maximising forest C stocks and maximising ecosystem C sinks are at the origin of
4 ongoing debates about optimum management strategies to achieve negative emissions (Keith et al.
5 2014; Kurz et al. 2016; Lundmark et al. 2014). Sustainable forest management, including the
6 intensification of carbon-focussed management strategies, can make long-term contributions towards
7 negative emissions if the sustainability of management is assured through appropriate governance,
8 monitoring and enforcement. As specified in the definition of sustainable forest management, other
9 criteria such as biodiversity must also be considered when assessing mitigation outcomes (Lecina-
10 Diaz et al. 2018). Moreover, the impacts of changes in management on albedo and other non-GHG
11 factors also need to be considered (Luyssaert et al. 2018) (See also Chapter 2). The contribution of
12 sustainable forest management for negative emissions is strongly affected by the use of the wood
13 products derived from forest harvest and the time horizon over which the carbon balance is assessed.
14 Sustainable forest management needs to anticipate the impacts of climate change on future tree
15 growth, mortality and disturbances when designing climate change mitigation and adaptation
16 strategies (Valade et al. 2017; Seidl et al. 2017).

17 **4.8.5 Policy responses to land degradation**

18 The 1992 United Nations Conference on Environment and Development (UNCED), also known as
19 the Rio de Janeiro Earth Summit, recognised land degradation as a major challenge to sustainable
20 development, and led to the establishment of the United Nations Convention to Combat
21 Desertification (UNCCD), which addressed specifically land degradation in the drylands. The
22 UNCCD emphasizes sustainable land use to link poverty reduction on one hand and environmental
23 protection on the other. The two other “Rio Conventions” emerging from the UNCED, the United
24 Nations Framework Convention on Climate Change (UNFCCC) and the Convention on Biological
25 Diversity (CBD), focus on climate change and biodiversity, respectively. The land has been
26 recognized as an aspect of common interest to the three conventions, and sustainable land
27 management (SLM) is proposed as a unifying theme for current global efforts on combating land
28 degradation, climate change and loss of biodiversity, as well as facilitating land-based adaptation to
29 climate change and sustainable development.

30 The Global Environmental Facility (GEF) funds developing countries to undertake activities that meet
31 the goals of the conventions and deliver global environmental benefits. Since 2002, the GEF has
32 invested in projects that support sustainable land management through its Land Degradation Focal
33 Area Strategy, to address land degradation within and beyond the drylands.

34 Under the UNFCCC, parties have devised National Adaptation Plans (NAPs) that identify medium-
35 and long-term adaptation needs. Parties have also developed their climate change mitigation plans,
36 presented as Nationally Determined Contributions (NDCs). These programs have the potential of
37 assisting the promotion of SLM. It is realised that the root causes of land degradation and successful
38 adaptation will not be realised until holistic solutions to land management are explored. SLM can help
39 address root causes of low productivity, land degradation, loss of income generating capacity as well
40 as contribute to the amelioration of the adverse effects of climate change.

41 The “4 per 1000” (4p1000) initiative (Soussana et al. 2019) launched by France during the UNFCCC
42 COP21 in 2015 aims at capturing CO₂ from the atmosphere through changes to agricultural and
43 forestry practices at a rate that would increase the carbon content of soils by 0.4% per year (Rumpel et
44 al. 2018). If global soil carbon content increases at this rate in the top 30-40 cm, the annual increase in
45 atmospheric CO₂ would be stopped (Dignac et al. 2017). This is an illustration of how extremely
46 important soils are for addressing climate change. The initiative is based on eight steps: stop carbon
47 loss (priority #1 is peat soils); promote carbon uptake; monitor, report, and verify impacts; deploy

1 technology for tracking soil carbon; test strategies for implementation and upscaling; involve
2 communities; coordinate policies; provide support (Rumpel et al. 2018). Questions remain however,
3 to what extent the 4p1000 is achievable as a universal goal (van Groenigen et al. 2017; Poulton et al.
4 2018; Schlesinger and Amundson 2018).

5 Land degradation neutrality (LDN) was introduced by the UNCCD at Rio +20, and adopted at
6 UNCCD COP12 (UNCCD 2016a). LDN is defined as "a state whereby the amount and quality of land
7 resources necessary to support ecosystem functions and services and enhance food security remain
8 stable or increase within specified temporal and spatial scales and ecosystems". Pursuit of LDN
9 requires effort to avoid further net loss of the land-based natural capital relative to a reference state, or
10 baseline. LDN encourages a dual-pronged effort involving sustainable land management to reduce the
11 risk of land degradation, combined with efforts in land restoration and rehabilitation, to maintain or
12 enhance land-based natural capital, and its associated ecosystem services (Orr et al., 2017; Cowie et
13 al. 2018;). Planning for LDN involves projecting the expected cumulative impacts of land use and
14 land management decisions, then counterbalancing anticipated losses with measures to achieve
15 equivalent gains, within individual land types (where land type is defined by land potential). Under
16 LDN framework developed by UNCCD, three primary indicators are used to assess whether LDN is
17 achieved by 2030: land cover change, net primary productivity and soil organic carbon (Cowie et al.
18 2018; Sims et al., 2019. Achieving LDN therefore requires integrated landscape management that
19 seeks to optimize land use to meet multiple objectives (ecosystem health, food security, human well-
20 being) (Cohen-Shacham, E., Walters, G., Janzen, C. and Maginnis 2016). The response hierarchy of
21 Avoid > Reduce > Reverse land degradation articulates the priorities in planning LDN interventions.
22 LDN provides the impetus for widespread adoption of SLM and efforts to restore or rehabilitate land.
23 Through its focus LDN ultimately provides tremendous potential for mitigation of and adaptation to
24 climate change by halting and reversing land degradation and transforming land from a carbon source
25 to a sink. There are strong synergies between the concept of LDN and the Nationally Determined
26 Contributions (NDCs) of many countries with linkages to national climate plans. LDN is also closely
27 related to many Sustainable Development Goals (SDG) in the areas of poverty, food security,
28 environmental protection and sustainable use of natural resources (UNCCD 2016b). The GEF is
29 supporting countries to set LDN targets and implement their LDN plans through its land degradation
30 focal area, which encourages application of integrated landscape approach to managing land
31 degradation (GEF 2018).

32 The 2030 agenda for sustainable development, adopted by the United Nations in 2015, comprises 17
33 Sustainable Development Goals (SDGs). Goal 15 is of direct relevance to land degradation with the
34 objective to protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage
35 forests, combat desertification and halt and reverse land degradation and halt biodiversity loss. Target
36 15.3 specifically addresses land degradation neutrality. Other goals that are relevant for land
37 degradation include goal 2 (Zero hunger), goal 3 (Good health and well-being), goal 7 (Affordable
38 and clean energy), goal 11 (Sustainable cities and communities), and goal 12 (Responsible production
39 and consumption). Sustainable management of land resources underpins the SDGs related to hunger,
40 climate change and environment. Further goals of a cross-cutting nature include 1 (No poverty), 6
41 (Clean water and sanitation) and 13 (Climate action). It remains to be seen how these interconnections
42 are dealt with in practice.

43 With a focus on biodiversity, IPBES published a comprehensive assessment of land degradation in
44 2018 (Montanarella et al. 2018). The IPBES report, together with this report focusing on climate
45 change, may contribute to create synergy between the two main global challenges for addressing land
46 degradation in order to help achieving the goals of SDG 15 (Protect, restore and promote sustainable
47 use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse
48 land degradation and halt biodiversity loss).

1 Market based mechanisms like the Clean Development Mechanism (CDM) under the UNFCCC and
2 the voluntary carbon market provide incentives to enhance carbon sinks on the land through
3 afforestation and reforestation. Implications for local land use and food security have been raised as a
4 concern and need to be assessed (Edstedt and Carton 2018b; Olsson et al. 2014b). Many projects
5 aimed at reducing emissions from deforestation and forest degradations (not to be confused with the
6 national REDD+ programs in accordance with the UNFCCC Warsaw Framework) are being planned
7 and implemented primarily targeting countries with high forest cover and high deforestation rates.
8 Some parameters of incentivising emissions reduction, quality of forest governance, conservation
9 priorities, local rights and tenure frameworks, and sub-national project potential are being looked into
10 with often very mixed results (Newton et al. 2016; Gebara and Agrawal 2017).

11 Besides international public initiatives, some actors in the private sector are increasingly aware of the
12 negative environmental impacts of some global value chains producing food, fibre, and energy
13 products (Lambin et al. 2018; van der Ven and Cashore 2018; van der Ven et al. 2018; Lyons-White
14 and Knight 2018). While improvement is under way in many supply chains, measures implemented so
15 far are often insufficient to be effective in reducing or stopping deforestation and forest degradation
16 (Lambin et al. 2018). The GEF is investing in actions to reduce deforestation in commodity supply
17 chains through its Food Systems, Land Use, and Restoration Impact Program (GEF 2018).

18 **4.8.5.1 Limits to adaptation**

19 SLM can be deployed as a powerful adaptation strategy in most instances of climate change impacts
20 on natural and social systems, yet there are limits to adaptation (Klein, R.J.T., G.F. Midgley, B.L.
21 Preston, M. Alam, F.G.H. Berkhout, K. Dow 2014; Dow et al. 2013a). Such limits are dynamic and
22 interact with social and institutional conditions (Barnett et al. 2015; Filho and Nalau 2018). Exceeding
23 adaptation limits will trigger escalating losses or require undesirable transformational change, such as
24 forced migration. The rate of change in relation to the rate of possible adaptation is crucial (Dow et al.
25 2013b). How limits to adaptation are defined and how they can be measured is contextual and
26 contested. Limits must be assessed in relation to the ultimate goals of adaptation, which is subject to
27 diverse and differential values (Dow et al. 2013b; Adger et al. 2009). A particularly sensitive issue is
28 whether migration is accepted as adaptation or not (Black et al. 2011; Tacoli 2009; Bardsley and
29 Hugo 2010). If migration were understood and accepted as a form of successful adaptation, it would
30 change the limits to adaptation by reducing or even avoiding future humanitarian crises caused by
31 climate extremes (Adger et al. 2009; Upadhyay et al. 2017; Nalau et al. 2018).

32 In the context of land degradation potential limits to adaptation exist if land degradation becomes so
33 severe and irreversible that livelihoods cannot be maintained, and if migration is either not acceptable
34 or possible. Examples are coastal erosion where land disappears (Gharbaoui and Blocher 2016; Luetz
35 2018), collapsing livelihoods due to thawing of permafrost (Landauer and Juhola 2019), and extreme
36 forms of soil erosion (e.g., landslides (Van der Geest and Schindler 2016) and gully erosion leading to
37 badlands (Poesen et al. 2003)).

38 **4.8.6 Resilience and thresholds**

39 Resilience refers to the capacity of interconnected social, economic and ecological systems, such as
40 farming systems, to absorb disturbance (e.g., drought, conflict, market collapse), and respond or
41 reorganise, to maintain their essential function, identity and structure. Resilience can be described as
42 “coping capacity”. The disturbance may be a shock - sudden events such as a flood or disease
43 epidemic – or it may be a trend that develops slowly, like a drought or market shift. The shocks and
44 trends anticipated to occur due to climate change are expected to exacerbate risk of land degradation.
45 Therefore, assessing and enhancing resilience to climate change is a critical component of designing
46 sustainable land management strategies.

1 Resilience as an analytical lens is particularly strong in ecology and related research on natural
2 resource management (Folke et al. 2010; Quinlan et al. 2016) while in the social sciences the
3 relevance of resilience for studying social and ecological interactions is contested (Cote and
4 Nightingale 2012; Olsson et al. 2015; Cretney 2014; Béné et al. 2012; Joseph 2013). In the case of
5 adaptation to climate change (and particularly regarding limits to adaptation), a crucial ambiguity of
6 resilience is the question whether resilience is a normative concept (i.e. resilience is good or bad) or is
7 a descriptive characteristic of a system (i.e. neither good nor bad). Previous IPCC reports have
8 defined resilience as a normative (positive) attribute (see AR5 Glossary), while the wider scientific
9 literature is divided on this (Weichselgartner and Kelman 2015; Strunz 2012; Brown 2014; Grimm
10 and Calabrese 2011; Thorén and Olsson 2018). For example, is outmigration from a disaster prone
11 area considered a successful adaptation (high resilience) or a collapse of the livelihood system (lack of
12 resilience) (Thorén and Olsson 2018)? In this report resilience is considered a positive attribute when
13 it maintains capacity for adaptation, learning and/or transformation.

14 Furthermore, resilience and the related terms adaptation and transformation are defined and used
15 differently by different communities (Quinlan et al. 2016). The relationship and hierarchy of
16 resilience with respect to vulnerability and adaptive capacity are also debated, with different
17 perspectives between the disaster management, and global change communities, (e.g., Cutter et al.
18 2008). Nevertheless, these differences in usage need not inhibit the application of “resilience
19 thinking” in managing land degradation; researchers using these terms, despite variation in
20 definitions, apply the same fundamental concepts to inform management of human-environment
21 systems, to maintain or improve the resource base, and sustain livelihoods.

22 Applying resilience concepts involves viewing the land as a component of an interlinked social-
23 ecological system; identifying key relationships that determine system function and vulnerabilities of
24 the system; identifying thresholds or tipping points beyond which the system transitions to an
25 undesirable state; and devising management strategies to steer away from thresholds of potential
26 concern, thus facilitating healthy systems and sustainable production (Walker et al., 2009).

27 A threshold is a non-linearity between a controlling variable and system function, such that a small
28 change in the variable causes the system to shift to an alternative state. Bestelmeyer et al. (2015) and
29 Prince et al. (2018) illustrate this concept in the context of land degradation. Studies have identified
30 various biophysical and socio-economic thresholds in different land-use systems. For example, 50%
31 ground cover (living and dead plant material and biological crusts) is a recognised threshold for
32 dryland grazing systems (e.g., Tighe et al. 2012); below this threshold infiltration rate declines, risk
33 of erosion causing loss of topsoil increases, a switch from perennial to annual grass species occurs and
34 there is a consequential sharp decline in productivity. This shift to a lower-productivity state cannot
35 be reversed without significant human intervention. Similarly, the combined pressure of water
36 limitations and frequent fire can lead to transition from closed forest to savannah or grassland: if fire
37 is too frequent trees do not reach reproductive maturity and post-fire regeneration will fail; likewise,
38 reduced rainfall / increased drought prevents successful forest regeneration (Reyer et al. 2015;
39 Thompson et al. 2009) see also Cross-chapter box 3 on Fire and climate change, Chapter 2.

40 In managing land degradation, it is important to assess the resilience of the existing system, and the
41 proposed management interventions. If the existing system is in an undesirable state or considered
42 unviable under expected climate trends, it may be desirable to promote adaptation or even
43 transformation to a different system that is more resilient to future changes. For example, in an
44 irrigation district where water shortages are predicted, measures could be implemented to improve
45 water use efficiency, for example by establishing drip irrigation systems for water delivery, although
46 transformation to pastoralism or mixed dryland cropping/livestock production may be more
47 sustainable in the longer term, at least for part of the area. Application of sustainable land
48 management practices, especially those focussed on ecological functions (e.g., agroecology,

ecosystem-based approaches, regenerative agriculture, organic farming), can be effective in building resilience of agro-ecosystems (Henry et al. 2018). Similarly, the resilience of managed forests can be enhanced by sustainable forest management that protects or enhances biodiversity, including assisted migration of tree species within their current range limit (Winder et al. 2011; Pedlar et al. 2012) or increasing species diversity in plantation forests (Felton et al. 2010; Liu et al. 2018a). The essential features of a resilience approach to management of land degradation under climate change are described by (O’Connell et al. 2016; Simonsen et al. 2014).

Consideration of resilience can enhance effectiveness of interventions to reduce or reverse land degradation (*medium agreement, limited evidence*). This approach will increase the likelihood that SLM/SFM and land restoration/rehabilitation interventions achieve long-term environmental and social benefits. Thus, consideration of resilience concepts can enhance the capacity of land systems to cope with climate change and resist land degradation, and assist land use systems to adapt to climate change.

4.8.7 Barriers to implementation of sustainable land management

There is a growing recognition that addressing barriers and designing solutions to complex environmental problems, such as land degradation, requires awareness of the larger system into which the problems and solutions are embedded (Laniak et al. 2013). An ecosystem approach to SLM based on understanding of the processes of land degradation has been recommended that can separate multiple drivers, pressures and impacts (Kassam et al. 2013), but large uncertainty in model projections of future climate, and associated ecosystem processes (IPCC 2013a) pose additional challenges to the implementation of SLM. As discussed earlier in this chapter, many SLM practices, including both technologies and approaches, are available that can increase yields and contribute to closing the yield gap between actual and potential crop or pasture yield, while also enhancing resilience to climate change (Yengoh and Ardö 2014; WOCAT). However, there are often systemic barriers to adoption and scaling up of SLM practices, especially in developing countries.

Uitto (2016) identified areas that the GEF, the financial mechanism of the UNCCD, UNFCCC and other multilateral environmental agreements, can address to solve global environmental problems. This includes removal of barriers related to knowledge and information; strategies for implementation of technologies and approaches; and institutional capacity. Strengthening these areas would drive transformational change leading to behavioral change and broader adoption of sustainable environmental practices. Detailed analysis of barriers as well as strategies, methods and approaches to scale up SLM have been undertaken for GEF programs in Africa, China and globally (Tengberg and Valencia 2018; Liniger et al. 2011; Tengberg et al. 2016). A number of interconnected barriers and bottlenecks to the scaling up of SLM have been identified in this context and are related to:

- Limited access to knowledge and information, including new SLM technologies and problem-solving capacities;
- Weak enabling environment, including the policy, institutional and legal framework for SLM, and land tenure and property rights;
- Inadequate learning and adaptive knowledge management in the project cycle, including monitoring and evaluation of impacts; and
- Limited access to finance for scaling up, including public and private funding, innovative business models for SLM technologies and financial mechanisms and incentives, such as payments for ecosystem services (PES), insurance and micro-credit schemes (see also Shames et al 2014).

Adoption of innovations and new technologies are increasingly analysed using the transition theory framework (Geels 2002), the starting point being the recognition that many global environmental problems cannot be solved by technological change alone but require more far-reaching change of

1 social-ecological systems. Using transition theory makes it possible to analyse how adoption and
2 implementation follow the four stages of sociotechnical transitions, from predevelopment of
3 technologies and approaches at the niche level, take-off and acceleration, to regime shift and
4 stabilisation at the landscape level. According to a recent review of sustainability transitions in
5 developing countries (Wieczorek 2018), three internal niche processes are important, including the
6 formation of networks that support and nurture innovation, the learning process and the articulation of
7 expectations to guide the learning process. While technologies are important, institutional and
8 political aspects form the major barriers to transition and upscaling. In developing and transition
9 economies, informal institutions play a pivotal role and transnational linkages are also important, such
10 as global value chains. In these countries, it is therefore more difficult to establish fully coherent
11 regimes or groups of individuals who share expectations, beliefs or behavior, as there is a high level
12 of uncertainty about rules and social networks or dominance of informal institutions, which creates
13 barriers to change. This uncertainty is further exacerbated by climate change. Landscape forces
14 comprise a set of slow changing factors, such as broad cultural and normative values, long-term
15 economic effects such as urbanisation, and shocks such as war and crises that can lead to change.

16 A study on SLM in the Kenyan highlands using transition theory concluded that barriers to adoption
17 of SLM included high poverty levels, a low input-low output farming system with limited potential to
18 generate income, diminishing land sizes and low involvement of the youth in farming activities.
19 Coupled with a poor coordination of government policies for agriculture and forestry, these barriers
20 created negative feedbacks in the SLM transition process. Other factors to consider include gender
21 issues and lack of secure land tenure. Scaling up of SLM technologies would require collaboration of
22 diverse stakeholders across multiple scales, a more supportive policy environment and substantial
23 resource mobilisation (Mutoko et al. 2014). Tengberg and Valencia (2018) analysed the findings from
24 a review of the GEF integrated natural resources management portfolio of projects using the transition
25 theory framework (Figure 4.7). They concluded that to remove barriers to SLM, an agricultural
26 innovations systems approach that supports co-production of knowledge with multiple stakeholders,
27 institutional innovations, a focus on value chains and strengthening of social capital to facilitate
28 shared learning and collaboration could accelerate the scaling up of sustainable technologies and
29 practices from the niche to the landscape level. Policy integration and establishment of financial
30 mechanisms and incentives could contribute to overcoming barriers to a regime shift. The new SLM
31 regime could in turn be stabilised and sustained at the landscape level by multi-stakeholder
32 knowledge platforms and strategic partnerships. However, transitions to more sustainable regimes and
33 practices are often challenged by lock-in mechanisms in the current system (Lawhon and Murphy
34 2012), such as economies of scale, investments already made in equipment, infrastructure and
35 competencies, lobbying, shared beliefs, and practices, which could hamper wider adoption of SLM.

1
2 **Figure 4.7 The transition from SLM niche adoption to regime shift and landscape development (figure**
3 **draws inspiration from (Geels 2002)). Adapted from (Tengberg and Valencia 2018)**

4 Adaptive, multi-level and participatory governance of social-ecological systems is considered
5 important for regime shifts and transitions to take place (Wieczorek 2018) and essential to secure the
6 capacity of environmental assets to support societal development over longer time periods (Folke et
7 al. 2005). There is also recognition that effective environmental policies and programs need to be
8 informed by a comprehensive understanding of the biophysical, social, and economic components and
9 processes of a system, their complex interactions, and how they respond to different changes (Kelly
10 (Letcher) et al. 2013). But blueprint policies will not work due to the wide diversity of rules and
11 informal institutions used across sectors and regions of the world, especially in traditional societies
12 (Ostrom 2009).

13 The most effective way of removing barriers to funding of SLM has been mainstreaming of SLM
14 objectives and priorities into relevant policy and development frameworks and combining SLM best
15 practices with economic incentives for land users. As the short-term costs for establishing and
16 maintaining SLM measures are generally high and constitute a barrier to adoption, land users may
17 need to be compensated for generation of longer-term public goods, such as ecosystem services. Cost-
18 benefit analyses can be conducted on SLM interventions to facilitate such compensations (Liniger et
19 al. 2011; Nkonya et al. 2016; Tengberg et al. 2016). The landscape approach is a means to reconcile
20 competing demands on the land and remove barriers to implementation of SLM (e.g. Sayer et al.
21 2013; Bürgi et al. 2017). It involves an increased focus on participatory governance, development of
22 new SLM business models, and innovative funding schemes including insurance (Shames et al. 2014).
23 The Land Degradation Neutrality (LDN) Fund takes a landscape approach and raises private finance
24 for SLM and promotes market-based instruments, such as Payment for Ecosystem Services (PES),
25 certification and carbon trading, that can support scaling up of SLM to improve local livelihoods,
26 sequester carbon and enhance the resilience to climate change.

27 4.9 Case-studies

28 Climate change impacts on land degradation can be avoided, reduced or even reversed, but need to be
29 addressed in a context sensitive manner. Many of the responses described in this section can also

1 provide synergies of adaptation and mitigation. In this section we provide more in-depth analysis of a
 2 number of salient aspects of how land degradation and climate change interact. Table 4.3 is a
 3 synthesis of how of these case studies relate to climate change and other broader issues in terms of co-
 4 benefits.

5

6 **Table 4.3 Synthesis of how the case studies interact with climate change and a broader set of co-benefits**

Case studies (4.10)	(4.9)	Mitigation benefits and potential	Adaptation benefits	Co-benefits	Legend	
Urban green infrastructure (4.10.1) An increasing majority of the world population live in cities and land degradation is an urgent matter for urban areas	(4.9.1)			human health, recreation		carbon sink
Perennial grains (4.10.2) After 40 years of breeding, perennial grains now seem to have the potential of reducing climate impacts of agriculture while increasing its overall sustainability	(4.9.2)			reduced use of herbicides, reduced soil erosion and nutrient leakage		reduced emission
Reforestation (4.10.3) Two cases of successful reforestation serve as illustrations of the potential of sustained efforts into reforestation	(4.9.3)			economic return from sustainable forestry, reduced flood risk downstream		
Management of peat soils (4.10.4) Degradation of peat soils in tropical and arctic regions is a major source of greenhouse gases, hence an urgent mitigation option	(4.9.4)			improved air quality in tropical regions		reduced flood risk
Biochar (4.10.5) Biochar is a land management technique of high potential, but controversial	(4.9.5)			improved soil fertility		reduced heat stress
Protection against hurricane damages (4.10.6) More severe tropical cyclones increase the risk of land degradation in some areas, hence the need for increased adaptation	(4.9.6)			reduced losses (human lives, livelihoods, and assets)		drought resistance
Responses to salt water intrusion (4.10.7) The combined effect of climate induced sea level rise and land use change in coastal regions increases the risk of saltwater intrusion in many coastal regions	(4.9.7)			improved food and water security,		storm protection
Avoiding coastal maladaptation (4.10.8) Low lying coastal areas are in urgent need of adaptation, but examples have resulted in maladaptation	(4.9.8)			reduced losses (human lives, livelihoods, and assets)		protection against sea level rise

7

8 **4.9.1 Urban green infrastructure**

9 Over half the world's population now lives in towns and cities, a proportion that is predicted to
 10 increase to ~70% by the middle of the century (United Nations 2015). Rapid urbanisation is a severe
 11 threat to land and the provision of ecosystem services (Seto et al. 2012). However, as cities expand,
 12 the avoidance of land degradation, or the maintenance/enhancement of ecosystem services is rarely
 13 considered in planning processes. Instead economic development and the need for space for
 14 construction is prioritised, which can result in substantial pollution of air and water sources, the
 15 degradation of existing agricultural areas and indigenous, natural or semi-natural ecosystems both
 16 within and outside of urban areas. For instance, urban areas are characterised by extensive impervious
 17 surfaces. Degraded, sealed soils beneath these surfaces do not provide the same quality of water
 18 retention as intact soils. Urban landscapes comprising 50-90% impervious surfaces can therefore
 19 result in 40-83% of rainfall becoming surface water runoff (Pataki et al. 2011). With rainfall intensity
 20 predicted to increase in many parts of the world under climate change (Royal Society 2016), increased

1 water runoff is going to get worse. Urbanisation, land degradation and climate change are therefore
2 strongly interlinked, suggesting the need for common solutions (Reed and Stringer 2016b).

3 There is now a large body of research and application demonstrating the importance of retaining
4 urban green infrastructure (UGI) for the delivery of multiple ecosystem services (DG Environment
5 News Alert Service, 2012; Wentworth, 2017) as an important tool to mitigate and adapt to climate
6 change. UGI can be defined as all green elements within a city, including but not limited to retained
7 indigenous ecosystems, parks, public greenspaces, green corridors, street trees, urban forests, urban
8 agriculture, green roofs/walls and private domestic gardens (Tzoulas et al. 2007). The definition is
9 usually extended to include ‘blue’ infrastructure, such as rivers, lakes, bioswales and other water
10 drainage features. The related concept of Nature Based Solutions (defined as: living solutions inspired
11 by, continuously supported by and using nature, which are designed to address various societal
12 challenges in a resource-efficient and adaptable manner and to provide simultaneously economic,
13 social, and environmental benefits) has gained considerable traction within the European Commission
14 as one approach to mainstreaming the importance of UGI (Maes and Jacobs 2017; European Union
15 2015).

16 Through retaining existing vegetation and ecosystems, revegetating previous developed land or
17 integrating vegetation into buildings in the form of green walls and roofs, UGI can play a direct role
18 in mitigating climate change through carbon sequestration. However, compared to overall carbon
19 emissions from cities, effects will be small. Given that UGI necessarily involves the retention and
20 management of non-sealed surfaces, co-benefits for land degradation (e.g. soil compaction avoidance,
21 reduced water run-off, carbon storage and vegetation productivity; (Davies et al. 2011; Edmondson et
22 al. 2011, 2014; Yao et al. 2015) will also be apparent. Although not currently a priority, its role in
23 mitigating land degradation could be substantial. For instance, appropriately managed innovative
24 urban agricultural production systems, such as vertical farms, could have the potential to both meet
25 some of the food needs of cities and reduce the production (and therefore degradation) pressure on
26 agricultural land in rural areas, although thus far this is unproven (for a recent review (Wilhelm and
27 Smith 2018)).

28 The importance of UGI as part of a climate change adaptation approach has received greater attention
29 and application (Gill et al. 2007; Fryd et al. 2011; Demuzere et al. 2014; Sussams et al. 2015). The
30 EU’s Adapting to Climate Change White Paper emphasises the “crucial role in adaptation in
31 providing essential resources for social and economic purposes under extreme climate conditions”
32 (CEC, 2009, p. 9). Increasing vegetation cover, planting street trees and maintaining/expanding public
33 parks reduces temperatures (Cavan et al. 2014; Di Leo et al. 2016; Feyisa et al. 2014; Tonosaki K,
34 Kawai S 2014; Zölch et al. 2016). Further, the appropriate design and spatial distribution of
35 greenspaces within cities can help to alter urban climates to improve human health and comfort (e.g.
36 (Brown and Nicholls 2015; Klemm et al. 2015)). The use of green walls and roofs can also reduce
37 energy use in buildings (e.g. (Coma et al. 2017)). Similarly, natural flood management and ecosystem
38 based approaches of providing space for water, renaturalising rivers and reducing surface run-off
39 through the presence of permeable surfaces and vegetated features (including walls and roofs) can
40 manage flood risks, impacts and vulnerability (e.g. (Gill et al. 2007; Munang et al. 2013)). Access to
41 UGI in times of environmental stresses and shock can provide safety nets for people and can,
42 therefore, be an important adaptation mechanism, both to climate change (Potschin et al. 2016) and
43 land degradation.

44 Most examples of UGI implementation as a climate change adaptation strategy have centered on its
45 role in water management for flood risk reduction. The importance for land degradation is either not
46 stated, or not prioritized. In Beira, Mozambique, the government is using UGI to mitigate against
47 increased flood risks predicted to occur under climate change and urbanisation, which will be done by
48 improving the natural water capacity of the Chiveve River. As part of the UGI approach, mangrove

1 habitats have been restored and future phases include developing new multi-functional urban green
2 spaces along the river (World Bank 2016). The retention of green spaces within the city will have the
3 added benefit of halting further degradation in those areas. Elsewhere, planning mechanisms promote
4 the retention and expansion of green areas within cities to ensure ecosystem service delivery, which
5 directly halts land degradation, but are largely viewed and justified in the context of climate change
6 adaptation and mitigation. For instance, the Landscape Programme in Berlin includes five plans, one
7 of which covers adapting to climate change through the recognition of the role of UGI (Green Surge
8 2016). Major climate related challenges facing Durban, South Africa, include sea level rise, urban
9 heat island, water runoff and conservation (Roberts and O'Donoghue 2013). Now considered a global
10 leader in climate adaptation planning (Roberts 2010), Durban's Climate Change Adaptation plan
11 includes the retention and maintenance of natural ecosystems in particular those which are important
12 for mitigating flooding, coastal erosion, water pollution, wetland siltation and climate change
13 (eThekweni Municipal Council 2014).

14 **4.9.2 Perennial Grains and Soil Organic Carbon**

15 The severe ecological perturbation that is inherent in the conversion of native perennial vegetation to
16 annual crops, and the subsequent high frequency of perturbation required to maintain annual crops,
17 results in at least four forms of soil degradation that will be exacerbated by the effects of climate
18 change (Crews et al. 2016). First, soil erosion is a very serious consequence of annual cropping with
19 median losses exceeding rates of formation by 1-2 orders of magnitude in conventionally plowed
20 agroecosystems, and while erosion is reduced with conservation tillage, median losses still exceed
21 formation by several fold (Montgomery 2007). More severe storm intensity associated with climate
22 change is expected to cause even greater losses to wind and water erosion (Nearing et al. 2004b).
23 Secondly, the periods of time in which live roots are reduced or altogether absent from soils in annual
24 cropping systems allow for substantial losses of nitrogen from fertilised croplands, averaging 50%
25 globally (Ladha et al. 2005). This low retention of nitrogen is also expected to worsen with more
26 intense weather events (Bowles et al. 2018). A third impact of annual cropping is the degradation of
27 soil structure caused by tillage, which can reduce infiltration of precipitation, and increase surface
28 runoff. It is predicted that the percentage of precipitation that infiltrates into agricultural soils will
29 decrease further under climate change scenarios (Basche and DeLonge 2017; Wuest et al. 2006). The
30 fourth form of soil degradation that results from annual cropping is the reduction of soil organic
31 matter (SOM), a topic of particular relevance to climate change mitigation and adaptation.

32 Undegraded cropland soils can theoretically hold far more SOM (which is ~58% carbon) than they
33 currently do (Soussana et al. 2006). We know this deficiency because, with few exceptions,
34 comparisons between cropland soils and those of proximate mature native ecosystems commonly
35 show a 40-75% decline in soil carbon attributable to agricultural practices. What happens when native
36 ecosystems are converted to agriculture that induces such significant losses of SOM? Wind and water
37 erosion commonly results in preferential removal of light organic matter fractions that can accumulate
38 on or near the soil surface (Lal 2003). In addition to the effects of erosion, the fundamental practices
39 of growing annual food and fiber crops alters both inputs and outputs of organic matter from most
40 agroecosystems resulting in net reductions in soil carbon equilibria (Soussana et al. 2006;
41 McLauchlan 2006; Crews et al. 2016). Native vegetation of almost all terrestrial ecosystems is
42 dominated by perennial plants, and the belowground carbon allocation of these perennials is a key
43 variable in determining formation rates of stable soil organic carbon (SOC) (Jastrow et al. 2007;
44 Schmidt et al. 2011). When perennial vegetation is replaced by annual crops, inputs of root-associated
45 carbon (roots, exudates, mycorrhizae) decline substantially. For example, perennial grassland species
46 allocate around 67% of productivity to roots, whereas annual crops allocate between 13-30% (Saugier
47 2001; Johnson et al. 2006).

1 At the same time inputs of SOC are reduced in annual cropping systems, losses are increased because
2 of tillage, compared to native perennial vegetation. Tillage breaks apart soil aggregates, which, among
3 other functions, are thought to inhibit soil bacteria, fungi and other microbes from consuming and
4 decomposing soil organic matter (Grandy and Neff 2008). Aggregates reduce microbial access to
5 organic matter by restricting physical access to mineral-stabilized organic compounds as well as
6 reducing oxygen availability (Cotrufo et al. 2015; Lehmann and Kleber 2015). When soil aggregates
7 are broken open with tillage in the conversion of native ecosystems to agriculture, microbial
8 consumption of SOC and subsequent respiration of CO₂ increase dramatically, reducing soil carbon
9 stocks (Grandy and Robertson 2006; Grandy and Neff 2008).

10 Many management approaches are being evaluated to reduce soil degradation in general, especially
11 by increasing mineral-protected forms of SOC in the world's croplands (Paustian et al. 2016). The
12 menu of approaches being investigated focus either on increasing belowground carbon inputs, usually
13 through increases in total crop productivity, or by decreasing microbial activity, usually through
14 reduced soil disturbance (Crews and Rumsey 2017). However, the basic biogeochemistry of terrestrial
15 ecosystems managed for production of annual crops presents serious challenges to achieving the
16 standing stocks of SOC accumulated by native ecosystems that preceded agriculture. A novel new
17 approach that is just starting to receive significant attention is the development of perennial cereal,
18 legume and oilseed crops (Glover et al. 2010; Baker 2017).

19 There are two basic strategies that plant breeders and geneticists are using to develop new perennial
20 grain crop species. The first involves making wide hybrid crosses between existing elite lines of
21 annual crops, such as wheat, sorghum and rice, with related wild perennial species in order to
22 introgress perennialism into the genome of the annual (Cox et al. 2018; Huang et al. 2018; Hayes et
23 al. 2018). The other approach is *de novo* domestication of wild perennial species that have crop-like
24 traits of interest (DeHaan et al. 2016; DeHaan and Van Tassel 2014). New perennial crop species
25 undergoing *de novo* domestication include intermediate wheatgrass, a relative of wheat that produces
26 grain also known as Kernza (DeHaan et al. 2018; Cattani and Asselin 2018) and *Silphium*
27 *integrifolium*, an oilseed crop in the sunflower family (Van Tassel et al. 2017). Other perennial grain
28 crops receiving attention include pigeon pea, barley, buckwheat and maize (Batello et al. 2014; Chen
29 et al. 2018c) and a number of legume species (Schlautman et al. 2018). In most cases, the seed yields
30 of perennial grain crops under development are well below those of elite modern grain varieties. In
31 the time that it takes intensive breeding efforts to close the yield and other trait gaps between annual
32 and perennial grains, perennial proto-crops may be used for purposes other than grain, including
33 forage production (Ryan et al. 2018). Perennial rice stands out as a high-yielding exception, as its
34 yields matched those of elite local varieties in the Yunnan Province for six growing seasons over three
35 years (Huang et al. 2018).

36 In a perennial agroecosystem, the biogeochemical controls on SOC accumulation shift dramatically,
37 and begin to resemble the controls that govern native ecosystems (Crews et al. 2016). When erosion
38 is reduced or halted, and crop allocation to roots increases by 100-200%, and when soil aggregates are
39 not disturbed thus reducing microbial respiration, SOC levels are expected to increase (Crews and
40 Rumsey 2017). Deep roots growing year-round are also effective at increasing nitrogen retention
41 (Culman et al. 2013; Jungers et al. 2019). Substantial increases in SOC have been measured where
42 croplands that had historically been planted to annual grains were converted to perennial grasses, such
43 as in the Conservation Reserve Program (CRP) of the US, or in plantings of second generation
44 perennial biofuel crops. Two studies have assessed carbon accumulation in soils when croplands were
45 converted to the perennial grain Kernza. In one, researchers found no differences in soil labile
46 (permanganate-oxidizable) C after 4 years of cropping to perennial Kernza versus annual wheat in a
47 sandy textured soil. Given that coarse textured soils do not offer the same physicochemical protection
48 against microbial attack as many finer textured soils, these results are not surprising, but these results

1 do underscore how variable rates of carbon accumulation can be (Jastrow et al. 2007). In the second
2 study, researchers assessed the carbon balance of a Kernza field in Kansas USA over 4.5 years using
3 eddy covariance observations (de Oliveira et al. 2018). They found the net C accumulation rate of
4 about $1500 \text{ g C m}^{-2} \text{ yr}^{-1}$ in the first year of the study corresponding to the biomass of Kernza
5 increasing, to about $300 \text{ g C m}^{-2} \text{ yr}^{-1}$ in the final year where CO_2 respiration losses from the
6 decomposition of roots and soil organic matter approached new carbon inputs from photosynthesis.
7 Based on measurements of soil carbon accumulation in restored grasslands in this part of US, the net
8 carbon accumulation in stable organic matter under a perennial grain crop might be expected to
9 sequester $30\text{-}50 \text{ g C m}^{-2} \text{ yr}^{-1}$ (Post and Kwon 2000) until a new equilibrium is reached. Sugar cane, a
10 highly productive perennial, has been shown to accumulate a mean of $187 \text{ g C m}^{-2} \text{ yr}^{-1}$ in Brazil (La
11 Scala Júnior et al. 2012).

12 Reduced soil erosion, increased nitrogen retention, greater water uptake efficiency and enhanced
13 carbon sequestration represent improved ecosystem functions made possible in part by deep and
14 extensive root systems of perennial crops (Figure 4.8).

15
16 **Figure 4.8 Comparison of root systems between the newly domesticated intermediate wheatgrass (left)**
17 **and annual wheat (right). Photo and copyright: Jim Richardson**

18 When compared to annual grains like wheat, single species stands of deep rooted perennial grains
19 such as Kernza are expected to reduce soil erosion, increase nitrogen retention, achieve greater water
20 uptake efficiency and enhance carbon sequestration (Crews et al. 2018) (Figure 4.8). An even higher
21 degree of ecosystem services can at least theoretically be achieved by strategically combining
22 different functional groups of crops such as a cereal and a nitrogen-fixing legume (Soussana and
23 Lemaire 2014). Not only is there evidence from plant diversity experiments that communities with
24 higher species richness sustain higher concentrations of soil organic carbon (Hungate et al. 2017;
25 Sprunger and Robertson 2018; Chen et al. 2018b; Yang et al. 2019), but other valuable ecosystem
26 services such as pest suppression, lower greenhouse gas emissions, and greater nutrient retention may
27 be enhanced (Schnitzer et al. 2011; Culman et al. 2013).

1 Similar to perennial forage crops such as alfalfa, perennial grain crops are expected to have a definite
2 productive life span, probably in the range of 3-10 years. A key area of research on perennial grains
3 cropping systems is to minimise losses of soil organic carbon during conversion of one stand of
4 perennial grains to another. Recent work demonstrates that no-till conversion of a mature perennial
5 grassland to another perennial crop will experience several years of high net CO₂ emissions as
6 decomposition of copious crop residues exceeds ecosystem uptake of carbon by the new crop (Abraha
7 et al. 2018). Most if not all of this lost carbon will be recaptured in the replacement crop. It is not
8 known whether mineral-stabilised carbon that is protected in soil aggregates is vulnerable to loss in
9 perennial crop succession.

10 Perennial grains hold promises of agricultural practices which can significantly reduce soil erosion
11 and nutrient leakage while sequestering carbon. When cultivated in mixes with N-fixing species
12 (legumes) such polycultures also reduce the need for external inputs of nitrogen - a large source of
13 GHG from conventional agriculture.

14 **4.9.3 Reversing land degradation through reforestation**

15 **4.9.3.1 South Korea Case Study on Reforestation Success**

16 In the first half of the 20th century, forests in the Republic of South Korea were severely degraded and
17 deforested during foreign occupations and the Korean War. Unsustainable harvest for timber and fuel
18 wood resulted in severely degraded landscapes, heavy soil erosion and large areas denuded of
19 vegetation cover. Recognising that South Korea's economic health would depend on a healthy
20 environment, South Korea established a national forest service (1967) and embarked on the first phase
21 of a 10-year reforestation program in 1973 (Forest Development Program), which was followed by
22 subsequent reforestation programs that ended in 1987, after 2.4 Mha of forests were restored, see
23 Figure 4.9.

24 As a consequence of reforestation, forest volume increased from 11.3 m³ ha⁻¹ in 1973 to 125.6 m³ ha⁻¹
25 in 2010 and 150.2 m³ ha⁻¹ in 2016 (Korea Forest Service 2017). Increases in forest volume had
26 significant co-benefits such as increasing water yield by 43% and reducing soil losses by 87% from
27 1971 to 2010 (Kim et al. 2017).

28 The forest carbon density in South Korea has increased from 5–7 Mg C ha⁻¹ in the period 1955–1973
29 to more than 30 Mg C ha⁻¹ in the late 1990s (Choi et al. 2002). Estimates of C uptake rates in the late
30 1990s were 12 Tg C yr⁻¹ (Choi et al. 2002). For the period 1954 to 2012 C uptake was 8.3 Tg C yr⁻¹
31 (Lee et al. 2014), lower than other estimates because reforestation programs did not start until 1973.
32 NEP in South Korea was 10.55 ± 1.09 Tg C yr⁻¹ in the 1980s, 10.47 ± 7.28 Tg C yr⁻¹ in the 1990s,
33 and 6.32 ± 5.02 Tg C yr⁻¹ in the 2000s, showing a gradual decline as average forest age increased
34 (Cui et al. 2014). The estimated past and projected future increase in the carbon content of South
35 Korea's forest area during 1992-2034 was 11.8 Tg C yr⁻¹ (Kim et al. 2016).

1

2 **Figure 4.9 Example of severely degraded hills in South Korea and stages of forest restoration. The top**
 3 **two photos are taken in the early 1970s, before and after restoration, the third photo about 5 years after**
 4 **restoration and the bottom photo was taken about 20 years after restoration. Many examples of such**
 5 **restoration success exist throughout South Korea (Source: Korea Forest Service).**

6 During the period of forest restoration, South Korea also promoted inter-agency cooperation and
 7 coordination, especially between the energy and forest sectors, to replace firewood with fossil fuels,
 8 and by reducing demand for firewood helped forest recovery (Bae et al. 2012). As experience with
 9 forest restoration programs has increased, emphasis has shifted from fuelwood plantations, often with
 10 exotic species and hybrid varieties to planting more native species and encouraging natural
 11 regeneration (Kim and Zsuffa 1994; Lee et al. 2015). Avoiding monocultures in reforestation
 12 programs can reduce susceptibility to pests (Kim and Zsuffa 1994). Other important factors in the
 13 success of the reforestation program were that private landowners were heavily involved in initial
 14 efforts (both corporate entities and smallholders) and that the reforestation program was made part of
 15 the national economic development program (Lamb 2014).

16 The net present value and the benefit-cost ratio of the reforestation program were USD 54.3 billion
 17 and 5.84 billion in 2010, respectively. The breakeven point of the reforestation investment appeared
 18 within two decades. Substantial benefits of the reforestation program included disaster risk reduction
 19 and carbon sequestration (Lee et al. 2018a).

20 In summary, the reforestation program was a comprehensive technical and social initiative that
 21 restored forest ecosystems, enhanced the economic performance of rural regions, contributed to
 22 disaster risk reduction, and enhanced carbon sequestration (Kim et al. 2017; Lee et al. 2018a; UNDP
 23 2017).

1 The success of the reforestation program in South Korea and the associated significant carbon sink
2 indicate a high mitigation potential that might be contributed by a potential future reforestation
3 program in the Democratic People’s Republic of Korea (North Korea) (Lee et al. 2018b).

4 **4.9.3.2 China Case Study on Reforestation Success**

5 The dramatic decline in the quantity and quality of natural forests in China resulted in land
6 degradation, such as soil erosion, floods, droughts, carbon emission, and damage to wildlife habitat
7 (Liu and Diamond 2008). In response to failures of previous forestry and land policies, the severe
8 droughts in 1997, and the massive floods in 1998, the central government decided to implement a
9 series of land degradation control policies, including the National Forest Protection Program (NFPP),
10 Grain for Green or the Conversion of Cropland to Forests and Grasslands Program (GFGP) (Liu et al.
11 2008; Yin 2009; Tengberg et al. 2016; Zhang et al. 2000). The NFPP aimed to completely ban
12 logging of natural forests in the upper reaches of the Yangtze and Yellow rivers as well as in Hainan
13 Province by 2000 and to substantially reduce logging in other places (Xu et al. 2006). In 2011, NFPP
14 was renewed for the 10-year second phase, which also added another 11 counties around Danjiangkou
15 Reservoir in Hubei and Henan Provinces, the water source for the middle route of the South-to-North
16 Water Diversion Project (Liu et al. 2013). Furthermore, the NFPP afforested 31 Mha by 2010 through
17 aerial seeding, artificial planting, and mountain closure (i.e., prohibition of human activities such as
18 fuelwood collection and livestock grazing) (Xu et al. 2006). China banned commercial logging in all
19 natural forests by the end of 2016, which imposed logging bans and harvesting reductions in 68.2
20 Mha of forest land – including 56.4 Mha of natural forest (approximately 53% of China’s total natural
21 forests).

22 GFGP became the most ambitious of China’s ecological restoration efforts with over USD 45 billion
23 devoted to its implementation since 1990 (Kolinjivadi and Sunderland 2012) The program involves
24 the conversion of farmland on slopes of 15-25° or greater to forest or grassland (Bennett 2008). The
25 pilot program started in three provinces –Sichuan, Shaanxi, and Gansu – in 1999 (Liu and Diamond
26 2008). After initial success, it was extended to 17 provinces by 2000 and finally to all provinces by
27 2002, including the headwaters of the Yangtze and Yellow rivers (Liu et al. 2008).

28 NFPP and GFGP have dramatically improved China’s land conditions and ecosystem services, and
29 thus have mitigated the unprecedented land degradation in China (Liu et al. 2013; Liu et al 2002;
30 Long et al. 2006; Xu et al. 2006). NFPP protected 107 Mha forest area and increased forest area by 10
31 Mha between 2000 and 2010. For the second phase (2011–2020), the NFPP plans to increase forest
32 cover by a further 5.2 Mha, capture 416 million tons of carbon, provide 648,500 forestry jobs, further
33 reduce land degradation, and enhance biodiversity (Liu et al. 2013). During 2000–2007, sediment
34 concentration in the Yellow River had declined by 38%. In the Yellow River basin, it was estimated
35 that surface runoff would be reduced by 450 million m³ from 2000 to 2020, which is equivalent to
36 0.76% of the total surface water resources (Jia et al. 2006). GFGP had cumulatively increased
37 vegetative cover by 25 Mha, with 8.8 Mha of cropland being converted to forest and grassland, 14.3
38 Mha barren land being afforested, and 2.0 million ha of forest regeneration from mountain closure.
39 Forest cover within the GFGP region has increased 2% during the first 8 years (Liu et al. 2008). In
40 Guizhou Province, GFGP plots had 35–53% less loss of phosphorus than non-GFGP plots (Liu et al.
41 2002). In Wuqi County of Shaanxi Province, the Chaigou Watershed had 48% and 55% higher soil
42 moisture and moisture-holding capacity in GFGP plots than in non-GFGP plots, respectively (Liu et
43 al. 2002). According to reports on China’s first national ecosystem assessment (2000–2010), for
44 carbon sequestration and soil retention, coefficients for the GTGP targeting forest restoration and
45 NFPP are positive and statistically significant. For sand fixation, GTGP targeting grassland
46 restoration is positive and statistically significant. Remote sensing observations confirm vegetation
47 cover increases and bare soil decline in China over the period 2001 to 2015 (Qiu et al. 2017) (Qiu et
48 al. 2017). But where afforestation is sustained by drip irrigation from groundwater, questions about

1 plantation sustainability arise (Chen et al. 2018a). Moreover, greater gains in biodiversity could be
2 achieved by promoting mixed forests over monocultures (Hua et al. 2016).

3 NFPP-related activities received a total commitment of 93.7 billion yuan (about USD 14 billion with
4 today's exchange rate) between 1998 and 2009. Most of the money was used to offset economic
5 losses of forest enterprises caused by the transformation from logging to tree plantations and forest
6 management (Liu et al. 2008). By 2009, the cumulative total investment through the NFPP and GFGP
7 exceeded USD 50 billion and directly involved more than 120 million farmers in 32 million
8 households in the GFGP alone (Liu et al. 2013). All programs reduce or reverse land degradation and
9 improve human well-being. Thus, a coupled human and natural systems perspective (Liu et al. 2008)
10 would be helpful to understand the complexity of policies and their impacts, and to establish long-
11 term management mechanisms to improve the livelihood of participants in these programs and other
12 land management policies in both China and many other parts of the world.

13 **4.9.4 Degradation and management of peat soils**

14 Globally, peatlands cover 3-4 % of the Earth's land area (~430 Mha) (Xu et al. 2018a; Wu et al.
15 2017b) and store 26-44% of estimated global soil organic carbon (Moore 2002). They are most
16 abundant in high northern latitudes, covering large areas in North America, Russia and Europe. At
17 lower latitudes, the largest areas of tropical peatlands are located in Indonesia, the Congo Basin and
18 the Amazon Basin in the form of peat swamp forests (Gumbrecht et al. 2017; Xu et al. 2018a). It is
19 estimated that while 80-85% of the global peatland areas is still largely in a natural state, they are such
20 carbon-dense ecosystems that degraded peatlands (0.3% of the terrestrial land) are responsible for a
21 disproportional 5% of global anthropogenic carbon dioxide (CO₂) emissions, that is an annual
22 addition of 0.9-3 Gt of CO₂ to the atmosphere (Dommain et al. 2012; IPCC 2014c).

23 Peatland degradation is not well quantified globally, but regionally peatland degradation can involve a
24 large percentage of the areas. Land-use change and degradation in tropical peatlands have primarily
25 been quantified in Southeast Asia, where drainage and conversion to plantation crops is the dominant
26 transition (Miettinen et al. 2016). Degradation of peat swamps in Peru is also a growing concern and
27 one pilot survey showed that over 70% of the peat swamps were degraded in one region that was
28 surveyed (Hergoualc'h et al. 2017a). Around 65,000km² or 10% of the European peatland area has
29 been lost and 44% of the remaining European peatlands are degraded (Joosten, H., Tanneberger
30 2017). Large areas of fens have been entirely 'lost' or greatly reduced in thickness due to peat
31 wastage (Lamers et al. 2015).

32 The main drivers of the acceleration of peatland degradation in the twentieth century were associated
33 with drainage for agriculture, peat extraction and afforestation related activities (burning, over-
34 grazing, fertilisation) with a variable scale and severity of impact depending on existing resources in
35 the various countries (O'Driscoll et al. 2018; Abu et al. 2017; Dommain et al. 2018; Lamers et al.
36 2015). New drivers include urban development, wind farm construction (Smith et al. 2012), hydro-
37 electric development, tar sands mining and recreational (Joosten, H., Tanneberger 2017).
38 Anthropogenic pressures are now affecting peatlands in previously geographically isolated areas with
39 consequences for global environmental concerns and impacts on local livelihoods (Dargie et al. 2017;
40 Lawson et al. 2015; Butler et al. 2009).

41 Drained and managed peatlands are GHG emissions hotspots (Swails et al. 2018; Hergoualc'h et al.
42 2017b; Roman-Cuesta et al. 2016; Hergoualc'h et al. 2017a). In most cases, lowering of the water
43 table leads to direct and indirect CO₂ and N₂O emissions to the atmosphere with rates dependent on a
44 range of factors, including the groundwater level and the water content of surface peat layers, nutrient
45 content, temperature, and vegetation communities. The exception is nutrient limited boreal peatlands
46 (Minkinen et al. 2018; Ojanen et al. 2014). Drainage also increases erosion and dissolved organic C

1 loss, removing stored carbon into streams as dissolved and particulate organic carbon, which
2 ultimately returns to the atmosphere (Moore et al. 2013; Evans et al. 2016).

3 In tropical peatlands, oil palm is the most widespread plantation crop and on average it emits around
4 40 t CO₂ ha⁻¹ yr⁻¹; Acacia plantations for pulpwood are the second most widespread plantation crop
5 and emit around 73 t CO₂ ha⁻¹ yr⁻¹ (Drösler et al. 2013). Other land uses typically emit less than 37 t
6 CO₂ ha⁻¹ yr⁻¹. Total emissions from peatland drainage in the region are estimated to be between 0.07
7 and 1.1 Gt CO₂ yr⁻¹ (Houghton and Nassikas 2017; Frohking et al. 2011). Land-use change also affects
8 the fluxes of N₂O and CH₄. Undisturbed tropical peatlands emit about 0.8 Mt CH₄ yr⁻¹ and 0.002 Mt
9 N₂O yr⁻¹, while disturbed peatlands emit 0.1 Mt CH₄ yr⁻¹ and 0.2 Mt N₂O–N yr⁻¹ (Frohking et al. 2011).
10 These N₂O emissions are probably low as new findings show that emissions from fertilised oil palm
11 can exceed 20 kg N₂O–N ha⁻¹ yr⁻¹ (Oktarita et al. 2017).

12 In the temperate and boreal zones, peatland drainage often leads to emissions on the order of 0.9 to
13 9.5 t CO₂ ha⁻¹ y⁻¹ in forestry plantations and 21 to 29 t CO₂ ha⁻¹ y⁻¹ in grasslands and croplands.
14 Nutrient poor sites often continue to be CO₂ sinks for long periods (e.g. 50 y) following drainage and
15 in some cases sinks for atmospheric CH₄, even when drainage ditch emissions are considered
16 (Minkinen et al. 2018; Ojanen et al. 2014). Undisturbed boreal and temperate peatlands emit about
17 0.30 Mt CH₄ yr⁻¹ and 0.02 Mt N₂O–N yr⁻¹, while disturbed peatlands emit 0.1 Mt CH₄ yr⁻¹ and 0.2 Mt yr⁻¹
18 ¹N₂O (Frohking et al. 2011).

19 Fire emissions from tropical peatlands are only a serious issue in Southeast Asia, where they are
20 responsible for 634 (66–4070) Mt CO₂ yr⁻¹ (van der Werf et al. 2017). Much of the variability is
21 linked with the El Niño Southern Oscillation, which produces drought conditions in this region.
22 Anomalously active fire seasons have also been observed in non-drought years and this has been
23 attributed to the increasing effect of high temperatures that dry vegetation out during short dry spells
24 in otherwise normal rainfall years (Fernandes et al. 2017; Gaveau et al. 2014). Fires have significant
25 societal impacts; for example, the 2015 fires caused over 100,000 additional deaths across Indonesia,
26 Malaysia and Singapore and this event was more than twice as deadly as the 2006 El Niño event
27 (Koplitz et al. 2016).

28 Peatland degradation in other parts of the world differs from Asia. In Africa large peat deposits like
29 those found in the Cuvette Centrale in the Congo Basin or in the Okavango inland delta, the principle
30 threat is changing rainfall regimes due to climate variability and change (Weinzierl et al. 2016; Dargie
31 et al. 2017). Expansion of agriculture is not yet a major factor in these regions. In the Western
32 Amazon, extraction of non-timber forest products like the fruits of *Mauritia flexuosa* (morange palm)
33 and Suri worms are major sources of degradation that lead to losses of carbon stocks (Hergoualc'h et
34 al. 2017a).

35 The effects of peatland degradation on livelihoods have not been systematically characterised. In
36 places where plantation crops are driving the conversion of peat swamps, the financial benefits can be
37 considerable. One study in Indonesia found that the net present value of an oil palm plantation is
38 between USD 3,835 and 9,630 per ha to land owners (Butler et al. 2009). High financial returns are
39 creating the incentives for the expansion of smallholder production in peatlands. Smallholder
40 plantations extend over 22% of the peatlands in insular Southeast Asia compared to 27% for industrial
41 plantations (Miettinen et al. 2016). In places where income is generated from extraction of
42 marketable products, ecosystem degradation probably has a negative effect on livelihoods. For
43 example, the sale of fruits of *M. flexuosa* in some parts of the western Amazon constitutes as much as
44 80% of the winter income of many rural households, but information on trade values and value chains
45 of *M. flexuosa* is still sparse (Sousa et al. 2018; Virapongse et al. 2017).

46 There is little experience with peatland restoration in the tropics. Experience from northern latitudes
47 suggests that extensive damage and changes in hydrological conditions mean that restoration in many

1 cases is unachievable (Andersen et al. 2017). In the case of Southeast Asia, where peatlands form as
2 raised bogs, drainage leads to collapse of the dome and this collapse cannot be reversed by rewetting.
3 Nevertheless, efforts are underway to develop solutions or at least partial solutions in Southeast Asia,
4 for example, by the Indonesian Peatland Restoration Agency. The first step is to restore the
5 hydrological regime in drained peatlands and experiences with canal blocking and re-flooding of the
6 peat. These efforts have been only partially successful (Ritzema et al. 2014). Market incentives with
7 certification through the Roundtable on Sustainable Palm Oil have also not been particularly
8 successful as many concessions seek certification only after significant environmental degradation has
9 been accomplished (Carlson et al. 2017). Certification had no discernible effect on forest loss or fire
10 detection in peatlands in Indonesia. To date there is no documentation of restoration methods or
11 successes in many other parts of the tropics, but in situations where degradation does not involve
12 drainage, ecological restoration may be possible. In South America, for example, there is growing
13 interest in restoration of palm swamps, and as experiences are gained it will be important to document
14 success factors to inform successive efforts (Virapongse et al. 2017).

15 In higher latitudes where degraded peatlands have been drained, the most effective option to reduce
16 losses from these large organic carbon stocks is change hydrological conditions and increase soil
17 moisture and surface wetness (Regina et al. 2015). Long-term GHG monitoring in boreal sites has
18 demonstrated that rewetting and restoration noticeably reduce emissions compared to degraded
19 drained sites and can restore the carbon sink function when vegetation is re-established (Wilson et al.
20 2016; IPCC 2014a; Nugent et al. 2018) although restored ecosystems may not yet be as resilient as
21 their undisturbed counterparts (Wilson et al. 2016). Several studies have demonstrated the co-benefits
22 of rewetting specific degraded peatlands for biodiversity, carbon sequestration, (Parry et al. 2014;
23 Ramchunder et al. 2012; Renou-Wilson et al. 2018) and other ecosystem services such as
24 improvement of water storage and quality (Martin-Ortega et al. 2014) with beneficial consequences
25 for human well-being (Bonn et al. 2016; Parry et al. 2014).

26 **4.9.5 Biochar**

27 Biochar is organic matter that is carbonised by heating in an oxygen-limited environment, and used as
28 a soil amendment. The properties of biochar vary widely, dependent on the feedstock and the
29 conditions of production. Biochar could make a significant contribution to mitigating both land
30 degradation and climate change, simultaneously.

31 **4.9.5.1 Role of biochar in climate change mitigation**

32 Biochar is relatively resistant to decomposition compared with fresh organic matter or compost, so
33 represents a long-term C store (*very high confidence*). Biochars produced at higher temperature (>
34 450°C) and from woody material have greater stability than those produced at lower temperature
35 (300-450°C), and from manures (*very high confidence*) (Singh et al. 2012; Wang et al. 2016b).
36 Biochar stability is influenced by soil properties: biochar carbon can be further stabilised by
37 interaction with clay minerals and native soil organic matter (*medium evidence*) (Fang et al. 2015).
38 Biochar stability is estimated to range from decades to thousands of years, for different biochars in
39 different applications (Singh et al., 2015; Wang et al., 2016). Biochar stability decreases as ambient
40 temperature increases (*limited evidence*) (Fang et al. 2017).

41 Biochar can enhance soil carbon stocks through “negative priming”, in which rhizodeposits are
42 stabilised through sorption of labile C on biochar, and formation of biochar-organo-mineral
43 complexes (Weng et al. 2015, 2017, 2018; Wang et al. 2016b). Conversely, some studies show
44 increased turnover of native soil carbon (“positive priming”) due to enhanced soil microbial activity
45 induced by biochar. In clayey soils, positive priming is minor and short-lived compared to negative
46 priming effects, which dominate in the medium to long-term (Singh and Cowie 2014; Wang et al.
47 2016b). Negative priming has been observed particularly in loamy grassland soil (Ventura et al.

1 2015) and clay-dominated soils, whereas positive priming is reported in sandy soils (Wang et al.
2 2016b) and those with low C content (Ding et al. 2018).

3 Biochar can provide additional climate change mitigation by decreasing nitrous oxide (N₂O)
4 emissions from soil, due in part to decreased substrate availability for denitrifying organisms, related
5 to the molar H/C ratio of the biochar (Cayuela et al. 2015). However, this impact varies widely: meta-
6 analyses found an average decrease in N₂O emissions from soil of 30-54%, (Cayuela et al. 2015)
7 (Moore 2002; Borchard et al. 2019), although another study found no significant reduction in field
8 conditions when weighted by the inverse of the number of observations per site (Verhoeven et al.
9 2017). Biochar has been observed to reduce methane emissions from flooded soils, such as rice
10 paddies, though, as for N₂O, results vary between studies and increases have also been observed (He
11 et al. 2017; KAMMANN et al. 2017). Biochar has also been found to reduce methane uptake by
12 dryland soils, though the effect is small in absolute terms (Jeffery et al. 2016).

13 Additional climate benefits of biochar can arise through reduced N fertiliser requirements, due to
14 reduced losses of N through leaching and/or volatilization (Singh, Hatton, Balwant, & Cowie, 2010)
15 and enhanced biological nitrogen fixation (Van Zwieten et al. 2015); increased yields of crop, forage,
16 vegetable and tree species (Biederman and Stanley Harpole 2013), particularly in sandy soils and
17 acidic tropical soils (Simon et al. 2017) ; avoided GHG emissions from manure that would otherwise
18 be stockpiled, crop residues that would be burned or processing residues that would be landfilled; and
19 reduced GHG emissions from compost when biochar is added (Agyarko-Mintah et al. 2017; Wu et al.
20 2017a).

21 Climate benefits of biochar could be substantially reduced through reduction in albedo if biochar is
22 surface-applied at high rates to light-colored soils (Genesio et al. 2012; Bozzi et al. 2015; Woolf et al.
23 2010), or if black carbon dust is released (Genesio et al. 2016). Pelletizing or granulating biochar, and
24 applying below the soil surface or incorporating into the soil, minimises the release of black carbon
25 dust and reduces the effect on albedo (Woolf et al. 2010).

26 Biochar is a potential “negative emissions” technology: the thermochemical conversion of biomass to
27 biochar slows mineralisation of the biomass, delivering long term C storage; gases released during
28 pyrolysis can be combusted for heat or power, displacing fossil energy sources, and could be captured
29 and sequestered if linked with infrastructure for carbon capture and storage (Smith 2016). Studies of
30 the life cycle climate change impacts of biochar systems generally show emissions reduction in the
31 range 0.4 -1.2 t CO₂e t⁻¹ (dry) feedstock (Cowie et al. 2015). Use of biomass for biochar can deliver
32 greater benefits than use for bioenergy, if applied in a context where it delivers agronomic benefits
33 and/or reduces non-CO₂ GHG emissions (Ji et al. 2018; Woolf et al. 2010, 2018; Xu et al. 2019). A
34 global analysis of technical potential, in which biomass supply constraints were applied to protect
35 against food insecurity, loss of habitat and land degradation, estimated technical potential abatement
36 of 3.7 - 6.6 Gt CO₂e yr⁻¹ (including 2.6-4.6 GtCO₂e yr⁻¹ carbon stabilization), with theoretical
37 potential to reduce total emissions over the course of a century by 240 – 475 Gt CO₂e (Woolf et al.
38 2010). Fuss et al. 2018 propose a range of 0.5-2 GtCO₂e as the sustainable potential for negative
39 emissions through biochar. Mitigation potential of biochar is reviewed in Chapter 2.

40 **4.9.5.2 Role of biochar in management of land degradation**

41 Biochars generally have high porosity, high surface area and surface-active properties that lead to
42 high absorptive and adsorptive capacity, especially after interaction in soil (Joseph et al. 2010). As a
43 result of these properties, biochar could contribute to avoiding, reducing and reversing land
44 degradation through the following documented benefits:

- 45 • Improved nutrient use efficiency due to reduced leaching of nitrate and ammonium (e.g.
46 (Haider et al. 2017) and increased availability of phosphorus (P) in soils with high P fixation
47 capacity (Liu et al. 2018c), potentially reducing N and P fertiliser requirements.

- 1 • Management of heavy metals and organic pollutants: through reduced bioavailability of toxic
2 elements (O'Connor et al., 2018; Peng ; Deng, ; Peng, & Yue, 2018), by reducing availability,
3 through immobilization due to increased pH and redox effects (Rizwan et al. 2016) and
4 adsorption on biochar surfaces (Zhang et al. 2013) thus providing a means of remediating
5 contaminated soils, and enabling their utilisation for food production.
- 6 • Stimulation of beneficial soil organisms, including earthworms and mycorrhizal fungi (Thies
7 et al. 2015).
- 8 • Improved porosity and water holding capacity (Quin et al. 2014), particularly in sandy soils
9 (Omondi et al. 2016), enhancing microbial function during drought (Paetsch et al. 2018).
- 10 • Amelioration of soil acidification, through application of biochars with high pH and acid
11 neutralising capacity (Chan et al. 2008)(Van Zwieten et al. 2010).

12
13 Biochar systems can deliver a range of other co-benefits including destruction of pathogens and weed
14 propagules, avoidance of landfill, improved handling and transport of wastes such as sewage sludge,
15 management of biomass residues such as environmental weeds and urban greenwaste, reduction of
16 odors and management of nutrients from intensive livestock facilities, reduction in environmental N
17 pollution and protection of waterways. As a compost additive, biochar has been found to reduce
18 leaching and volatilisation of nutrients, increasing nutrient retention, through absorption and
19 adsorption processes (Joseph et al. 2018).

20 While many studies report positive responses, some studies have found negative or zero impacts on
21 soil properties or plant response (e.g. Kuppusamy, Thavamani, Megharaj, Venkateswarlu, & Naidu,
22 2016). The risk that biochar may enhance PAH in soil or sediments has been raised (Quilliam et al.
23 2013; Ojeda et al. 2016), but bioavailability of PAH in biochar has been shown to be very low (Hilber
24 et al. 2017) Pyrolysis of biomass leads to losses of volatile nutrients, especially N. While availability
25 of N and P in biochar is lower in biochar than in fresh biomass (Xu et al. 2016) the impact of biochar
26 on plant uptake is determined by the interactions between biochar, soil minerals and activity of
27 microorganisms (e.g. (Vanek and Lehmann 2015); (Nguyen et al. 2017). To avoid negative responses,
28 it is important to select biochar formulations to address known soil constraints, and to apply biochar
29 prior to planting (Nguyen et al., 2017). Nutrient enrichment improves the performance of biochar
30 from low nutrient feedstocks (Joseph et al. 2013). While there are many reports of biochar reducing
31 disease or pest incidence, there are also reports of nil or negative effects (Bonanomi et al. 2015).
32 Biochar may induce systemic disease resistance (e.g., Elad et al. 2011)), though (Viger et al. 2015)
33 reported down-regulation of plant defence genes, suggesting increased susceptibility to insect and
34 pathogen attack. Disease suppression where biochar is applied is associated with increased microbial
35 diversity and metabolic potential of the rhizosphere microbiome (Kolton et al. 2017). Differences in
36 properties related to feedstock (Bonanomi et al. 2018) and differential response to biochar dose, with
37 lower rates more effective (Frenkel et al. 2017) in contributing to variable disease responses.

38 Constraints to biochar adoption are high cost and limited availability due to limited large-scale
39 production; limited amount of unutilised biomass; and competition for land for growing biomass.
40 While early biochar research tended to use high rates of application (10 t ha⁻¹ or more) subsequent
41 studies have shown that biochar can be effective at lower rates especially when combined with
42 chemical or organic fertilisers (Joseph et al. 2013). Biochar can be produced at many scales and
43 levels of engineering sophistication, from simple cone kilns and cookstoves to large industrial scale
44 units processing several tonnes of biomass per hour (Lehmann and Stephen 2015). Substantial
45 technological development has occurred recently, though large-scale deployment is limited to date.

46 Governance of biochar is required to manage climate, human health and contamination risks
47 associated with biochar production in poorly-designed or operated facilities that release methane or
48 particulates (Downie et al. 2012)(Buss et al. 2015), to ensure quality control of biochar products, and

1 to ensure biomass is sourced sustainably and is uncontaminated. Measures could include labelling
2 standards, sustainability certification schemes and regulation of biochar production and use.
3 Governance mechanisms should be tailored to context, commensurate with risks of adverse outcomes.

4 In summary, application of biochar to soil can improve soil chemical, physical and biological
5 attributes, enhancing productivity and resilience to climate change, while also delivering climate
6 change mitigation through carbon sequestration and reduction in GHG emissions (*medium agreement,*
7 *robust evidence*). However, responses to biochar depend on biochar properties, in turn dependent on
8 feedstock and biochar production conditions, and the soil and crop to which it is applied. Negative or
9 nil results have been recorded. Agronomic and methane reduction benefits appear greatest in tropical
10 regions, where acidic soils predominate and suboptimal rates of lime and fertiliser are common, while
11 carbon stabilisation is greater in temperate regions. Biochar is most effective when applied in low
12 volumes to the most responsive soils and when properties are matched to the specific soil constraints
13 and plant needs. Biochar is thus a practice that has potential to address land degradation and climate
14 change simultaneously, while also supporting sustainable development. The potential of biochar is
15 limited by the availability of biomass for its production. Biochar production and use requires
16 regulation and standardisation to manage risks (*strong agreement*).

17 **4.9.6 Management of land degradation induced by tropical cyclones**

18 Tropical cyclones are normal disturbances that natural ecosystems have been affected by and
19 recovered from for millennia. Climate models mostly predict decreasing frequency of tropical
20 cyclones, but dramatically increasing intensity of the strongest storms as well as increasing rainfall
21 rates (Bacmeister et al. 2018; Walsh et al. 2016b). Large amplitude fluctuations in the frequency and
22 intensity complicate both the detection and attribution of tropical cyclones to climate change (Lin and
23 Emanuel 2016b). Yet, the intensity of high-intensity cyclones have increased and are expected to
24 increase further due to global climate change (Knutson et al. 2010; Bender et al. 2010; Vecchi et al.
25 2008; Bhatia et al. 2018; Tu et al. 2018; Sobel et al. 2016) (*medium agreement, robust evidence*).
26 Tropical cyclone paths are also shifting towards the poles increasing the area subject to tropical
27 cyclones (Sharmila and Walsh 2018; Lin and Emanuel 2016b). Climate change alone will affect the
28 hydrology of individual wetland ecosystems mostly through changes in precipitation and temperature
29 regimes with great global variability (Erwin 2009). Over the last seven decades, the speed at which
30 tropical cyclones move has decreased significantly as expected from theory, exacerbating the damage
31 on local communities from increasing rainfall amounts and high wind speed (Kossin 2018). Tropical
32 cyclones will accelerate changes in coastal forest structure and composition. The heterogeneity of
33 land degradation at coasts that are affected by tropical cyclones can be further enhanced by the
34 interaction of its components (for example, rainfall, wind speed, and direction) with topographic and
35 biological factors (for example, species susceptibility) (Luke et al. 2016).

36 Small Island Developing States (SIDS) are particularly affected by land degradation induced by
37 tropical cyclones, recent examples are Matthew (2016) in the Caribbean, and Pam (2015) and
38 Winston (2016) in the Pacific (Klöck and Nunn 2019; Handmer and Nalau 2019). Even if the Pacific
39 Ocean has experienced cyclones of unprecedented intensity in the recent years, their
40 geomorphological effects may not be unprecedented (Terry and Lau 2018).

41 Cyclone impacts on coastal areas is not restricted to SIDS, but a problem for all low-lying coastal
42 areas (Petzold and Magnan 2019). The Sundarban, one of the world's largest coastal wetlands, covers
43 about one million hectares between Bangladesh and India. Large areas of the Sundarban mangroves
44 have been converted into paddy fields over the past two centuries and more recently into shrimp farms
45 (Ghosh et al. 2015). In 2009 the cyclone Aila caused incremental stresses on the socioeconomic
46 conditions of the Sundarban coastal communities through rendering huge areas of land unproductive
47 for a long time (Abdullah et al. 2016). The impact of Aila was wide spread throughout the Sundarbans

1 mangroves showing changes between pre- and post-cyclonic period of 20-50% in the enhanced
2 vegetation index (Dutta et al. 2015). Although the magnitude of the effects of the Sundarban
3 mangroves derived from climate change is not yet defined (Payo et al. 2016; Loucks et al. 2010;
4 Gopal and Chauhan 2006; Ghosh et al. 2015; Chaudhuri et al. 2015). There is *high agreement* that the
5 joint effect of climate change and land degradation will be very negative for the area, strongly
6 affecting the environmental services provided by these forests, including the extinction of large
7 mammal species (Loucks et al. 2010). This changes in vegetation are mainly due to inundation and
8 erosion (Payo et al. 2016).

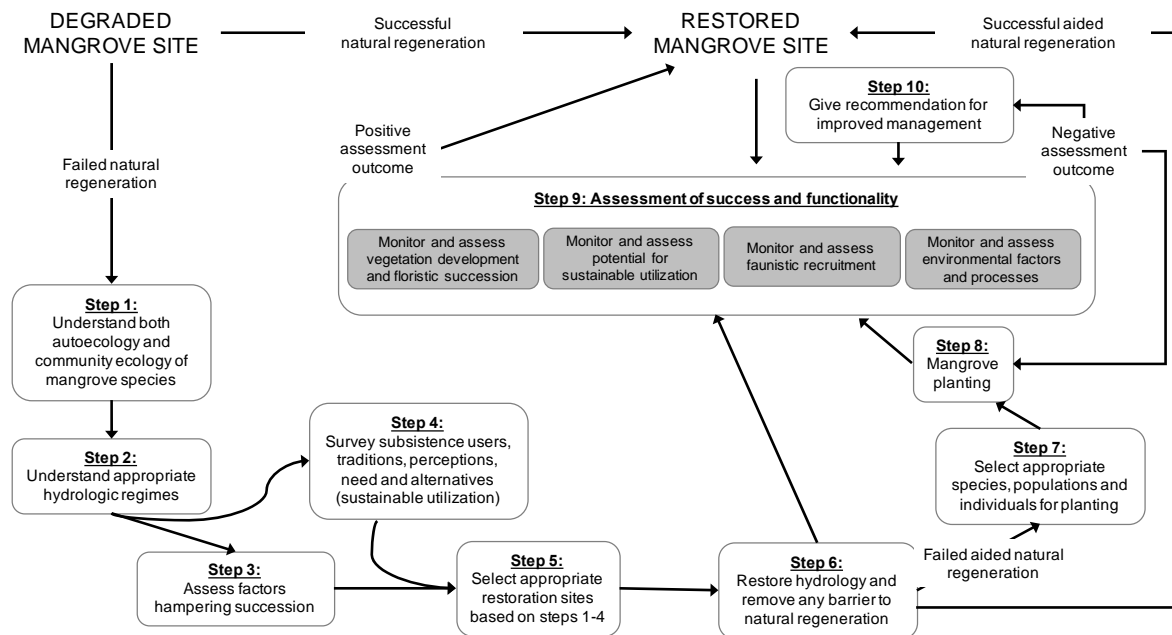

9 The tropical cyclone Nargis hit unexpectedly the Ayeyarwady River delta (Myanmar) in 2008 with
10 unprecedented and catastrophic damages to livelihoods, destruction of forests and erosion of fields
11 (Fritz et al. 2009) as well as eroding the shoreline 148 m compared with the long-term average (1974-
12 2015) of 0.62 m yr⁻¹. This is an example of the disastrous effects that changing cyclone paths can have
13 on areas previously not affected by cyclones (Fritz et al. 2010).

14 **4.9.6.1 Management of coastal wetlands**

15 Tropical cyclones mainly, but not exclusively, affect coastal regions, threatening maintenance of the
16 associated ecosystems, mangroves, wetlands, seagrasses, etc. This areas not only provide food, water
17 and shelter for fish, birds and other wildlife, but also provide important ecosystem services such as
18 water quality improvement, flood abatement and carbon sequestration (Meng et al. 2017).

19 Despite its importance coastal wetlands are listed amongst the most heavily damaged of natural
20 ecosystems worldwide. Starting in the 1990s, wetland restoration and re-creation became a “hotspot”
21 in the ecological research fields (Zedler 2000). The coastal wetland restoration and preservation is an
22 extremely cost-effective strategy for society, for example the preservation of coastal wetlands in the
23 USA provide storm protection services with the cost of 23.2 billion yr⁻¹ USD (Costanza et al. 2008).

24 There is a *high agreement* with *medium evidence* that the success of wetland restoration depends
25 mainly on the flow of the water through the system and the degree to which re-flooding occurs, the
26 disturbance regimes, and the control of invasive species (Burlakova et al. 2009; López-Rosas et al.
27 2013). The implementation of the Ecological Mangrove Rehabilitation (EMR) protocol (López-
28 Portillo et al. 2017) that includes monitoring and reporting tasks, has been proven to deliver
29 successful rehabilitation of wetland ecosystem services.

1
2 **Figure 4.10 Decision tree showing recommended steps and tasks to restore a mangrove wetland based on**
3 **original site conditions (Modified from Bosire et al. (2008))**

4 **4.9.7 Saltwater intrusion**

5 Current environmental changes, including climate change, have caused sea levels to rise worldwide,
6 particularly in tropical and subtropical regions (Fasullo and Nerem 2018). Combined with scarcity of
7 water in river channels, such rises have been instrumental in the intrusion of highly saline seawater
8 inland, posing a threat to coastal areas and an emerging challenge to land managers and policy
9 makers. Assessing the extent of salinisation due to sea water intrusion at a global scale nevertheless
10 remains challenging. Wicke et al. (2011) suggest that across the world, approximately 1.1 Gha of land
11 is affected by salt, with 14% of this categorised as forest, wetland or some other form of protected
12 area. Seawater intrusion is generally caused by: i) increased tidal activity, storm surges, cyclones and
13 sea storms due to changing climate, ii) heavy groundwater extraction or land use changes as a result
14 of changes in precipitation, and droughts/floods, iii) coastal erosion as a result of destruction of
15 mangrove forests and wetlands iv) construction of vast irrigation canals and drainage networks
16 leading to low river discharge in the deltaic region; and v) sea level rise contaminating nearby
17 freshwater aquifers as a result of subsurface intrusion (Uddameri et al. 2014).

18 The Indus delta, located in the south-eastern coast of Pakistan near Karachi in the North Arabian sea,
19 is one of the six largest estuaries in the world spanning an area of 600,000 ha. The Indus delta is a
20 clear example of seawater intrusion and land degradation due to local as well as up-country climatic
21 and environmental conditions (Rasul et al. 2012). Salinisation and waterlogging in the up-country
22 areas including provinces of Punjab and Sindh is, however, caused by the irrigation network and over-
23 irrigation (Qureshi 2011).

24 Such degradation takes the form of high soil salinity, inundation and waterlogging, erosion and
25 freshwater contamination. The inter-annual variability of precipitation with flooding conditions in
26 some years and drought conditions in others has caused variable river flows and sediment runoff
27 below Kotri barrage (about 200 km upstream of the Indus delta). This has affected hydrological
28 processes in the lower reaches of the river and the delta, contributing to the degradation (Rasul et al.
29 2012).

30 Over 480,000 ha of fertile land is now affected by sea water intrusion, wherein eight coastal
31 subdivisions of the districts of Badin and Thatta are mostly affected (Chandio et al. 2011). A very
32 high intrusion rate of $0.179 \pm 0.0315 \text{ km yr}^{-1}$, based on the analysis of satellite data, was observed in

1 the Indus delta during the past 10 years (2004–2015) (Kalhor et al. 2016). The area of agricultural
2 crops under cultivation has been declining with economic losses of millions of USD (IUCN 2003).
3 Crop yields have reduced due to soil salinity, in some places failing entirely. Soil salinity varies
4 seasonally, depending largely on the river discharge: during the wet season (August 2014), salinity
5 (0.18 mg L^{-1}) reached 24 km upstream while during the dry season (May 2013), it reached 84 km
6 upstream (Kalhor et al. 2016). The freshwater aquifers have also been contaminated with sea water
7 rendering them unfit for drinking or irrigation purposes. Lack of clean drinking water and sanitation
8 causes widespread diseases, of which diarrhoea is most common (IUCN 2003).

9 Lake Urmia in northwest Iran, the second largest saltwater lake in the world and the habitat for
10 endemic Iranian brine shrimp, *Artemia urmiana*, has also been affected by salty water intrusion.
11 During a 17-year period between 1998 and 2014, human disruption including agriculture and years of
12 dam building affected the natural flow of freshwater as well as salty sea water in the surrounding area
13 of Lake Urmia. Water quality has also been adversely affected, with salinity fluctuating over time, but
14 in recent years reaching a maximum of 340 g L^{-1} (similar to levels in the Dead Sea). This has rendered
15 the underground water unfit for drinking and agricultural purposes and risky to human health and
16 livelihoods. Adverse impacts of global climate change as well as direct human impacts have caused
17 changes in land use, overuse of underground water resources and construction of dams over rivers
18 which resulted in the drying-up of the lake in large part. This condition created sand, dust and salt
19 storms in the region which affected many sectors including agriculture, water resources, rangelands,
20 forests and health, and generally presented desertification conditions around the lake (Karbassi et al.
21 2010; Marjani and Jamali 2014; Shadkam et al. 2016).

22 Rapid irrigation expansion in the basin has, however, indirectly contributed to inflow reduction.
23 Annual inflow to Lake Urmia has dropped by 48% in recent years. About three fifths of this change
24 was caused by climate change and two fifths by water resource development and agriculture (Karbassi
25 et al. 2010; Marjani and Jamali 2014; Shadkam et al. 2016).

26 In the drylands of Mexico, intensive production of irrigated wheat and cotton using groundwater
27 (Halvorson et al. 2003) resulted in sea water intrusion into the aquifers of La Costa de Hermosillo, a
28 coastal agricultural valley at the center of Sonora Desert in Northwestern Mexico. Production of these
29 crops in 1954 was on 64,000 ha of cultivated area, increasing to 132,516 ha in 1970, but decreasing to
30 66,044 ha in 2009 as a result of saline intrusion from the Gulf of California (Romo-Leon et al. 2014).
31 In 2003, only 15% of the cultivated area was under production, with around 80,000 ha abandoned due
32 to soil salinisation whereas in 2009, around 40,000 ha was abandoned (Halvorson et al. 2003; Romo-
33 Leon et al. 2014). Salinisation of agricultural soils could be exacerbated by climate change, as
34 Northwestern Mexico is projected to be warmer and drier under climate change scenarios (IPCC
35 2013a).

36 In other countries, intrusion of seawater is exacerbated by destruction of mangrove forests.
37 Mangroves are important coastal ecosystems that provide spawning bed for fish, timber for building,
38 livelihoods to dependent communities, act as barriers against coastal erosion, storm surges, tropical
39 cyclones and tsunamis (Kalhor et al. 2017) and are among the most carbon-rich stocks on Earth
40 (Atwood et al. 2017). They nevertheless face a variety of threats: climatic (storm surges, tidal
41 activities, high temperatures) and human (coastal developments, pollution, deforestation, conversion
42 to aquaculture, rice culture, oil palm plantation), leading to declines in their areas. In Pakistan, using
43 remote sensing (RS), the mangrove forest cover in the Indus delta decreased from 260,000 ha in
44 1980s to 160,000 ha in 1990 (Chandio et al. 2011). Based on remotely sensed data, a sharp decline in
45 the mangrove area was also found in the arid coastal region of Hormozgan province in southern Iran
46 during 1972, 1987 and 1997 (Etemadi et al. 2016). Myanmar has the highest rate (about $1\% \text{ yr}^{-1}$) of
47 mangrove deforestation in the world (Atwood et al. 2017). Regarding global loss of carbon stored in
48 the mangrove due to deforestation, four countries exhibited high levels of loss: Indonesia (3,410 Gg

1 CO₂ yr⁻¹), Malaysia (1,288 GgCO₂ yr⁻¹), US (206 Gg CO₂ yr⁻¹) and Brazil (186 GgCO₂ yr⁻¹). Only in
2 Bangladesh and Guinea Bissau there was no decline in the mangrove area from 2000 to 2012
3 (Atwood et al. 2017).

4 Frequency and intensity of average tropical cyclones will continue to increase (Knutson et al. 2015)
5 and global sea level will continue to rise. The IPCC (2013) projected with *medium confidence* that sea
6 level in the Asia Pacific region will rise from 0.4 to 0.6 m, depending on the emission pathway, by the
7 end of this century. Adaptation measures are urgently required to protect the world's coastal areas
8 from further degradation due to saline intrusion. A viable policy framework is needed to ensure the
9 environmental flows to deltas in order to repulse the intruding seawater.

10 **4.9.8 Avoiding coastal maladaptation**

11 Coastal degradation—for example, beach erosion, coastal squeeze, and coastal biodiversity loss—as a
12 result of rising sea levels is a major concern for low lying coasts and small islands (*high confidence*).
13 The contribution of climate change to increased coastal degradation has been well documented in
14 AR5 (Nurse et al. 2014; Wong et al. 2014) and is further discussed in Section 4.4.1.3. as well as in the
15 IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC). However,
16 coastal degradation can also be indirectly induced by climate change as the result of adaptation
17 measures that involve changes to the coastal environment, for example, coastal protection measures
18 against increased flooding and erosion due to sea level rise and storm surges transforming the natural
19 coast to a ‘stabilised’ coastline (Cooper and Pile 2014; French 2001). Every kind of adaptation
20 response option is context-dependent, and, in fact, sea walls play an important role for adaptation in
21 many places. Nonetheless, there are observed cases where the construction of sea walls can be
22 considered ‘maladaptation’ (Barnett and O’Neill 2010; Magnan et al. 2016) by leading to increased
23 coastal degradation, such as in the case of small islands, where due to limitations of space coastal
24 retreat is less of an option than in continental coastal zones. There is emerging literature on the
25 implementation of alternative coastal protection measures and mechanisms on small islands to avoid
26 coastal degradation induced by sea walls (e.g., Mycoo and Chadwick 2012; Sovacool 2012).

27 In many cases, increased rates of coastal erosion due to the construction of sea walls are the result of
28 the negligence of local coastal morphological dynamics and natural variability as well as the interplay
29 of environmental and anthropogenic drivers of coastal change (*medium evidence, high agreement*).
30 Sea walls in response to coastal erosion may be ill-suited for extreme wave heights under cyclone
31 impacts and can lead to coastal degradation by keeping overflowing sea water from flowing back into
32 the sea, and therefore affect the coastal vegetation through saltwater intrusion, as observed in Tuvalu
33 (Government of Tuvalu 2006; Wairiu 2017). Similarly, in Kiribati, poor construction of sea walls has
34 resulted in increased erosion and inundation of reclaimed land (Donner 2012; Donner and Webber
35 2014). In the Comoros and Tuvalu, sea walls have been constructed from climate change adaptation
36 funds and ‘often by international development organizations seeking to leave tangible evidence of
37 their investments’ (Marino and Lazrus 2015, p. 344). In these cases, they have even increased coastal
38 erosion, due to poor planning and the negligence of other causes of coastal degradation, such as sand
39 mining (Marino and Lazrus 2015; Betzold and Mohamed 2017; Ratter et al. 2016). On the Bahamas,
40 the installation of sea walls as a response to coastal erosion in areas with high wave action has led to
41 the contrary effect and even increased sand loss in those areas (Sealey 2006). The reduction of natural
42 buffer zones—i.e., beaches and dunes—due to vertical structures, such as sea walls, increased the
43 impacts of tropical cyclones on Reunion Island (Duvat et al. 2016). Such a process of ‘coastal
44 squeeze’ (Pontee 2013) also results in the reduction of intertidal habitat zones, such as wetlands and
45 marshes (Linham and Nicholls 2010). Coastal degradation resulting from the construction of sea
46 walls, however, is not only observed in Small Island Developing States (SIDS), as described above,
47 but also on islands in the Global North, for example, the North Atlantic (Muir et al. 2014; Young et al.
48 2014; Cooper and Pile 2014; Bush 2004).

1 The adverse effects of coastal protection measures may be avoided by the consideration of local
2 social-ecological dynamics, including the critical studying of diverse drivers of ongoing shoreline
3 changes, and the according implementation of locally adequate coastal protection options (French
4 2001; Duvat 2013). Critical elements for avoiding maladaptation include profound knowledge of local
5 tidal regimes, availability of relative sea level rise scenarios and projections for extreme water levels.
6 Moreover, the downdrift effects of sea walls need to be considered, since undefended coasts may be
7 exposed to increased erosion (Linham and Nicholls 2010). In some cases, it may be possible to keep
8 intact and restore natural buffer zones as an alternative to the construction of hard engineering
9 solutions. Otherwise, changes in land-use, building codes, or even coastal realignment can be an
10 option in order to protect and avoid the loss of the buffer function of beaches (Duvat et al. 2016;
11 Cooper and Pile 2014). Examples of Barbados show that combinations of hard and soft coastal
12 protection approaches can be sustainable and reduce the risk of coastal ecosystem degradation while
13 keeping the desired level of protection for coastal users (Mycoo and Chadwick 2012). Nature-based
14 solutions and approaches such as ‘building with nature’ (Slobbe et al. 2013) may allow for more
15 sustainable coastal protection mechanisms and avoid coastal degradation. Examples from the
16 Maldives, several Pacific islands and the North Atlantic show the importance of the involvement of
17 local communities in coastal adaptation projects, considering local skills, capacities, as well as
18 demographic and socio-political dynamics, in order to ensure the proper monitoring and maintenance
19 of coastal adaptation measures (Sovacool 2012; Muir et al. 2014; Young et al. 2014; Buggy and
20 McNamara 2016; Petzold 2016).

21 **4.10 Knowledge gaps and key uncertainties**

22 The co-benefits of improved land management, such as mitigation of climate change, increased
23 climate resilience of agriculture, and impacts on rural areas/societies are well-known in theory but
24 there is a lack of a coherent and systematic global inventory of such integrated efforts. Both successes
25 and failures are important to document systematically.

26 Efforts to reduce climate change through land-demanding mitigation actions aimed at removing
27 atmospheric carbon, such as afforestation, reforestation, bioenergy crops, intensification of land
28 management and plantation forestry can adversely affect land conditions and lead to degradation.
29 However, they may also lead to avoidance, reduction and reversal of degradation. Regionally
30 differentiated, socially and ecologically appropriate sustainable land management strategies need to
31 be identified, implemented, monitored and the results communicated widely to ensure climate
32 effective outcomes.

33 Impacts of new technologies on land degradation and their social and economic ramifications need
34 more research.

35 Improved quantification of the global extent, severity and rates of land degradation by combining
36 remote sensing with a systematic use of ancillary data is a priority. The current attempts need a better
37 scientific underpinning and appropriate funding.

38 Land degradation is defined using multiple criteria but the definition does not provide thresholds or
39 the magnitude of acceptable change. In practice, human interactions with land will result in a variety
40 of changes, some may contribute positively to one criterion while adversely affecting another.
41 Research is required on the magnitude of impacts and the resulting trade-offs. Given the urgent need
42 to remove carbon from the atmosphere and to reduce climate change impacts, it is important to reach
43 agreement on what level of reduction in one criterion (biological productivity, ecological integrity)
44 may be acceptable for a given increase in another criterion (ecological integrity, biological
45 productivity)?

1 Attribution of land degradation to the underlying drivers is a challenge because a complex web of
2 causality rather than simple cause-effect relationships. Also, diverging views on land degradation in
3 relation to other challenges is hampering such efforts.

4 A more systematic treatment of the views and experiences of land users would be useful in land
5 degradation studies.

6 Much research has tried to understand how social and ecological systems are affected by a particular
7 stressor, for example drought, heat, or waterlogging. But less research has tried to understand how
8 such systems are affected by several simultaneous stressors – which of course is more realistic in the
9 context of climate change (Mittler 2006).

10 More realistic modelling of carbon dynamics, including better appreciation of belowground biota,
11 would help us to better quantify the role of soils and soil management for soil carbon sequestration.

12

13 **Frequently Asked Questions**

14 **FAQ 4.1 How do climate change and land degradation interact with land use?**

15 Climate change, land degradation, and land use are linked in a complex web of causality. One
16 important impact of climate change (e.g. flood and drought) on land degradation is that increasing
17 global temperatures intensify the hydrological cycle resulting in more intense rainfall, which is an
18 important driver of soil erosion. This means that sustainable land management (SLM) becomes even
19 more important with climate change. Land-use change in the form of clearing of forest for rangeland
20 and cropland (e.g., for provision of bio-fuels), and cultivation of peat soils, is a major source of
21 greenhouse gas emission from both biomass and soils. Many SLM practices (e.g., agroforestry,
22 shifting perennial crops, restoration, etc.) increase carbon content of soil and vegetation cover and
23 hence provide both local and immediate adaptation benefits combined with global mitigation benefits
24 in the long term, while providing many social and economic co-benefits. Avoiding, reducing and
25 reversing land degradation has a large potential to mitigate climate change and help communities to
26 adapt to climate change.

27

28 **FAQ 4.2 How does climate change affect land-related ecosystem services and 29 biodiversity?**

30 Climate change will affect land-related ecosystem services (e.g. pollination, resilience to extreme
31 climate events, water yield, soil conservation, carbon storage, etc.) and biodiversity, both directly and
32 indirectly. The direct impacts range from subtle reductions or enhancements of specific services, such
33 as biological productivity, resulting from changes in temperature, temperature variability or rainfall,
34 to complete disruption and elimination of services. Disruptions of ecosystem services can occur where
35 climate change causes transitions from one biome to another, e.g., forest to grassland as a result of
36 changes in water balance or natural disturbance regimes. Climate change will result in range shifts
37 and, in some cases, extinction of species. Climate change can also alter the mix of land-related
38 ecosystem services, such as groundwater recharge, purification of water, and flood protection. While
39 the net impacts are specific to ecosystem types, ecosystem services and time, there is an asymmetry of
40 risk such that overall impacts of climate change are expected to reduce ecosystem services. Indirect
41 impacts of climate change on land-related ecosystem services include those that result from changes
42 in human behavior, including potential large-scale human migrations or the implementation of
43 afforestation, reforestation or other changes in land management, which can have positive or negative
44 outcomes on ecosystem services.

1 **Executive summary**

2 **The current food system (production, transport, processing, packaging, storage, retail,**
3 **consumption, loss and waste) feeds the great majority of world population and supports the**
4 **livelihoods of ca. 200 million people.** Since 1961, food supply per capita has increased more than
5 30%, accompanied by greater use of nitrogen fertilisers (increase of about 800%) and water resources
6 for irrigation (increase of more than 100%). However, an estimated 821 million people are currently
7 undernourished, 151 million children under 5 are stunted, 613 million women and girls aged 15 to 49
8 suffer from iron deficiency, and 2 billion adults are overweight or obese. The food system is under
9 pressure from non-climate stressors (e.g., population and income growth, demand for animal-sourced
10 products), and from climate change. These climate and non-climate stresses are impacting the four
11 pillars of food security (availability, access, utilisation, and stability). {5.1.1, 5.1.2}

12 **Observed climate change is already affecting food security through increasing temperatures,**
13 **changing precipitation patterns, and greater frequency of some extreme events (*high***
14 ***confidence*).** Increasing temperatures are affecting agricultural productivity in higher latitudes, raising
15 yields of some crops (maize, cotton, wheat, sugar beets), while yields of others (maize, wheat, barley)
16 are declining in lower-latitude regions. Warming compounded by drying has caused yield declines in
17 parts of Southern Europe. Based on indigenous and local knowledge, climate change is affecting food
18 security in drylands, particularly those in Africa, and high mountain regions of Asia and South
19 America. {5.2.2}

20 **Food security will be increasingly affected by projected future climate change (*high confidence*).**
21 Across SSPs 1, 2, and 3, global crop and economic models projected a 1-29% cereal price increase in
22 2050 due to climate change (RCP 6.0), which would impact consumers globally through higher food
23 prices; regional effects will vary (*high confidence*). Low-income consumers are particularly at risk,
24 with models projecting increases of 1-183 million additional people at risk of hunger across the SSPs
25 compared to a no climate change scenario (*high confidence*). While increased CO₂ is projected to be
26 beneficial for crop productivity at lower temperature increases, it is projected to lower nutritional
27 quality (*high confidence*) (e.g., wheat grown at 546-586 ppm CO₂ has 5.9–12.7% less protein, 3.7–
28 6.5% less zinc, and 5.2–7.5% less iron). Distributions of pests and diseases will change, affecting
29 production negatively in many regions (*high confidence*). Given increasing extreme events and
30 interconnectedness, risks of food system disruptions are growing (*high confidence*). {5.2.3, 5.2.4}

31 **Vulnerability of pastoral systems to climate change is very high (*high confidence*).** Pastoralism is
32 practiced in more than 75% of countries by between 200 and 500 million people, including nomadic
33 communities, transhumant herders, and agro-pastoralists. Impacts in pastoral systems include lower
34 pasture and animal productivity, damaged reproductive function, and biodiversity loss. Pastoral
35 system vulnerability is exacerbated by non-climate factors (land tenure, sedentarisation, changes in
36 traditional institutions, invasive species, lack of markets, and conflicts). {5.2.2}

37 **Fruit and vegetable production, a key component of healthy diets, is also vulnerable to climate**
38 **change (*medium evidence, high agreement*).** Declines in yields and crop suitability are projected
39 under higher temperatures, especially in tropical and semi-tropical regions. Heat stress reduces fruit
40 set and speeds up development of annual vegetables, resulting in yield losses, impaired product
41 quality, and increasing food loss and waste. Longer growing seasons enable a greater number of
42 plantings to be cultivated and can contribute to greater annual yields. However, some fruits and
43 vegetables need a period of cold accumulation to produce a viable harvest, and warmer winters may
44 constitute a risk. {5.2.2}

45 **Food security and climate change have strong gender and equity dimensions (*high confidence*).**
46 Worldwide, women play a key role in food security, although regional differences exist. Climate
47 change impacts vary among diverse social groups depending on age, ethnicity, gender, wealth, and

1 class. Climate extremes have immediate and long-term impacts on livelihoods of poor and vulnerable
2 communities, contributing to greater risks of food insecurity that can be a stress multiplier for internal
3 and external migration (*medium confidence*). {5.2.6} Empowering women and rights-based
4 approaches to decision-making can create synergies among household food security, adaptation, and
5 mitigation. {5.6.4}

6 **Many practices can be optimised and scaled up to advance adaptation throughout the food**
7 **system (*high confidence*)**. Supply-side options include increased soil organic matter and erosion
8 control, improved cropland, livestock, and grazing land management, and genetic improvements for
9 tolerance to heat and drought. Diversification in the food system (e.g., implementation of integrated
10 production systems, broad-based genetic resources, and heterogeneous diets) is a key strategy to
11 reduce risks (*medium confidence*). Demand-side adaptation, such as adoption of healthy and
12 sustainable diets, in conjunction with reduction in food loss and waste, can contribute to adaptation
13 through reduction in additional land area needed for food production and associated food system
14 vulnerabilities. Indigenous and local knowledge can contribute to enhancing food system resilience
15 (*high confidence*). {5.3, 5.6.3 Cross-Chapter Box 6}.

16 **Ca. 25-30% of total GHG emissions are attributable to the food system. These are from**
17 **agriculture and land use, storage, transport, packaging, processing, retail, and consumption**
18 **(*medium confidence*)**. This estimate includes emissions of 10–12% from crop and livestock activities
19 within the farm gate and 8-10% from land use and land use change including deforestation and
20 peatland degradation (*high confidence*); 5–10% is from supply chain activities (*medium confidence*).
21 This estimate includes GHG emissions from food loss and waste. Within the food system, during the
22 period 2007-2016, the major sources of emissions from the supply side were agricultural production,
23 with crop and livestock activities within the farm gate generating respectively 142 ± 43 Tg CH₄ yr⁻¹
24 (*high confidence*) and 8.3 ± 2.3 Tg N₂O yr⁻¹ (*high confidence*), and CO₂ emissions linked to relevant
25 land use change dynamics such as deforestation and peatland degradation, generating 4.8 ± 2.4 Gt
26 CO₂ yr⁻¹. Using 100-year GWP values (no climate feedback) from the IPCC AR5, this implies that
27 total GHG emissions from agriculture were 6.2 ± 1.9 Gt CO₂eq yr⁻¹, increasing to 11.0 ± 3.1 Gt CO₂eq
28 yr⁻¹ including relevant land use. Without intervention, these are likely to increase by about 30%–40%
29 by 2050, due to increasing demand based on population and income growth and dietary change (*high*
30 *confidence*). {5.4}

31 **Supply-side practices can contribute to climate change mitigation by reducing crop and**
32 **livestock emissions, sequestering carbon in soils and biomass, and by decreasing emissions**
33 **intensity within sustainable production systems (*high confidence*)**. Total mitigation potential of
34 crop and livestock activities is estimated as 1.5–4.0 GtCO₂-eq yr⁻¹ by 2030 at prices ranging from 20-
35 100 USD/tCO₂eq (*high confidence*). Options with large potential for GHG mitigation in cropping
36 systems include soil carbon sequestration (at decreasing rates over time), reductions in N₂O emissions
37 from fertilisers, reductions in CH₄ emissions from paddy rice, and bridging of yield gaps. Options
38 with large potential for mitigation in livestock systems include better grazing land management, with
39 increased net primary production and soil carbon stocks, improved manure management, and higher-
40 quality feed. Reductions in GHG emissions intensity (emissions per unit product) from livestock can
41 support reductions in absolute emissions, provided appropriate governance to limit total production is
42 implemented at the same time (*medium confidence*). {5.5.1}

43 **Consumption of healthy and sustainable diets presents major opportunities for reducing GHG**
44 **emissions from food systems and improving health outcomes (*high confidence*)**. Examples of
45 healthy and sustainable diets are high in coarse grains, pulses, fruits and vegetables, and nuts and
46 seeds; low in energy-intensive animal-sourced and discretionary foods (such as sugary beverages);
47 and with a carbohydrate threshold. Total mitigation potential of dietary changes is estimated as 1.8-
48 3.4 GtCO₂eq yr⁻¹ by 2050 at prices ranging from 20-100 USD/tCO₂ (*medium confidence*). This

1 estimate includes reductions in emissions from livestock and soil carbon sequestration on spared land,
2 but co-benefits with health are not taken into account. Mitigation potential of dietary change may be
3 higher, but achievement of this potential at broad scales depends on consumer choices and dietary
4 preferences that are guided by social, cultural, environmental, and traditional factors, as well as
5 income growth. Meat analogues such as imitation meat (from plant products), cultured meat, and
6 insects may help in the transition to more healthy and sustainable diets, although their carbon
7 footprints and acceptability are uncertain. {5.5.2, 5.6.5}

8 **Reduction of food loss and waste could lower GHG emissions and improve food security**
9 **(medium confidence)**. Combined food loss and waste amount to a third of global food production
10 **(high confidence)**. During 2010-2016, global food loss and waste equalled 8–10% of total GHG
11 emissions from food systems **(medium confidence)**; and cost about USD 1 trillion per year (2012
12 prices) **(low confidence)**. Technical options for reduction of food loss and waste include improved
13 harvesting techniques, on-farm storage, infrastructure, and packaging. Causes of food loss (e.g., lack
14 of refrigeration) and waste (e.g., behaviour) differ substantially in developed and developing
15 countries, as well as across regions **(robust evidence, medium agreement)**. {5.5.2}

16 **Agriculture and the food system are key to global climate change responses. Combining supply-**
17 **side actions such as efficient production, transport, and processing with demand-side**
18 **interventions such as modification of food choices, and reduction of food loss and waste, reduces**
19 **GHG emissions and enhances food system resilience (high confidence)**. Such combined measures
20 can enable the implementation of large-scale land-based adaptation and mitigation strategies without
21 threatening food security from increased competition for land for food production and higher food
22 prices. Without combined food system measures in farm management, supply chains, and demand,
23 adverse effects would include increased number of malnourished people and impacts on smallholder
24 farmers **(medium evidence, high agreement)**. Just transitions are needed to address these effects. {5.5,
25 5.6, 5.7}

26 **For adaptation and mitigation throughout the food system, enabling conditions need to be**
27 **created through policies, markets, institutions, and governance (high confidence)**. For adaptation,
28 resilience to increasing extreme events can be accomplished through risk sharing and transfer
29 mechanisms such as insurance markets and index-based weather insurance **(high confidence)**. Public
30 health policies to improve nutrition – such as school procurement, health insurance incentives, and
31 awareness-raising campaigns – can potentially change demand, reduce health-care costs, and
32 contribute to lower GHG emissions **(limited evidence, high agreement)**. Without inclusion of
33 comprehensive food system responses in broader climate change policies, the mitigation and
34 adaptation potentials assessed in this chapter will not be realised and food security will be jeopardised
35 **(high confidence)**. {5.7}

38
39
40
41

1 **5.1 Framing and context**

2 The current food system (production, transport, processing, packaging, storage, retail, consumption,
3 loss and waste) feeds the great majority of world population and supports the livelihoods of ca. 200
4 million people. Agriculture as an economic activity generates between 1% and 60% of national GDP
5 in many countries, with a world average of about 4% in 2017 (World Bank 2019). Since 1961, food
6 supply per capita has increased more than 30%, accompanied by greater use of nitrogen fertiliser
7 (increase of about 800%) and water resources for irrigation (increase of more than 100%).

8 The rapid growth in agricultural productivity since the 1960s has underpinned the development of the
9 current global food system that is both a major driver of climate change, and increasingly vulnerable
10 to it (from production, transport, and market activities). Given the current food system, the FAO
11 estimates that there is a need to produce about 50% more food by 2050 in order to feed the increasing
12 world population (FAO 2018a). This would engender significant increases in GHG emissions and
13 other environmental impacts, including loss of biodiversity. FAO (2018a) projects that by 2050
14 cropland area will increase 90-325 Mha, between 6-21% more than the 1,567 Mha cropland area of
15 2010, depending on climate change scenario and development pathway (the lowest increase arises
16 from reduced food loss and waste and adoption of more sustainable diets).

17 Climate change has direct impacts on food systems, food security, and, through the need to mitigate,
18 potentially increases the competition for resources needed for agriculture. Responding to climate
19 change through deployment of land-based technologies for negative emissions based on biomass
20 production would increasingly put pressure on food production and food security through potential
21 competition for land.

22 Using a food system approach, this chapter addresses how climate change affects food security,
23 including nutrition, the options for the food system to adapt and mitigate, synergies and trade-offs
24 among these options, and enabling conditions for their adoption. The chapter assesses the role of
25 incremental and transformational adaptation, and the potential for combinations of supply-side
26 measures such as sustainable intensification (increasing productivity per hectare) and demand-side
27 measures (e.g., dietary change and waste reduction) to contribute to climate change mitigation.

28

29 **5.1.1 Food security and insecurity, the food system, and climate change**

30 The *food system* encompasses all the activities and actors in the production, transport, manufacturing,
31 retailing, consumption, and waste of food, and their impacts on nutrition, health and well-being, and
32 the environment (Figure 5.1).

1
2 **Figure 5.1 Interlinkages between the climate system, food system, ecosystem (land, water and oceans),**
3 **and socio-economic system. These systems operate at multiple scales, both global and regional. Food**
4 **security is an outcome of the food system leading to human well-being, which is also indirectly linked with**
5 **climate and ecosystems through the socio-economic system. Response options for sustainable (S)**
6 **practices, mainly in terms of climate change mitigation (M) and adaptation (A) are represented by grey**
7 **arrows. Adaptation measures can help to reduce negative impacts of climate change on the food system**
8 **and ecosystems. Mitigation measures can reduce greenhouse gas emissions coming from the food system**
9 **and ecosystems.**

10 5.1.1.1 Food security as an outcome of the food system

11 The activities and the actors in the food system leads to outcomes such as food security and generate
12 impacts on the environment. As part of the environmental impacts, food systems are a considerable
13 contributor to greenhouse gas emissions, and thus climate change (Section 5.4). In turn climate
14 change has complex interactions with food systems, leading to food insecurity through impacts on
15 food availability, access, utilisation and stability (Table 5.1; Section 5.2).

16 We take a *food systems lens* in the Special Report on Climate Change and Land (SRCLL) to recognise
17 that demand for and supply of food are interlinked and need to be jointly assessed in order to identify
18 the challenges of mitigation and adaptation to climate change. Outcomes cannot be disaggregated
19 solely to, for example, agricultural production, because the demand for food shapes what is grown,
20 where it is grown, and how much is grown. Thus, greenhouse gas emissions from agriculture result, in
21 large part, from ‘pull’ from the demand side. Mitigation and adaptation involve modifying production,
22 supply chain, and demand practices (through for example dietary choices, market incentives, and
23 trade relationships), so as to evolve a more sustainable and healthy food system.

24 According to FAO (2001a), *food security* is a situation that exists when all people, at all times, have
25 physical, social, and economic access to sufficient, safe, and nutritious food that meets their dietary
26 needs and food preferences for an active and healthy life. “All people at all times” implies the need
27 for equitable and stable food distribution, but it is increasingly recognised that it also covers the need
28 for inter-generational equity, and therefore “sustainability” in food production. “Safe and nutritious
29 food ...for a healthy life” implies that food insecurity can occur if the diet is not nutritious, including
30 when there is consumption of an excess of calories, or if food is not safe, meaning free from harmful
31 substances.

1 A prime impact of food insecurity is *malnourishment* (literally “bad nourishment”) leading to
 2 *malnutrition*, which refers to deficiencies, excesses, or imbalances in a person’s intake of energy
 3 and/or nutrients. As defined by FAO et al. (2018), undernourishment occurs when an individual’s
 4 habitual food consumption is insufficient to provide the amount of dietary energy required to maintain
 5 a normal, active, healthy life. In addition to undernourishment in the sense of insufficient calories
 6 (“hunger”), undernourishment occurs in terms of nutritional deficiencies in vitamins (e.g., Vitamin A)
 7 and minerals (e.g., iron, zinc, iodine), so-called “hidden hunger”. Hidden hunger tends to be present in
 8 countries with high levels of undernourishment (Muthayya et al. 2013), but micronutrient deficiency
 9 can occur in societies with low prevalence of undernourishment. For example, in many parts of the
 10 world teenage girls suffer from iron deficiency (Whitfield et al. 2015) and calcium deficiency is
 11 common in Western-style diets (Aslam and Varani 2016). Food security is related to nutrition, and
 12 conversely food insecurity is related to malnutrition. Not all malnourishment arises from food
 13 insecurity, as households may have access to healthy diets but choose to eat unhealthily, or it may
 14 arise from illness. However, in many parts of the world, poverty is linked to poor diets (FAO et al.
 15 2018). This may be through lack of resources to produce or access food in general, or healthy food, in
 16 particular, as healthier diets are more expensive than diets rich in calories but poor in nutrition (*high*
 17 *confidence*) (see meta-analysis by Darmon and Drewnowski 2015). The relationship between poverty
 18 and poor diets may also be linked to unhealthy “food environments,” with retail outlets in a locality
 19 only providing access to foods of low-nutritional quality (Gamba et al. 2015) – such areas are
 20 sometimes termed “food deserts” (Battersby 2012).

21 Whilst conceptually the definition of food security is clear, it is not straightforward to measure in a
 22 simple way that encompasses all its aspects. Although there are a range of methods to assess food
 23 insecurity, they all have some shortcomings. For example, the UN FAO has developed the Food
 24 Insecurity Experience Scale (FIES), a survey-based tool to measure the severity of overall
 25 households’ inability to access food. While it provides reliable estimates of the prevalence of food
 26 insecurity in a population, it does not reveal whether actual diets are adequate or not with respect to
 27 all aspects of nutrition (see Section 5.1.2.1).

28

29 **5.1.1.2 Effects of climate change on food security**

30 Climate change is projected to negatively impact the four pillars of food security – availability,
 31 access, utilisation and stability – and their interactions (FAO et al. 2018) (*high confidence*). This
 32 chapter assesses recent work since AR5 that has strengthened understanding of how climate change
 33 affects each of these pillars across the full range of food system activities (Table 5.1, Section 5.2).

34 While most studies continue to focus on availability via impacts on food production, more studies are
 35 addressing related issues of access (e.g., impacts on food prices), utilisation (e.g., impacts on
 36 nutritional quality), and stability (e.g., impacts of increasing extreme events) as they are affected by a
 37 changing climate (Bailey et al. 2015). Low-income producers and consumers are likely to be most
 38 affected because of a lack of resources to invest in adaptation and diversification measures (UNCCD
 39 2017; Bailey et al. 2015).

40

41 **Table 5.1 Relationships between food security, the food system, and climate change and guide to chapter.**

Food security pillar	Examples of observed and projected climate change impacts	Sections	Examples of adaptation and mitigation	Section
Availability <i>Production</i>	Reduced yields in crop and livestock systems	5.2.2.1, 5.2.2.2	Development of adaptation practices	5.3

<i>of food and its readiness for use through storage, processing, distribution, sale and/or exchange</i>	Reduced yields from lack of pollinators; pests and diseases	5.2.2.3, 5.2.2.4	Adoption of new technologies, new and neglected varieties	5.3.2.3, 5.3.3.1,
	Reduced food quality affecting availability (e.g., food spoilage and loss from mycotoxins)	5.2.4.1, 5.5.2.5	Enhanced resilience by integrated practices, better food storage	5.3.2.3, 5.3.3.4, 5.6.4
	Disruptions to food storage and transport networks from change in climate, including extremes	5.2.5.1, 5.3.3.4, 5.8.1, Box 5.5	Reduction of demand on by reducing waste, modifying diets	5.3.4, 5.5.2, 5.7
			Closing of crop yield and livestock productivity gaps	5.6.4.4, 5.7
			Risk management, including marketing mechanisms, financial insurance	5.3.2, 5.7
<i>Access: Ability to obtain food, including effects of price</i>	Yield reductions, changes in farmer livelihoods, limitations on ability to purchase food	5.2.2.1, 5.2.2.2	Integrated agricultural practices to build resilient livelihoods	5.6.4
	Price rise and spike effects on low-income consumers, in particular women and children, due to lack of resources to purchase food	5.1.3, 5.2.3.1, 5.2.5.1, Box 5.1	Increased supply chain efficiency (e.g., reducing loss and waste)	5.3.3, 5.3.4
	Effects of increased extreme events on food supplies, disruption of agricultural trade and transportation infrastructure	5.8.1	More climate-resilient food systems, shortened supply chains, dietary change, market change	5.7
<i>Utilisation Achievement of food potential through nutrition, cooking, health</i>	Impacts on food safety due to increased prevalence of microorganisms and toxins	5.2.4.1	Improved storage and cold chains	5.3.3, 5.3.4
	Decline in nutritional quality resulting from increasing atmospheric CO ₂	5.2.4.2	Adaptive crop and livestock varieties, healthy diets, better sanitation	5.3.4, 5.5.2, 5.7
	Increased exposure to diarrheal and other infectious diseases due to increased risk of flooding	5.2.4.1		
<i>Stability Continuous availability and access to food without disruption</i>	Greater instability of supply due to increased frequency and severity of extreme events; food price rises and spikes; instability of agricultural incomes	5.2.5, 5.8.1	Resilience via integrated systems and practices, diversified local agriculture, infrastructure investments, modifying markets and trade, reducing food loss and waste	5.6.4, 5.7, 5.8.1
	Widespread crop failure contributing to migration and conflict	5.8.2	Crop insurance for farmers to cope with extreme events	5.3.2.2, 5.7
			Capacity building to develop resilient systems	5.3.6, 5.7.4

Combined <i>Systemic impacts from interactions of all four pillars</i>	Increasing undernourishment as food system is impacted by climate change	5.1	Increased food system productivity and efficiency (e.g., supply side mitigation, reducing waste, dietary change)	5.5.1, 5.7
	Increasing obesity and ill health through narrow focus on adapting limited number commodity crops	5.1	Increased production of healthy food and reduced consumption of energy-intensive products	5.5.2, 5.7
	Increasing environmental degradation and GHG emissions	Cross-Chapter Box 6	Development of climate smart food systems by reducing GHG emissions, building resilience, adapting to climate change	5.3.3, 5.7
	Increasing food insecurity due to competition for land and natural resources (e.g., for land-based mitigation)	5.6.1	Governance and institutional responses (including food aid) that take into consideration gender and equity	5.2.5, 5.7

1

2 **5.1.2 Status of the food system, food insecurity, and malnourishment**

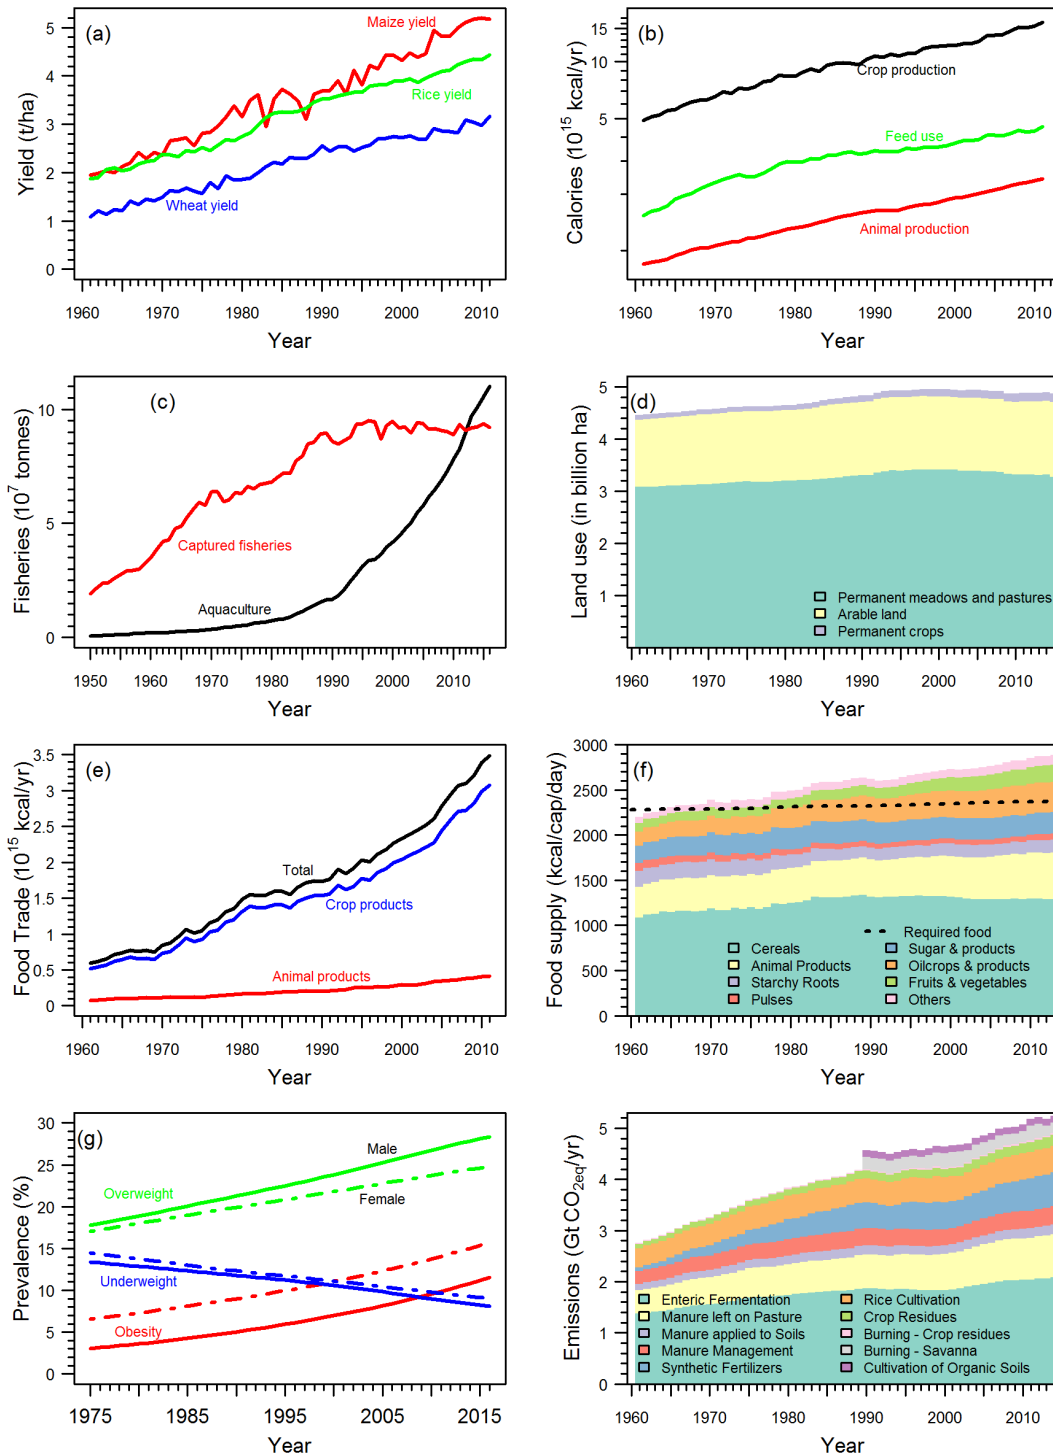

3 **5.1.2.1 Trends in the global food system**

4 Food is predominantly produced on land, with, on average, 83% of the 697 kg of food consumed per
 5 person per year, 93% of the 2884 kcal per day, and 80% of the 81 g of protein eaten per day coming
 6 from terrestrial production in 2013 (FAOSTAT 2018)¹. With increases in crop yields and production
 7 (Figure 5.2), the absolute supply of food has been increasing over the last five decades. Growth in
 8 production of animal-sourced food is driving crop utilisation for livestock feed (FAOSTAT 2018;
 9 Pradhan et al. 2013a). Global trade of crop and animal-sourced food has increased by around 5 times
 10 between 1961 and 2013 (FAOSTAT 2018). During this period, global food availability has increased
 11 from 2200 kcal/cap/day to 2884 kcal/cap/day, making a transition from a food deficit to a food surplus
 12 situation (FAOSTAT 2018; Hiç et al. 2016).

13 The availability of cereals, animal products, oil crops, and fruits and vegetables has mainly grown
 14 (FAOSTAT 2018), reflecting shifts towards more affluent diets. This, in general, has resulted in a
 15 decrease in prevalence of underweight and an increase in prevalence of overweight and obesity
 16 among adults (Abarca-Gómez et al. 2017). During the period 1961-2016, anthropogenic greenhouse
 17 gas emissions associated with agricultural production has grown from 3.1 Gt CO₂-eq yr⁻¹ to 5.8 Gt
 18 CO₂-eq yr⁻¹ (Section 5.4.2, Chapter 2). The increase in emissions is mainly from the livestock sector
 19 (from enteric fermentation and manure left on pasture), use of synthetic fertiliser, and rice cultivation
 20 (FAOSTAT 2018).

21

¹ FOOTNOTE: Does not take into account terrestrial production of feed.

Figure 5.2 Global trends in (a) yields of maize, rice, and wheat (FAOSTAT 2018) – the top three crops grown in the world; (b) production of crop and animal calories and use of crop calories as livestock feed (FAOSTAT 2018); (c) production from marine and aquaculture fisheries (FishStat 2019); (d) land used for agriculture (FAOSTAT 2018); (e) food trade in calories (FAOSTAT 2018); (f) food supply and required food (i.e., based on human energy requirements for medium physical activities) from 1961–2012 (FAOSTAT 2018; Hiç et al. 2016); (g) prevalence of overweight, obesity and underweight from 1975–2015 (Abarca-Gómez et al. 2017); and (h) GHG emissions for the agriculture sector, excluding land use change (FAOSTAT 2018). For figures (b) and (e), data provided in mass units were converted into calories using nutritive factors (FAO 2001b). Data on emissions due to burning of savanna and cultivation of organic soils is provided only after 1990 (FAOSTAT 2018).

5.1.2.2 Food insecurity status and trends

In addressing food security the dual aspects of malnutrition – under-nutrition and micro-nutrient deficiency, as well as over-consumption, overweight, and obesity – need to be considered (Figure 5.2g and Table 5.2). The UN agencies' *State of Food Security and Nutrition 2018* report (FAO et al. 2018) and the *Global Nutrition Report 2017* (Development Initiatives 2017) summarise the global data. The *State of Food Security* report's estimate for undernourished people on a global basis is 821 million, up from 815 million the previous year and 784 million the year before that. Previous to 2014/2015 the prevalence of hunger had been declining over the last three decades. The proportion of young children (under 5) who are stunted (low height-for-age), has been gradually declining, and was 22% in 2017 compared to 31% in 2012 (150.8 million, down from 165.2 million in 2012). In 2017, 50.5 million children (7.5%) under 5 were wasted (low weight for height). Since 2014, undernutrition has worsened, particularly in parts of sub-Saharan Africa, South-Eastern Asia and Western Asia, and recently Latin America. Deteriorations have been observed most notably in situations of conflict and conflict combined with droughts or floods (FAO et al. 2018).

Regarding micronutrient deficiencies known as 'hidden hunger', reporting suggests a prevalence of one in three people globally (FAO 2013a; von Grebmer et al. 2014; Tulchinsky 2010) (Table 5.2). In the last decades, hidden hunger (measured through proxies targeting iron, vitamin A, and zinc deficiencies) worsened in Africa, while it mainly improved in Asia and Pacific (Ruel-Bergeron et al. 2015). In 2016, 613 million women and girls aged 15 to 49 suffered from iron deficiency (Development Initiatives 2018); in 2013, 28.5% of the global population suffered from iodine deficiency; and in 2005, 33.3% of children under five and 15.3% of pregnant women suffered from vitamin A deficiency, and 17.3% of the global population suffered from zinc deficiency (HLPE 2017).

Table 5.2 Global prevalence of various forms of malnutrition

	HLPE 2017 (UN)	SOFI 2017 (FAO)	GNR 2017	SOFI 2018 (FAO)	GNR2018
Overweight but not obese ^a	1.3 billion		1.93 billion		1.34 billion (38,9%) ^c
Overweight under five	41 million	41 million	41 million	38 million	38 million
Obesity ^b	600 million	600 million (13%)	641 million	672 million	678 million (13,1%) ^c

9

10 Globally, as the availability of inexpensive calories from commodity crops increases, so does per
11 capita consumption of calorie-dense foods (Ng et al. 2014; NCD-RisC 2016a; Abarca-Gómez et al.
12 2017; Doak and Popkin 2017). As a result, in every region of the world, the prevalence of obesity
13 (body mass index >30 kg/m²) and overweight (body mass index range between normality [18.5-24.9]
14 and obesity) is increasing. There are now more obese adults in the world than underweight adults (Ng
15 et al. 2014; NCD-RisC 2016a; Abarca-Gómez et al. 2017; Doak and Popkin 2017). In 2016, around
16 two billion adults were overweight, including 678 million suffering from obesity (NCD-RisC 2016a;
17 Abarca-Gómez et al. 2017). The prevalence of overweight and obesity has been observed in all age
18 groups.

19 Around 41 million children under five years and 340 million children and adolescents aged 5–19
20 years were suffering from overweight or obesity in 2016 (NCD-RisC 2016a; FAO et al. 2017; WHO
21 2015). In many high-income countries, the rising trends in children and adolescents suffering from
22 overweight and obesity have stagnated at high levels; however, these have accelerated in parts of Asia
23 and have very slightly reduced in European and Central Asian lower and middle-income countries
24 (Abarca-Gómez et al. 2017; Doak and Popkin 2017; Christmann et al. 2009).

25 There are associations between obesity and non-communicable diseases such as diabetes, dementia,
26 inflammatory diseases (Saltiel and Olefsky 2017), cardio-vascular disease (Ortega et al. 2016) and
27 some cancers, e.g., of the colon, kidney, and liver (Moley and Colditz 2016). There is a growing
28 recognition of the rapid rise in overweight and obesity on a global basis and its associated health
29 burden created through the non-communicable diseases (NCD-RisC 2016a; HLPE 2017).

30 Analyses reported in FAO et al. (2018) highlight the link between food insecurity, as measured by the
31 FIES scale, and malnourishment (*medium agreement, robust evidence*). This varies by
32 malnourishment measure as well as country (FAO et al. 2018). For example, there is *limited evidence*
33 (*low agreement* but multiple studies) that food insecurity and childhood wasting (i.e., or low weight
34 for height) are closely related, but it is very likely (*high agreement, robust evidence*) that childhood
35 stunting and food insecurity are related (FAO et al. 2018). With respect to adult obesity there is *robust*
36 *evidence, with medium agreement*, that food insecurity, arising from poverty reducing access to
37 nutritious diets, is related to the prevalence of obesity, especially in high-income countries and adult
38 females. An additional meta-analysis (for studies in Europe and North America) also finds a negative
39 relationship between income and obesity, with some support for an effect of obesity causing low
40 income (as well as vice versa) (Kim and von dem Knesebeck 2018).

41 As discussed in Section 5.1.1.1, different methods of assessing food insecurity can provide differential
42 pictures. Of particular note is the spatial distribution of food insecurity, especially in higher-income
43 countries. FAO et al. (2018) reports FIES estimates of severe food insecurity in Africa, Asia and Latin
44 America of 29.8%, 6.9% and 9.8% of the population, respectively, but of 1.4% of the population (i.e.,
45 about 20 million in total; pro rata <5 million for US, <1 million for UK) in Europe and North
46 America. However, in the United States, USDA estimates 40 million people were exposed to varying
47 degrees of food insecurity, from mild to severe (overall prevalence about 12%) (Coleman-Jensen et al.
48 2018). In the UK, estimates from 2017 and 2018 indicate about 4 million adults are moderately to

1 severely food insecure (prevalence 8%) (End Hunger UK 2018; Bates et al. 2017). The UK food bank
2 charity, the Trussell Trust, over a year in 2017/18, distributed 1,332,952 three-day emergency food
3 parcels to people referred to the charity as being in food crisis. Furthermore, a 2003 study in the UK
4 (Schenker 2003) estimated that 40% of adults, and 15% of children, admitted to hospitals were
5 malnourished, and that 70% of undernourishment in the UK was unreported.

6 In total, more than half the world's population are underweight or overweight (NCD-RisC 2017a), so
7 their diets do not provide the conditions for 'an active and healthy life'. This will be more
8 compromised under the impacts of climate change by changing the availability, access, utilisation,
9 and stability of diets of sufficient nutritional quality as shown in Table 5.2 and discussed in detail
10 below (see Section 5.2).

12 **5.1.3 Climate change, gender, and equity**

13 Throughout, the chapter considers many dimensions of gender and equity in regard to climate change
14 and the food system (Box 5.1). Climate change impacts differ among diverse social groups depending
15 on factors such as age, ethnicity, ability/disability, sexual orientation, gender, wealth, and class (*high*
16 *confidence*) (Vincent and Cull 2014; Kaijser and Kronsell 2014). Poverty, along with socio-economic
17 and political marginalisation, cumulatively put women, children and the elderly in a disadvantaged
18 position in coping with the adverse impacts of the changing climate (UNDP 2013; Skoufias et al.
19 2011). The contextual vulnerability of women is higher due to their differentiated relative power,
20 roles, and responsibilities at the household and community levels (Bryan and Behrman 2013; Nelson
21 et al. 2002). They often have a higher reliance on subsistence agriculture, which will be severely
22 impacted by climate change (Aipira et al. 2017).

23 Through impacts on food prices (section 5.2.3.1) poor people's food security is particularly
24 threatened. Decreased yields can impact nutrient intake of the poor by decreasing supplies of highly
25 nutritious crops and by promoting adaptive behaviours that may substitute crops that are resilient but
26 less nutritious (Thompson et al. 2012; Lobell and Burke 2010). In Guatemala, food prices and poverty
27 have been correlated with lower micronutrient intakes (Iannotti et al. 2012). In the developed world,
28 poverty is more typically associated with calorically-dense but nutrient-poor diets, obesity,
29 overweight, and other related diseases (Darmon and Drewnowski 2015).

30 Rural areas are especially affected by climate change (Dasgupta et al. 2014), through impacts on
31 agriculture-related livelihoods and rural income (Mendelsohn et al. 2007) and through impacts on
32 employment. Jessoe et al. (2018) using a 28-year panel on individual employment in rural Mexico,
33 found that years with a high occurrence of heat lead to a reduction in local employment by up to 1.4%
34 with a medium emissions scenario, particularly for wage work and non-farm labour, with impacts on
35 food access. Without employment opportunities in areas where extreme poverty is prevalent, people
36 may be forced to migrate, exacerbating potential for ensuing conflicts (FAO 2018a).

37 Finally, climate change can affect human health in other ways that interact with food utilisation. In
38 many parts of the world where agriculture relies still on manual labour, projections are that heat stress
39 will reduce the hours people can work, and increase their risk (Dunne et al. 2013). For example,
40 Takakura et al (2017) estimates that under RCP8.5, the global economic loss from people working
41 shorter hours to mitigate heat loss may be 2.4–4% of GDP. Furthermore, as discussed by (Watts et al.
42 2018); people's nutritional status interacts with other stressors and affects their susceptibility to ill
43 health (the "utilisation pillar" of food security): so food-insecure people are more likely to be
44 adversely affected by extreme heat, for example.

45 In the case of food price hikes, those more vulnerable are more affected (Uraguchi 2010), especially
46 in urban areas (Ruel et al. 2010), where livelihood impacts are particularly severe for the individuals

1 and groups that have scarce resources or are socially isolated (Revi et al. 2014; Gasper et al. 2011)
2 (*high confidence*). These people often lack power and access to resources, adequate urban services
3 and functioning infrastructure. As climate events become more frequent and intense, this can increase
4 the scale and depth of urban poverty (Rosenzweig et al. 2018b). Urban floods and droughts may result
5 in water contamination increasing the incidence of diarrhoeal illness in poor children (Bartlett 2008).
6 In the near destruction of New Orleans by Hurricane Katrina, about 40,000 jobs were lost (Rosemberg
7 2010).

9 **Box 5.1 Gender, food security, and climate change**

10 Differentiated impacts, vulnerability, risk perception, behaviours and coping strategies for climate
11 change related to food security derive from cultural (gendered) norms, that is, the behaviours, tasks,
12 and responsibilities a society defines as “male” or “female”, and the differential gendered access to
13 resources (Paris and Rola-Rubzen 2018; Aberman and Tirado 2014; Lebel et al. 2014; Bee 2016). In
14 many rural areas women often grow most of the crops for domestic consumption and are primarily
15 responsible for storing, processing, and preparing food; handling livestock; gathering food, fodder and
16 fuelwood; managing domestic water supply; and providing most of the labour for post-harvest
17 activities (FAO 2011a). They are mostly impacted through increased hardship, implications for
18 household roles, and subsequent organisational responsibilities (Boetto and McKinnon 2013; Jost et
19 al. 2016). Water scarcity can particularly affect women because they need to spend more time and
20 energy to collect water, where they may be more exposed to physical and sexual violence (Sommer et
21 al. 2015; Aipira et al. 2017). They may be forced to use unsafe water in the household increasing risk
22 of water-borne diseases (Parikh 2009). Climate change also has differentiated gendered impacts on
23 livestock-holders food security (McKune et al. 2015; Ongoro and Ogara 2012; Fratkin et al. 2004)
24 (See Supplementary Material Table SM5.1).

25 **Gender dimensions of the four pillars**

26 Worldwide, women play a key role in food security (World Bank 2015) and the four pillars of food
27 security have strong gender dimensions (Thompson 2018). In terms of food availability, women tend
28 to have less access to productive resources, including land, and thus less capacity to produce food
29 (Cross-chapter box 11: Gender in Chapter 7).

30 In terms of food access, gendered norms in how food is divided at mealtimes may lead to smaller food
31 portions for women and girls. Women’s intra-household inequity limits their ability to purchase food;
32 limitations also include lack of women’s mobility impacting trips to the market and lack of decision-
33 making within the household (Ongoro and Ogara 2012; Mason et al. 2017; Riley and Dodson 2014).

34 In terms of food utilisation, men, women, children and the elderly have different nutritional needs
35 (e.g., during pregnancy or breast-feeding).

36 In terms of stability, women are more likely to be disproportionately affected by price spikes
37 (Vellakkal et al. 2015; Arndt et al. 2016; Hossain and Green 2011; Darnton-Hill and Cogill 2010;
38 Cohen and Garrett 2010; Kumar and Quisumbing 2013) because when food is scarce women reduce
39 food consumption relative to other family members, although these norms vary according to age,
40 ethnicity, culture, region, and social position, as well as by location in rural or urban areas (Arora-
41 Jonsson 2011; Goh 2012; Niehof 2016; Ongoro and Ogara 2012).

42 **Integrating gender into adaptation**

43 Women have their own capabilities to adapt to climate change. In the Pacific Islands, women hold
44 critical knowledge on where or how to find clean water; which crops to grow in a flood or a drought
45 season; how to preserve and store food and seeds ahead of approaching storms, floods or droughts;

1 and how to carry their families through the recovery months. They also play a pivotal role in
2 managing household finances and investing their savings in education, health, livelihoods, and other
3 activities that assist their families to adapt and respond to climate effects (Aipira et al. 2017).
4 Decreasing women’s capacity to adapt to the impacts of climate change also decreases that of the
5 household (Bryan and Behrman 2013).

6 However, gender norms and power inequalities also shape the ability of men, women, boys, girls and
7 the elderly to adapt to climate risks (Rossi and Lambrou 2008). For example, women pastoralists in
8 the Samburu district of Kenya cannot make decisions affecting their lives, limiting their adaptive
9 capacity (Ongoro and Ogara 2012).

10 Participation in decision-making and politics, division of labour, resource access and control, and
11 knowledge and skills (Nelson and Stathers 2009) are some of the barriers to adaptation. Women’s
12 adaptive capacity is also diminished because their work often goes unrecognised (Rao 2005; Nelson
13 and Stathers 2009). Many of women’s activities are not defined as “economically active employment”
14 in national accounts (FAO 2011a). This non-economic status of women’s activities implies that they
15 are not included in wider discussions of priorities or interventions for climate change. Their
16 perspectives and needs are not met; and thus, interventions, information, technologies, and tools
17 promoted are potentially not relevant, and even can increase discrimination (Alston 2009; Edvardsson
18 Björnberg and Hansson 2013; Huynh and Resurreccion 2014).

19 Where gender-sensitive policies to climate change may exist, effective implementation in practice of
20 gender equality and empowerment may not be achieved on the ground due to lack of technical
21 capacity, financial resources and evaluation criteria, as shown in the Pacific Islands (Aipira et al.
22 2017). Thus, corresponding institutional frameworks that are well-resourced, coordinated, and
23 informed are required, along with adequate technical capacity within government agencies, NGOs and
24 project teams, to strength collaboration and promote knowledge sharing (Aipira et al. 2017).

25 **Women’s empowerment: Synergies among adaptation, mitigation, and food security**

26 Empowered and valued women in their societies increases their capacity to improve food security
27 under climate change, make substantial contributions to their own well-being, to that of their families
28 and of their communities (Langer et al. 2015; Ajani et al. 2013; Alston 2014) (*high confidence*).
29 Women’s empowerment includes economic, social and institutional arrangements and may include
30 targeting men in integrated agriculture programs to change gender norms and improve nutrition (Kerr
31 et al. 2016). Empowerment through collective action and groups-based approaches in the near-term
32 has the potential to equalise relationships on the local, national and global scale (Ringler et al. 2014).
33 Empowered women are crucial to creating effective synergies among adaptation, mitigation, and food
34 security.

35 In Western Kenya, widows in their new role as main livelihood providers invested in sustainable
36 innovations like rainwater harvesting systems and agroforestry (this can serve as both adaptation and
37 mitigation), and worked together in formalised groups of collective action (Gabrielsson and Ramasar
38 2013) to ensure food and water security. In Nepal, women’s empowerment had beneficial outcomes in
39 maternal and children nutrition, reducing the negative effect of low production diversity (Malapit et
40 al. 2015). Integrated nutrition and agricultural programs have increased women’s decision-making
41 power and control over home gardens in Burkina Faso (van den Bold et al. 2015) with positive
42 impacts on food security.

44 **5.1.4 Food systems in AR5, SR15, and the Paris Agreement**

45 Food, and its relationship to the environment and climate change, has grown in prominence since the
46 Rio Declaration in 1992, where food production is Chapter 14 of Agenda 21, to the Paris Agreement

1 of 2015, which includes the need to ensure food security under the threat of climate change on its first
2 page. This growing prominence of food is reflected in recent IPCC reports, including its Fifth
3 Assessment Report (IPCC 2014a) and the Special Report on Global Warming of 1.5°C (SR15) (IPCC
4 2018a).

5

6 **5.1.4.1 Food systems in AR5 and SR15**

7 The IPCC Working Group (WG) II AR5 chapter on Food Security and Food Production Systems
8 broke new ground by expanding its focus beyond the effects of climate change primarily on
9 agricultural production (crops, livestock and aquaculture) to include a food systems approach as well
10 as directing attention to undernourished people (Porter et al. 2014). However, it focused primarily on
11 food production systems due to the prevalence of studies on that topic (Porter et al. 2017). It
12 highlighted that a range of potential adaptation options exist across all food system activities, not just
13 in food production, and that benefits from potential innovations in food processing, packaging,
14 transport, storage, and trade were insufficiently researched at that time.

15 The IPCC WG III AR5 chapter on Agriculture, Forestry and Other Land Use (AFOLU) assessed
16 mitigation potential considering not only the supply, but also the demand side of land uses, by
17 consideration of changes in diets; it also included food loss and waste (Smith et al. 2014). AR5
18 focused on crop and livestock activities within the farm gate and land use and land use change
19 dynamics associated with agriculture. It did not take a full food system approach to emissions
20 estimates that includes processing, transport, storage, and retail.

21 The IPCC WG II AR5 Rural Areas chapter (Revi et al. 2014) found that farm households in
22 developing countries are vulnerable to climate change due to socio-economic characteristics and non-
23 climate stressors, as well as climate risks (Dasgupta et al. 2014). They also found that a wide range of
24 on-farm and off-farm climate change adaptation measures are already being implemented and that the
25 local social and cultural context played a prominent role in the success or failure of different
26 adaptation strategies for food security, such as trade, irrigation or diversification. The IPCC WG II
27 AR5 Urban Areas chapter found that food security of people living in cities was severely affected by
28 climate change through reduced supplies, including urban-produced food, and impacts on
29 infrastructure, as well as a lack of access to food. Poor urban dwellers are more vulnerable to rapid
30 changes of food prices due to climate change.

1 Many climate change response options in IPCC WG II and WG III AR5 (IPCC 2014b) address
2 incremental adaptation or mitigation responses separately rather than being inclusive of more
3 systemic or transformational changes in multiple food systems that are large-scale, in depth, and
4 rapid, requiring social, technological, organisational and system responses (Rosenzweig and Solecki
5 2018; Mapfumo et al. 2017; Termeer et al. 2017). In many cases, transformational change will require
6 integration of resilience and mitigation across all parts of the food system including production,
7 supply chains, social aspects, and dietary choices. Further, these transformational changes in the food
8 system need to encompass linkages to ameliorative responses to land degradation (see Chapter 4),
9 desertification (see Chapter 3), and declines in quality and quantity of water resources throughout the
10 food-energy-water nexus (Chapter 2; Section 5.7).

11 The IPCC Special Report on Global Warming of 1.5°C found that climate-related risks to food
12 security are projected to increase with global warming of 1.5°C and increase further with 2°C (IPCC
13 2018a).

14

15 **5.1.4.2 Food systems and the Paris Agreement**

16 To reach the temperature goal put forward in the Paris Agreement of limiting warming to well below
17 2°C, and pursuing efforts to limit warming to 1.5°C, representatives from 196 countries signed the
18 United Nations Framework Convention on Climate Change (UNFCCC) Paris Agreement (UNFCCC
19 2015) in December 2015. The Agreement put forward a temperature target of limiting warming to
20 well below 2°C, and pursuing efforts to limit warming to 1.5°C. Under the Paris Agreement, Parties
21 are expected to put forward their best efforts through nationally determined contributions (NDCs) and
22 to strengthen these efforts in the years ahead. Article 2 of the Agreement makes clear the agreement is
23 within “the context of sustainable development” and states actions should be “in a manner that does
24 not threaten food production” to ensure food security.

25 Many countries have included food systems in their mitigation and adaptation plans as found in their
26 NDCs for the Paris Agreement (Rosenzweig et al. 2018a). Richards et al. (2015) analysed 160 Party
27 submissions and found that 103 include agricultural mitigation; of the 113 Parties that include
28 adaptation in their NDCs, almost all (102) include agriculture among their adaptation priorities. There
29 is much attention to conventional agricultural practices that can be climate-smart and sustainable (e.g.,
30 crop and livestock management), but less to the enabling services that can facilitate uptake (e.g.,
31 climate information services, insurance, credit). Considerable finance is needed for agricultural
32 adaptation and mitigation by least developed countries – in the order of USD 3 billion annually for
33 adaptation and USD 2 billion annually for mitigation, which may be an underestimate due to a small
34 sample size (Richards et al. 2015). On the mitigation side, none of the largest agricultural emitters
35 included sector-specific contributions from the agriculture sector in their NDCs, but most included
36 agriculture in their economy-wide targets (Richards et al. 2018).

37 *Carbon dioxide removal (CDR)*. A key aspect regarding the implementation of measures to achieve
38 the Paris Agreement goals involves measures related to carbon dioxide removal (CDR) through
39 bioenergy (Sections 5.5 and 5.6). To reach the temperature target put forward of limiting warming to
40 well below 2°C, and pursuing efforts to limit warming to 1.5°C, large investments and abrupt changes
41 in land use will be required to advance bioenergy with carbon capture and sequestration (BECCS),
42 afforestation and reforestation (AR), and biochar technologies. Existing scenarios estimate the global
43 area required for BECCS alone to help limit warming to 1.5°C in the range of 109-990 Mha, most
44 commonly around 380-700 Mha.

45 Most scenarios assume very rapid deployment between 2030 and 2050, reaching rates of expansion in
46 land use in 1.5°C scenarios exceeding 20 M ha yr⁻¹, which are unprecedented for crops and forestry
47 reported in the FAO database from 1961. Achieving the 1.5 °C target would thus result in major

1 competing demands for land between climate change mitigation and food production, with cascading
2 impacts on food security.

3 This chapter assesses how the potential conflict for land could be alleviated by sustainable
4 intensification to produce food with a lower land footprint (Section 5.6, Cross-Chapter Box 6:
5 Agricultural intensification). To accomplish this, farmers would need to produce the same amount of
6 food with lower land requirement, which depends on technology, skills, finance, and markets.
7 Achieving this would also rely on demand-side changes including dietary choices that enable
8 reduction of the land footprint for food production while still meeting dietary needs. Transitions
9 required for such transformative changes in food systems are addressed in Section 5.7.

10

11 *5.1.4.3 Charting the future of food security*

12 This chapter utilises the common framework of the Representative Concentration Pathways (RCPs)
13 and the Shared Socio-economic Pathways (SSPs) (Popp et al. 2017; Riahi et al. 2017; Doelman et al.
14 2018) to assess the impacts of future GHG emissions, mitigation measures, and adaptation on food
15 security (See Cross-Chapter Box 1: Scenarios in Chapter 1, Section 5.2 and 5.6).

16 New work utilising these scenario approaches has shown that the food system externalises costs onto
17 human health and the environment (Springmann et al. 2018a; Swinburn et al. 2019; Willett et al.
18 2019), leading to calls for transforming the food system to deliver better human and sustainability
19 outcomes (Willett et al. 2019; IAP 2018; Development Initiatives 2018; Lozano et al. 2018). Such a
20 transformation could be an important lever to address the complex interactions between climate
21 change and food security. Through acting on mitigation and adaptation in regard to both food demand
22 and food supply we assess the potential for improvements to both human health and the Sustainable
23 Development Goals (Section 5.6).

24 This chapter builds on the food systems and scenario approaches followed by AR5 and its focus on
25 climate change and food security, but new work since AR5 has extended beyond production to how
26 climate change interacts with the whole food system. The analysis of climate change and food
27 insecurity has expanded beyond undernutrition to include the overconsumption of unhealthy mass-
28 produced food high in sugar and fat, which also threatens health in different but highly damaging
29 ways and the role of dietary choices and consumption in greenhouse gas emissions. It focused on
30 land-based food systems, though highlighting in places the contributions of freshwater and marine
31 production.

32 The chapter assesses new work on the observed and projected effects of CO₂ concentrations on the
33 nutritional quality of crops (Section 5.2.4.2) and emphasises the role of extreme climate events
34 (Section 5.2.5.1), social aspects including gender and equity (Box 5.1. and Cross-chapter Box 11:
35 Gender in Chapter 7), and dietary choices (Section 5.4.6, 5.5.2). Other topics with considerable new
36 literature include impacts on smallholder farming systems (Section 5.2.2.6), food loss and waste
37 (Section **Error! Reference source not found.**), and urban and peri-urban agriculture (Section 5.6.5).
38 he chapter explores the potential competing demands for land that mitigation measures to achieve
39 temperature targets may engender, with cascading impacts on food production, food security, and
40 farming systems (Section 5.6), and the enabling conditions for achieving the mitigation and adaptation
41 in equitable and sustainable ways (Section 5.7). Section 5.8 presents challenges to future food
42 security, including food price spikes, migration, and conflict.

43

5.2 Impacts of climate change on food systems

There are many routes by which climate change can impact food security and thus human health (Watts et al. 2018; Fanzo et al. 2017). One major route is via climate change affecting the amount of food, both from direct impacts on yields (Section 5.2.2.1) and indirect effects through climate change's impacts on water availability and quality, pests and diseases (Section 5.2.2.3), and pollination services (Section 5.2.2.4). Another route is via changing CO₂ in the atmosphere, affecting biomass and nutritional quality (Section 5.2.4.2). Food safety risks during transport and storage can also be exacerbated by changing climate (Section 5.2.4.1).

Further, the direct impacts of changing weather can affect human health through the agricultural workforce's exposure to extreme temperatures (Section 5.2.5.1). Through changing metabolic demands and physiological stress for people exposed to extreme temperatures, there is also the potential for interactions with food availability: people may require more food to cope, whilst at the same time being impaired from producing it (Watts et al. 2018). All these factors have the potential to alter both physical health as well as cultural health, through changing the amount, safety and quality of food available for individuals within their cultural context.

This section assesses recent literature on climate change impacts on the four pillars of food security: availability (Section 5.2.2), access (Section 5.2.3), utilisation (Section 5.2.4), and stability (Section 5.2.5). It considers impacts on the food system from climate changes that are already taking place and how impacts are projected to occur in the future. See Supplementary Material Section SM5.2 for discussion of detection and attribution and improvement in projection methods.

5.2.1 Climate drivers important to food security

Climate drivers relevant to food security and food systems include temperature-related, precipitation-related, and integrated metrics that combine these and other variables. These are projected to affect many aspects of the food security pillars (FAO 2018b) (see Supplementary Material Table SM5.2 and Chapter 6 for assessment of observed and projected climate impacts). Climate drivers relevant to food production and availability may be categorised as modal climate changes (e.g., shifts in climate envelopes causing shifts in cropping varieties planted), seasonal changes (e.g., warming trends extending growing seasons), extreme events (e.g., high temperatures affecting critical growth periods, flooding/droughts), and atmospheric conditions (e.g., CO₂ concentrations, short-lived climate pollutants (SLCPs), and dust). Water resources for food production will be affected through changing rates of precipitation and evaporation, ground water levels, and dissolved oxygen content (Cruz-Blanco et al. 2015; Sepulcre-Canto et al. 2014; Huntington et al. 2017; Schmidtko et al. 2017). Potential changes in major modes of climate variability can also have widespread impacts such as occurred during late 2015 to early 2016 when a strong El Niño contributed to regional shifts in precipitation in the Sahel region. Significant drought across Ethiopia resulted in widespread crop failure and more than 10 million people in Ethiopia required food aid (U.S. Department of State 2016; Huntington et al. 2017) (see Figure 5.3).

1
2 **Figure 5.3** Precipitation anomaly and vegetation response in Eastern Africa. (a) Sep 2015–Feb 2016
3 **Climate Hazards Group Infrared Precipitation with Station (CHIRPS) precipitation anomaly over Africa**
4 **relative to the 1981–2010 average shows that large areas of Ethiopia received less than half of normal**
5 **precipitation. Consequently, widespread impacts to agricultural productivity, especially within pastoral**
6 **regions, were present across Ethiopia as evidenced by (d) reduced greenness in remote sensing images. (b)**
7 **MODIS NDVI anomalies for Sep 2015–Feb 2016 relative to 2000–2015 average are shown for the inset**
8 **box in (a). (c) Landsat NDVI anomalies for Sep 2015–Feb 2016 relative to 2000–2015 average are shown**
9 **for the inset box in (b) (Huntington et al. 2017).**

10 Other variables that affect agricultural production, processing, and/or transport are solar radiation,
11 wind, humidity, and (in coastal areas) salinisation and storm surge (Mutahara et al. 2016; Myers et al.
12 2017). Extreme climate events resulting in inland and coastal flooding, can affect the ability of people
13 to obtain and prepare food (Rao et al. 2016; FAO et al. 2018). For direct effects of atmospheric CO₂
14 concentrations on crop nutrient status see Section 5.2.4.2.

15 16 **5.2.1.1 Short-lived climate pollutants**

17 The important role of short-lived climate pollutants such as ozone and black carbon is increasingly
18 emphasised since they affect agricultural production through direct effects on crops and indirect
19 effects on climate (Emberson et al. 2018; Lal et al. 2017; Burney and Ramanathan 2014; Ghude et al.
20 2014) (see Chapters 2 and 4). Ozone causes damage to plants through damages to cellular metabolism
21 that influence leaf-level physiology to whole-canopy and root-system processes and feedbacks; these
22 impacts affect leaf-level photosynthesis senescence and carbon assimilation, as well as whole-canopy
23 water and nutrient acquisition and ultimately crop growth and yield (Emberson et al. 2018). Using
24 atmospheric chemistry and a global integrated assessment model, Chuwah et al. (2015) found that
25 without a large decrease in air pollutant emissions, high ozone concentration could lead to an increase
26 in crop damage of up to 20% in agricultural regions in 2050 compared to projections in which
27 changes in ozone are not accounted for. Higher temperatures are associated with higher ozone
28 concentrations; C3 crops are sensitive to ozone (e.g., soybeans, wheat, rice, oats, green beans,
29 peppers, and some types of cottons) and C4 crops are moderately sensitive (Backlund et al. 2008).

30 Methane increases surface ozone which augments warming-induced losses and some quantitative
31 analyses now include climate, long-lived (CO₂) and multiple short-lived pollutants (CH₄, O₃)
32 simultaneously (Shindell et al. 2017; Shindell 2016). Reduction of tropospheric ozone and black
33 carbon can avoid premature deaths from outdoor air pollution and increases annual crop yields
34 (Shindell et al. 2012). These actions plus methane reduction can influence climate on shorter time

1 scales than those of carbon dioxide–reduction measures. Implementing them substantially reduces the
2 risks of crossing the 2°C threshold and contributes to achievement of the SDGs (Haines et al. 2017;
3 Shindell et al. 2017).

5 5.2.2 Climate change impacts on food availability

6 Climate change impacts food availability through its effect on the production of food and its storage,
7 processing, distribution, and exchange.

9 5.2.2.1 Impacts on crop production

10 **Observed impacts.** Since AR5, there have been further studies that document impacts of climate
11 change on crop production and related variables (See Supplementary Material Table SM5.3). There
12 have been also a few studies that demonstrate a strengthening relationship between observed climate
13 variables and crop yields that indicate future expected warming will have severe impacts on crop
14 production (Mavromatis 2015; Innes et al. 2015). At the global scale, Iizumi et al. (2018) used a
15 counterfactual analysis and found that climate change between 1981-2010 has decreased global mean
16 yields of maize, wheat, and soybeans by 4.1, 1.8 and 4.5%, respectively, relative to preindustrial
17 climate, even when CO₂ fertilisation and agronomic adjustments are considered. Uncertainties (90%
18 probability interval) in the yield impacts are -8.5 to +.5% for maize, -7.5 to +4.3% for wheat, and -8.4
19 to -0.5% for soybeans. For rice, no significant impacts were detected. This study suggests that climate
20 change has modulated recent yields on the global scale and led to production losses, and that
21 adaptations to date have not been sufficient to offset the negative impacts of climate change,
22 particularly at lower latitudes.

23 Dryland settlements are perceived as vulnerable to climate change with regard to food security,
24 particularly in developing countries; such areas are known to have low capacities to cope effectively
25 with decreasing crop yields (Shah et al. 2008; Nellemann et al. 2009). This is of concern because
26 drylands constitute over 40% of the earth’s land area, and are home to 2.5 billion people (FAO et al.
27 2011).

28 *Australia.* In Australia, declines in rainfall and rising daily maximum temperatures based on
29 simulations of 50 sites caused water-limited yield potential to decline by 27% from 1990 to 2015,
30 even though elevated atmospheric CO₂ concentrations had a positive effect (Hochman et al. 2017). In
31 New South Wales, high-temperature episodes during the reproduction stage of crop growth were
32 found to have negative effects on wheat yields, with combinations of low rainfall and high
33 temperatures being the most detrimental (Innes et al. 2015).

34 *Asia.* There are numerous studies demonstrating that climate change is affecting agriculture and food
35 security in Asia. Several studies with remote sensing and statistical data have examined rice areas in
36 northeastern China, the northernmost region of rice cultivation, and found expansion over various
37 time periods beginning in the 1980s, with most of the increase occurring after 2000 (Liu et al. 2014;
38 Wang et al. 2014; Zhang et al. 2017). Rice yield increases have also been found over a similar period
39 (Wang et al. 2014). Multiple factors, such as structural adjustment, scientific and technological
40 progress, and government policies, along with regional warming (1.43°C in the past century)
41 (Fenghua et al. 2006) have been put forward as contributing to the observed expanded rice areas and
42 yield in the region. Shi et al. (2013) indicate that there is a partial match between climate change
43 patterns and shifts in extent and location of the rice-cropping area (2000-2010).

44 There have also been documented changes in winter wheat phenology in Northwest China (He 2015).
45 Consistent with this finding, dates of sowing and emergence of spring and winter wheat were delayed,
46 dates of anthesis and maturity was advanced, and length of reproductive growth period was prolonged

1 from 1981-2011 in a study looking at these crops across China (Liu et al. 2018b). Another study
2 looking in Norwest China demonstrated that there have been changes in the phenology and
3 productivity of spring cotton (Huang and Ji 2015). A study looking at wheat growth and yield in
4 different climate zones of China from 1981-2009 found that impacts were positive in Northern China
5 and negative in Southern China (Tao et al. 2014). Temperature increased across the zones while
6 precipitation changes were not consistent (Tao et al. 2014).

7 Crop yield studies focusing on India have found that warming has reduced wheat yields by 5.2% from
8 1981 to 2009, despite adaptation (Gupta et al. 2017); that maximum daytime temperatures have risen
9 along with some night-time temperatures (Jha and Tripathi 2017).

10 Agriculture in Pakistan has also been affected by climate change. From 1980 to 2014, spring maize
11 growing periods have shifted an average of 4.6 days per decade earlier, while sowing of autumn
12 maize has been delayed 3.0 days per decade (Abbas et al. 2017). A similar study with sunflower
13 showed that increases in mean temperature from 1980 to 2016 were highly correlated with shifts in
14 sowing, emergence, anthesis, and maturity for fall and spring crops (Tariq et al. 2018).

15 Mountain people in the Hindu-Kush Himalayan region encompassing parts of Pakistan, India, Nepal,
16 and China, are particularly vulnerable to food insecurity related to climate change because of poor
17 infrastructure, limited access to global markets, physical isolation, low productivity, and hazard
18 exposure, including Glacial Lake Outburst Floods (GLOFs) (Rasul et al. 2019; Rasul 2010; Tiwari
19 and Joshi 2012; Huddleston et al. 2003; Ward et al. 2013; FAO 2008; Nautiyal et al. 2007; Din et al.
20 2014). Surveys have been conducted to determine how climate-related changes have affected food
21 security (Hussain et al. 2016; Shrestha and Nepal 2016) with results showing that the region is
22 experiencing an increase in extremes, with farmers facing more frequent floods as well as prolonged
23 droughts with ensuing negative impacts on agricultural yields and increases in food insecurity
24 (Hussain et al. 2016; Manzoor et al. 2013).

25 *South America.* In another mountainous region, the Andes, inhabitants are also beginning to
26 experience changes in the timing, severity, and patterns of the annual weather cycle. Data collected
27 through participatory workshops, semi-structured interviews with agronomists, and qualitative
28 fieldwork from 2012 to 2014 suggest that in Colomi, Bolivia climate change is affecting crop yields
29 and causing farmers to alter the timing of planting, their soil management strategies, and the use and
30 spatial distribution of crop varieties (Saxena et al. 2016). In Argentina, there has also been an increase
31 in yield variability of maize and soybeans (Iizumi and Ramankutty 2016). These changes have had
32 important implications for the agriculture, human health, and biodiversity of the region (Saxena et al.
33 2016).

34 *Africa.* In recent years, yields of staple crops such as maize, wheat, sorghum, and fruit crops, such as
35 mangoes, have decreased across Africa, widening food insecurity gaps (Ketiem et al. 2017). In
36 Nigeria, there have been reports of climate change having impacts on the livelihoods of arable crop
37 farmers (Abiona et al. 2016; Ifeanyi-obi et al. 2016; Onyeneke 2018). The Sahel region of Cameroon
38 has experienced an increasing level of malnutrition, partly due to the impact of climate change since
39 harsh climatic conditions leading to extreme drought have a negative influence on agriculture
40 (Chabejong 2016).

41 Utilising farmer interviews in Abia State, Nigeria, researchers found that virtually all responders
42 agreed that the climate was changing in their area (Ifeanyi-obi et al. 2016). With regard to
43 management responses, a survey of farmers from Anambra State, Nigeria showed that farmers are
44 adapting to climate change by utilising such techniques as mixed cropping systems, crop rotation,
45 fertiliser application (Onyeneke et al. 2018). In Ebonyi State, Nigeria, Eze (2017) interviewed 160
46 women cassava farmers and found the major climate change risks in production to be severity of high
47 temperature stress, variability in relative humidity, and flood frequency.

1 *Europe*. The impacts of climate change are varied across the continent. Moore and Lobell (2015)
2 showed that climate trends are affecting European crop yields, with long-term temperature and
3 precipitation trends since 1989 reducing continent-wide wheat and barley yields by 2.5% and 3.8%,
4 respectively, and having slightly increased maize and sugar beet yields. Though these aggregate
5 affects appear small, the impacts are not evenly distributed. In cooler regions such as the United
6 Kingdom and Ireland, the effect of increased warming has been ameliorated by an increase in rainfall.
7 Warmer regions, such as Southern Europe, have suffered more from the warming; in Italy this effect
8 has been amplified by a drying, leading to yield declines of 5% or greater.

9 Another study examining the impacts of recent climate trends on cereals in Greece showed that crops
10 are clearly responding to changes in climate – and demonstrated via statistical analysis that significant
11 impacts on wheat and barley production are expected at the end of the twenty-first century
12 (Mavromatis 2015). In the Czech Republic, a study documented positive long-term impacts of recent
13 warming on yields of fruiting vegetables (cucumbers and tomatoes) (from 4.9 to 12% per 1°C
14 increase in local temperature) but decreases in yield stability of traditionally grown root vegetables in
15 the warmest areas of the country (Potopová et al. 2017). A study in Hungary also indicated the
16 increasingly negative impacts of temperature on crops and indicated that a warming climate is at least
17 partially responsible for the stagnation or reduction in crop yields since the mid-1980s in Eastern
18 Europe (Pinke and Lövei 2017).

19 In summary, climate change is already affecting some aspects of food security (*high confidence*).
20 Recent studies in both large-scale and smallholder farming systems document declines in crop
21 productivity related to rising temperatures and changes in precipitation. Evidence for climate change
22 impacts (e.g., declines and stagnation in yields, changes in sowing and harvest dates, increased
23 infestation of pests and diseases, and declining viability of some crop varieties) is emerging from
24 detection and attribution studies and indigenous and local knowledge in Australia, Europe, Asia,
25 Africa, North America, and South America (*medium evidence, robust agreement*).

26 **Projected impacts.** Climate change effects have been studied on a global scale following a variety of
27 methodologies that have recently been compared (Lobell and Asseng 2017; Zhao et al. 2017a; Liu et
28 al. 2016). Approaches to study global and local changes include global gridded crop model
29 simulations (e.g., (Deryng et al. 2014)), point-based crop model simulations (e.g., (Asseng et al.
30 2015)), analysis of point-based observations in the field (e.g., (Zhao et al. 2016)), and temperature-
31 yield regression models (e.g., (Auffhammer and Schlenker 2014)). For an evaluation of model skills
32 see e.g., used in AgMIP see Müller et al. (2017b).

33 Results from Zhao et al. (2017a) across different methods consistently showed negative temperature
34 impacts on crop yield at the global scale, generally underpinned by similar impacts at country and site
35 scales. A limitation of Zhao et al. (2017a) is that it is based on the assumption that yield responses to
36 temperature increase are linear, while yield response differs depending on growing season
37 temperature level. Iizumi et al. (2017) showed that the projected global mean yields of maize and
38 soybean at the end of this century do decrease monotonically with warming, whereas those of rice and
39 wheat increase with warming and level off at a warming of about 3°C (2091–2100 relative to 1850–
40 1900).

41 Empirical statistical models have been applied widely to different cropping systems, at multiple
42 scales. Analyses using statistical models for maize and wheat tested with global climate model
43 scenarios found that the RCP4.5 scenario reduced the size of average yield impacts, risk of major
44 slowdowns, and exposure to critical heat extremes compared to RCP8.5 in the latter decades of the
45 21st century (Tebaldi and Lobell 2018). Impacts on crops grown in the tropics are projected to be
46 more negative than in mid- to high-latitudes as stated in AR5 and confirmed by recent studies (e.g.,
47 (Levis et al. 2018)). These projected negative effects in the tropics are especially pronounced under
48 conditions of explicit nitrogen stress (Figure 5.4) (Rosenzweig et al. 2014).

GGCMs with explicit N stress

Figure 5.4 Median yield changes (%) for RCP8.5 (2070–2099 in comparison to 1980–2010 baseline) with CO₂ effects and explicit nitrogen stress over five GCMs x four Global Gridded Crop Models (GGCMs) for rainfed maize, wheat, rice, and soy (20 ensemble members from EPIC, GEPIC, pDSSAT, and PEGASUS; except for rice which has 15). Gray areas indicate historical areas with little to no yield capacity. All models use a 0.5° grid, but there are differences in grid cells simulated to represent agricultural land. While some models simulated all land areas, others simulated only potential suitable cropland area according to evolving climatic conditions; others utilised historical harvested areas in 2000 according to various data sources (Rosenzweig et al. 2014).

Reyer et al. (2017b) examined biophysical impacts in five world regions under different warming scenarios - 1, 1.5, 2, and 4 °C warming. For the Middle East and Northern Africa region a significant correlation between crop yield decrease and temperature increase was found, regardless of whether the effects of CO₂ fertilisation or adaptation measures are taken into account (Waha et al. 2017). For Latin America and the Caribbean the relationship between temperature and crop yield changes was only significant when the effect of CO₂ fertilisation is considered (Reyer et al. 2017a).

A review of recent scientific literature found that projected yield loss for West Africa depends on the degree of wetter or drier conditions and elevated CO₂ concentrations (Sultan and Gaetani 2016). Faye et al. (2018b) in a crop modelling study with RCPs 4.5 and 8.5 found that climate change could have limited effects on peanut yield in Senegal due to the effect of elevated CO₂ concentrations.

Crop productivity changes for 1.5°C and 2.0°C. The IPCC Special Report on Global Warming of 1.5°C found that climate-related risks to food security are projected to increase with global warming of 1.5°C and increase further with 2°C (IPCC 2018b). These findings are based among others on Schleussner et al. (2018); Rosenzweig et al. (2018a); Betts et al. (2018), Parkes et al. (2018) and Faye et al. (2018a). The importance of assumptions about CO₂ fertilisation was found to be significant by Ren et al. (2018) and Tebaldi and Lobell (2018)

AgMIP coordinated global and regional assessment (CGRA) results confirm that at the global scale, there are mixed results of positive and negative changes in simulated wheat and maize yields, with declines in some breadbasket regions, at both 1.5°C and 2.0°C (Rosenzweig et al. 2018a). In conjunction with price changes from the global economics models, productivity declines in the Punjab, Pakistan resulted in an increase in vulnerable households and poverty rate (Rosenzweig et al. 2018a).

Crop suitability. Another method of assessing the effects of climate change on crop yields that combined observations of current maximum-attainable yield with climate analogues also found strong reductions in attainable yields across a large fraction of current cropland by 2050 (Pugh et al. 2016).

1 However, the study found the projected total land area in 2050, including regions not currently used
2 for crops, climatically suitable for a high attainable yield similar to today. This indicates that large
3 shifts in land-use patterns and crop choice will likely be necessary to sustain production growth and
4 keep pace with current trajectories of demand.

5 *Fruits and vegetables.* Understanding the full range of climate impacts on fruits and vegetables is
6 important for projecting future food security, especially related to dietary diversity and healthy diets.
7 However, studies for vegetables are very limited (Bisbis et al. 2018). Of the 174 studies considered in
8 a recent review only 14 described results of field or greenhouse experiments studying impacts of
9 increased temperatures on yields of different root and leafy vegetables, tomatoes and legumes
10 (Scheelbeek et al. 2018). Bisbis et al. (2018) found similar effects for vegetables as have been found
11 for grain crops, that is, the effect of increased CO₂ on vegetables is mostly beneficial for production,
12 but may alter internal product quality, or result in photosynthetic down-regulation. Heat stress reduces
13 fruit set of fruiting vegetables, and speeds up development of annual vegetables, shortening their time
14 for photoassimilation. Yield losses and impaired product quality result, thereby increasing food loss
15 and waste. On the other hand, a longer growing season due to warmer temperatures enables a greater
16 number of plantings and can contribute to greater annual yields. However, some vegetables, such as
17 cauliflower and asparagus, need a period of cold accumulation to produce a harvest and warmer
18 winters may not provide those requirements.

19 For vegetables growing in higher baseline temperatures (>20°C), mean yield declines caused by 4°C
20 warming were 31.5%; for vegetables growing in cooler environments (<= 20°C), yield declines
21 caused by 4°C were much less, on the order of ~5% (Scheelbeek et al. 2018). Rippke et al. (2016)
22 found that 30–60% of the common bean growing area and 20–40% of the banana growing areas in
23 Africa will lose viability in 2078–2098 with a global temperature increase of 2.6°C and 4°C
24 respectively. Tripathi et al. (2016) found fruits and vegetable production to be highly vulnerable to
25 climate change at their reproductive stages and also due to potential for greater disease pressure.

26 In summary, studies assessed find that climate change will increasingly be detrimental to crop
27 productivity as levels of warming progress (*high confidence*). Impacts will vary depending on CO₂
28 concentrations, fertility levels, and region. Productivity of major commodity crops as well as crops
29 such as millet and sorghum yields will be affected. Studies on fruits and vegetables find similar
30 effects to those projected for grain crops in regard to temperature and CO₂ effects. Total land area
31 climatically suitable for high attainable yield, including regions not currently used for crops, will be
32 similar in 2050 to today.

34 **5.2.2.2 Impacts on livestock production systems**

35 Livestock systems are impacted by climate change mainly through increasing temperatures and
36 precipitation variation, as well as atmospheric carbon dioxide (CO₂) concentration and a combination
37 of these factors. Temperature affects most of the critical factors of livestock production, such as water
38 availability, animal production and reproduction, and animal health (mostly through heat stress)
39 (Figure 5.5). Livestock diseases are mostly affected by increases in temperature and precipitation
40 variation (Rojas-Downing et al. 2017). Impacts of climate change on livestock productivity,
41 particularly of mixed and extensive systems, are strongly linked to impacts on rangelands and
42 pastures, which include the effects of increasing CO₂ on their biomass and nutritional quality. This is
43 critical considering the very large areas concerned and the number of vulnerable people affected
44 (Steinfeld 2010; Morton 2007). Pasture quality and quantity are mainly affected through increases in
45 temperature and CO₂, and precipitation variation.

Figure 5.5 Impacts of climate change on livestock, based on (Rojas-Downing et al. 2017)

Among livestock systems, pastoral systems are particularly vulnerable to climate change (Dasgupta et al. 2014) (see Section 5.2.2.6 for impacts on smallholder systems that combine livestock and crops). Industrial systems will suffer most from indirect impacts leading to rises in the costs of water, feeding, housing, transport and the destruction of infrastructure due to extreme events, as well as an increasing volatility of the price of feedstuff which increases the level of uncertainty in production (Rivera-Ferre et al. 2016b; Lopez-i-Gelats 2014). Mixed systems and industrial or landless livestock systems could encounter several risk factors mainly due to the variability of grain availability and cost, and low adaptability of animal genotypes (Nardone et al. 2010).

Considering the diverse typologies of animal production, from grazing to industrial, Rivera-Ferre et al. (2016b) distinguished impacts of climate change on livestock between those related to extreme events and those related to more gradual changes in the average of climate-related variables. Considering vulnerabilities, they grouped the impacts as those impacting the animal directly, such as heat and cold stress, water stress, physical damage during extremes; and others impacting their environment, such as modification in the geographical distribution of vector-borne diseases, location, quality and quantity of feed and water and destruction of livestock farming infrastructures.

With severe negative impacts due to drought and high frequency of extreme events, the average gain of productivity might be cancelled by the volatility induced by increasing variability in the weather. For instance, semiarid and arid pasture will likely have reduced livestock productivity, while nutritional quality will be affected by CO₂ fertilisation (Schmidhuber and Tubiello 2007).

Observed impacts. Pastoralism is practiced in more than 75% of countries by between 200 and 500 million people, including nomadic communities, transhumant herders, and agro-pastoralists (McGahey et al. 2014). Observed impacts in pastoral systems reported in the literature include decreasing rangelands, decreasing mobility, decreasing livestock number, poor animal health, overgrazing, land degradation, decreasing productivity, decreasing access to water and feed, and increasing conflicts for the access to pasture land (López-i-Gelats et al. 2016; Batima et al. 2008; Njiru 2012; Fjelde and von Uexkull 2012; Raleigh and Kniveton 2012; Egeru 2016) (*high confidence*).

Pastoral systems in different regions have been affected differently. For instance, in China changes in precipitation were a more important factor in nomadic migration than temperature (Pei and Zhang 2014). There is some evidence that recent years have already seen an increase in grassland fires in

1 parts of China and tropical Asia (IPCC 2012). In Mongolia, grassland productivity has declined by
2 20-30% over the latter half of the 20th century, and ewe average weight reduced by 4 kg on an annual
3 basis, or about 8% since 1980 (Batima et al. 2008). Substantial decline in cattle herd sizes can be due
4 to increased mortality and forced off-take (Megersa et al. 2014). Important but less studied is the
5 impact of the interaction of grazing patterns with climate change on grassland composition. (Spence et
6 al. 2014) showed that climate change effects on Mongolia mountain steppe could be contingent on
7 land use.

8 Conflicts due to resource scarcity (as well as other socio-political factors (Benjaminsen et al. 2012))
9 aggravated by climate change has differentiated impact on women. In Turkana, female-headed
10 households have lower access to decision-making on resource use and allocation, investment and
11 planning (Omolo 2011), increasing their vulnerability (Section 5.1.3, Gender Box in Chapter 7).

12 Non-climate drivers add vulnerability of pastoral systems to climate change (McKune and Silva
13 2013). For instance, during environmental disasters, livestock holders have been shown to be more
14 vulnerable to food insecurity than their crop-producing counterparts because of limited economic
15 access to food and unfavorable market exchange rates (Nori et al. 2005). Sami reindeers in Finland
16 showed reduced freedom of action in response to climate change due to loss of habitat, increased
17 predation, and presence of economic and legal constraints) (Tyler et al. 2007; Pape and Löffler 2012).
18 In Tibet, emergency aid has provided shelters and privatised communally owned rangeland, which
19 have increased the vulnerability of pastoralists to climate change (Yeh et al. 2014; Næss 2013).

20 **Projected impacts.** The impacts of climate change on global rangelands and livestock have received
21 comparatively less attention than the impacts on crop production. Projected impacts on grazing
22 systems include changes in herbage growth (due to changes in atmospheric CO₂ concentrations and
23 rainfall and temperature regimes) and changes in the composition of pastures and in herbage quality,
24 as well as direct impacts on livestock (Herrero et al. 2016b). Droughts and high temperatures in
25 grasslands can also be a predisposing factor for fire occurrence (IPCC 2012).

26 *Net primary productivity, soil organic carbon, and length of growing period.* There are large
27 uncertainties related to grasslands and grazing lands (Erb et al. 2016), especially in regard to net
28 primary productivity (NPP) (Fetzel et al. 2017; Chen et al. 2018). Boone et al. (2017) estimated that
29 the mean global annual net primary production (NPP) in rangelands may decline by 10 g C m⁻² yr⁻¹ in
30 2050 under RCP 8.5, but herbaceous NPP is likely to increase slightly (i.e., average of 3 g C m⁻² yr⁻¹)
31 (Figure 5.6). Results of a similar magnitude were obtained by Havlík et al. (2015), using EPIC and
32 LPJmL on a global basis (Rojas-Downing et al. 2017). According to Rojas-Downing et al. (2017), an
33 increase of 2°C is estimate to negatively impact pasture and livestock production in arid and semiarid
34 regions and positively impact humid temperate regions.

35 Boone et al. (2017) identified significant regional heterogeneity in responses, with large increases in
36 annual productivity projected in northern regions (e.g., a 21% increase in productivity in the US and
37 Canada) and large declines in western Africa (-46% in sub-Saharan western Africa) and Australia (-
38 17%). Regarding the length of growing period (LGP, average number of growing days per year)
39 (Herrero et al. 2016b) projected reductions in the lower latitudes due to changes in rainfall patterns
40 and increases in temperatures, which indicate increasing limitations of water. They identified 35°C as
41 a critical threshold for rangeland vegetation and heat tolerance in some livestock species.

1
2 **Figure 5.6 Ensemble simulation results for projected annual net primary productivity of rangelands as**
3 **simulated in 2000 (top) and their change in 2050 (bottom) under emissions scenario RCP 8.5, with plant**
4 **responses enhanced by CO₂ fertilisation. Results from RCP 4.5 and 8.5, with and without positive effects**
5 **of atmospheric CO₂ on plant production, differed considerably in magnitude but had similar spatial**
6 **patterns, and so results from RCP 8.5 with increasing production are portrayed spatially here and in**
7 **other figures. Scale bar labels and the stretch applied to colors are based on the spatial mean value plus**
8 **or minus two standard deviations (Boone et al. 2017).**

9 *Rangeland composition.* According to Boone et al. (2017), the composition of rangelands is projected
10 to change as well (see Chapter 3). Bare ground cover is projected to increase, averaging 2.4% across
11 rangelands, with increases projected for the eastern Great Plains, eastern Australia, parts of southern
12 Africa, and the southern Tibetan Plateau. Herbaceous cover declines are projected in the Tibetan
13 Plateau, the eastern Great Plains, and scattered parts of the Southern Hemisphere. Shrub cover is
14 projected to decline in eastern Australia, parts of southern Africa, the Middle East, the Tibetan
15 Plateau, and the eastern Great Plains. Shrub cover could also increase in much of the Arctic and some
16 parts of Africa. In mesic and semi-arid savannahs south of the Sahara, both shrub and tree cover are
17 projected to increase, albeit at lower productivity and standing biomass. Rangelands in western and
18 southwestern parts of the Isfahan province in Iran were found to be more vulnerable to future drying–
19 warming conditions (Saki et al. 2018; Jaberlansar et al. 2017).

20 Soil degradation and expanding woody cover suggest that climate-vegetation-soil feedbacks
21 catalysing shifts toward less productive, possibly stable states (Ravi et al. 2010) may threaten mesic
22 and semi-arid savannahs south of the Sahara (see Chapter 3 and 4). This will also change their
23 suitability for grazing different animal species; switches from cattle, which mainly consume
24 herbaceous plants, to goats or camels are likely to occur as increases in shrubland occur.

25 *Direct and indirect effects on livestock.* Direct impacts of climate change in mixed and extensive
26 production systems are linked to increased water and temperature stress on the animals potentially
27 leading to animal morbidity, mortality and distress sales. Most livestock species have comfort zones

1 between 10°C–30°C, and at temperatures above this animals reduce their feed intake 3–5% per
2 additional degree of temperature (NRC 1981). In addition to reducing animal production, higher
3 temperatures negatively affect fertility (HLPE 2012).

4 Indirect impacts to mixed and extensive systems are mostly related to the impacts on the feed base,
5 whether pastures or crops, leading to increased variability and sometimes reductions in availability
6 and quality of the feed for the animals (Rivera-Ferre et al. 2016b). Reduced forage quality can
7 increase CH₄ emissions per unit of gross energy consumed. Increased risk of animal diseases is also
8 an important impact to all production systems (Bett et al. 2017). These depend on the geographical
9 region, land use type, disease characteristics, and animal susceptibility (Thornton et al. 2009). Also
10 important is the interaction of grazing intensity with climate change. Pfeiffer et al. (2019) estimated
11 that in a scenario of mean annual precipitation below 500 mm increasing grazing intensity reduced
12 rangeland productivity and increased annual grass abundance.

13 *Pastoral systems.* In Kenya, some 1.8 million extra cattle could be lost by 2030 because of increased
14 drought frequency, the value of the lost animals and production foregone amounting to USD 630
15 million (Herrero et al. 2010). Martin et al. (2014) assessed impacts of changing precipitation regimes
16 to identify limits of tolerance beyond which pastoral livelihoods could not be secured and found that
17 reduced mean annual precipitation had always negative effects as opposed to increased rainfall
18 variability. Similarly, Martin et al. (2016) found that drought effects on pastoralists in High Atlas in
19 Morocco depended on income needs and mobility options (see Section 5.2.2.6 for additional
20 information about impacts on smallholder farmers).

21 In summary, observed impacts in pastoral systems include changes in pasture productivity, lower
22 animal growth rates and productivity, damaged reproductive functions, increased pests and diseases,
23 and loss of biodiversity (*high confidence*). Livestock systems are projected to be adversely affected by
24 rising temperatures, depending on the extent of changes in pasture and feed quality, spread of
25 diseases, and water resource availability (*high confidence*). Impacts will differ for different livestock
26 systems and for different regions (*high confidence*). Vulnerability of pastoral systems to climate
27 change is very high (*high confidence*), and mixed systems and industrial or landless livestock systems
28 could encounter several risk factors mainly due to variability of grain availability and cost, and low
29 adaptability of animal genotypes. Pastoral system vulnerability is exacerbated by non-climate factors
30 (land tenure issues, sedentarisation programs, changes in traditional institutions, invasive species, lack
31 of markets, and conflicts) (*high confidence*).

33 **5.2.2.3 Impacts on pests and diseases**

34 Climate change is changing the dynamics of pests and diseases of both crops and livestock. The
35 nature and magnitude of future changes is likely to depend on local agro-ecological and management
36 context. This is because of the many biological and ecological mechanisms by which climate change
37 can affect the distribution, population size, and impacts of pests and diseases on food production
38 (Canto et al. 2009; Gale et al. 2009; Thomson et al. 2010; Pangga et al. 2011; Juroszek and von
39 Tiedemann 2013; Bett et al. 2017).

40 These mechanisms include changes in host susceptibility due to CO₂ concentration effects on crop
41 composition and climate stresses; changes in the biology of pests and diseases or their vectors (e.g.,
42 more generational cycles, changes in selection pressure driving evolution); mismatches in timing
43 between pests or vectors and their ‘natural enemies’; changes in survival or persistence of pests or
44 disease pathogens (e.g., changes in crop architecture driven by CO₂ fertilisation and increased
45 temperature, providing a more favourable environment for persistence of pathogens like fungi), and
46 changes in pest distributions as their “climate envelopes” shift. Such processes may affect pathogens,
47 and their vectors, as well as plant, invertebrate and vertebrate pests. (Latham et al. 2015) .

1 Furthermore, changes in diseases and their management, as well as changing habitat suitability for
2 pests and diseases in the matrix surrounding agricultural fields, have the ability to reduce or
3 exacerbate impacts (Bebber 2015). For example, changes in water storage and irrigation to adapt to
4 rainfall variation have the potential to enhance disease vector populations and disease occurrence
5 (Bett et al. 2017).

6 There is *robust evidence* that pests and diseases have already responded to climate change (Bebber et
7 al. 2014), and many studies have now built predictive models based on current incidence of pests,
8 diseases or vectors that indicate how they may respond in future (e.g., (Caminade et al. 2015; Kim et
9 al. 2015; Kim and Cho 2016; Samy and Peterson 2016; Yan et al. 2017)). Warren et al. (2018)
10 estimate that about 50% of insects, which are often pests or disease vectors, will change ranges by
11 about 50% by 2100 under current GHG emissions trajectories. These changes will lead to crop losses
12 due to changes in insect pests (Deutsch et al. 2018) and weed pressure (Ziska et al. 2018), and thus
13 affect pest and disease management at the farm level (Waryszak et al. 2018). For example, Samy and
14 Peterson (2016) modelled Blue-tongue virus (BTV), which is spread by biting *Culicoides* midges,
15 finding that the distribution of BTV is likely to be extended, particularly in central Africa, the US, and
16 western Russia.

17 There is some evidence (*medium confidence*) that exposure will, on average, increase (Bebber and
18 Gurr 2015; Yan et al. 2017), although there are a few examples where changing stresses may limit the
19 range of a vector. There is also a general expectation that perturbations may increase the likelihood of
20 pest and disease outbreaks by disturbing processes that may currently be at some quasi-equilibrium
21 (Canto et al. 2009; Thomson et al. 2010; Pangga et al. 2011). However, in some places, and for some
22 diseases, risks may decrease as well as increase (e.g., drying out may reduce the ability of fungi to
23 survive) (Kim et al. 2015; Skelsey and Newton 2015), or Tsetse fly's range may decrease (Terblanche
24 et al. 2008; Thornton et al. 2009) .

25 Pests, diseases, and vectors for both crop and livestock diseases are likely to be altered by climate
26 change (*high confidence*). Such changes are likely to depend on specifics of the local context,
27 including management, but perturbed agroecosystems are more likely, on theoretical grounds, to be
28 subject to pest and disease outbreaks (*low confidence*). Whilst specific changes in pest and disease
29 pressure will vary with geography, farming system, pest/pathogen – increasing in some situations
30 decreasing in others – there is robust evidence, with *high agreement*, that pest and disease pressures
31 are likely to change; such uncertainty requires robust strategies for pest and disease mitigation.

32 33 **5.2.2.4 Impacts on pollinators**

34 Pollinators play a key role on food security globally (Garibaldi et al. 2016). Pollinator-dependent
35 crops contribute up to 35% of global crop production volume and are important contributors to
36 healthy human diets and nutrition (IPBES 2016). On a global basis, some 1500 crops require
37 pollination (typically by insects, birds and bats) (Klein et al. 2007). Their importance to nutritional
38 security is therefore perhaps under-rated by valuation methodologies, which, nonetheless, include
39 estimates of the global value of pollination services at over USD 225 billion (2010 prices) (Hanley et
40 al. 2015). As with other ecosystem processes affected by climate change (e.g., changes in pests and
41 diseases), how complex systems respond is highly context-dependent. Thus, predicting the effects of
42 climate on pollination services is difficult (Tylianakis et al. 2008; Schweiger et al. 2010) and
43 uncertain, although there is *limited evidence* that impacts are occurring already (Section 5.2.2.4), and
44 *medium evidence* that there will be an effect.

45 Pollination services arise from a mutualistic interaction between an animal and a plant – which can be
46 disrupted by climate's impacts on one or the other or both (Memmott et al. 2007). Disruption can
47 occur through changes in species' ranges or by changes in timing of growth stages (Settele et al.

1 2016). For example, if plant development responds to different cues (e.g., day length) from insects
2 (e.g., temperature), the emergence of insects may not match the flowering times of the plants, causing
3 a reduction in pollination. Climate change will affect pollinator ranges depending on species, life-
4 history, dispersal ability and location. Warren et al. (2018) estimate that under a 3.2°C warming
5 scenario, the existing range of about 49% of insects will be reduced by half by 2100, suggesting either
6 significant range changes (if dispersal occurs) or extinctions (if it does not). However, in principle,
7 ecosystem changes caused by invasions, in some cases, could compensate for the decoupling
8 generated between native pollinators and pollinated species (Schweiger et al. 2010).

9 Other impacts include changes in distribution and virulence of pathogens affecting pollinators, such as
10 the fungus *Nosema ceranae*, which can develop at a higher temperature range than the less-virulent
11 *Nosema apis*; increased mortality of pollinators due to higher frequency of extreme weather events;
12 food shortage for pollinators due to reduction of flowering length and intensity; and aggravation of
13 other threats, such as habitat loss and fragmentation (González-Varo et al. 2013; Goulson et al. 2015;
14 Le Conte and Navajas 2008; Menzel et al. 2006; Walther et al. 2009; IPBES, 2016). The increase in
15 atmospheric CO₂ is also reducing the protein content of pollen, with potential impact on pollination
16 population biology (Ziska et al. 2016).

17 In summary, as with other complex agroecosystem processes affected by climate change (e.g.,
18 changes in pests and diseases), how pollination services respond will be highly context-dependent.
19 Thus, predicting the effects of climate on pollination services is difficult and uncertain, although there
20 is *medium evidence* that there will be an effect.

21

22 **5.2.2.5 Impacts on aquaculture**

23 This report focuses on land-based aquaculture; for assessment of impacts on marine fisheries both
24 natural and farmed see the IPCC Special Report on the Ocean and Cryosphere in a Changing Climate
25 (SROCC, forthcoming).

26 Aquaculture will be affected by both direct and indirect climate change drivers, both in the short and
27 the long-term. Barange et al. (2018) provides some examples of short-term loss of production or
28 infrastructure due to extreme events such as floods, increased risk of diseases, toxic algae and
29 parasites; and decreased productivity due to suboptimal farming conditions; and long-term impacts
30 may include scarcity of wild seed, limited access to freshwater for farming due to reduced
31 precipitation, limited access to feeds from marine and terrestrial sources, decreased productivity due
32 to suboptimal farming conditions, eutrophication and other perturbations.

33 FAO (2014a) assessed the vulnerability of aquaculture stakeholders to non-climate change drivers
34 which add to climate change hazards. Vulnerability arises from discrimination in access to inputs and
35 decision-making; conflicts; infrastructure damage; and dependence on global markets and
36 international pressures. Other non-climate drivers identified by McClanahan et al. (2015), which add
37 vulnerability to fisheries for food security include: declining fishery resources; a North–South divide
38 in investment; changing consumption patterns; increasing reliance on fishery resources for coastal
39 communities; and inescapable poverty traps creating by low net resource productivity and few
40 alternatives. In areas where vulnerability to climate change is heightened, increased exposure to
41 climate change variables and impacts is likely to exacerbate current inequalities in the societies
42 concerned, penalising further already disadvantaged groups such as migrant fishers (e.g. Lake Chad)
43 or women (e.g. employees in Chile’s processing industry) (FAO 2014a).

44 In many countries the projected declines co-occur across both marine fisheries and agricultural crops
45 (Blanchard et al. 2017), both of which will impact the aquaculture and livestock sectors (See
46 Supplementary Material Figure SM5.1). Countries with low Human Development Index, trade
47 opportunities and aquaculture technologies are likely to face greater challenges. These cross-sectoral

1 impacts point to the need for a more holistic account of the inter-connected vulnerabilities of food
2 systems to climate and global change.

3

4 **5.2.2.6 Impacts on smallholder farming systems**

5 New work has developed farming system approaches that take into account both biophysical and
6 economic processes affected by climate change and multiple activities. Farm households in the
7 developing world often rely on a complex mix of crops, livestock, aquaculture, and non-agricultural
8 activities for their livelihoods (Rosenzweig and Hillel 2015; Antle et al. 2015). Across the world,
9 smallholder farmers are considered to be disproportionately vulnerable to climate change because
10 changes in temperature, rainfall and the frequency or intensity of extreme weather events directly
11 affect their crop and animal productivity as well as their household's food security, income and well-
12 being (Vignola et al. 2015; Harvey et al. 2014b). For example, smallholder farmers in the Philippines,
13 whose survival and livelihood largely depend on the environment, constantly face risks and bear the
14 impacts of the changing climate (Peria et al. 2016).

15 Smallholder farming systems have been recognised as highly vulnerable to climate change (Morton,
16 2007) because they are highly dependent on agriculture and livestock for their livelihood (Dasgupta et
17 al. 2014) (*high confidence*). In Zimbabwe, farmers were found vulnerable due to their marginal
18 location, low levels of technology, and lack of other essential farming resources. Farmers observed
19 high frequency and severity of drought, excessive precipitation, drying up of rivers, dams and wells,
20 and changes in timing and pattern of seasons as evidence of climate change, and indicated that
21 prolonged wet, hot, and dry weather conditions resulted in crop damage, death of livestock, soil
22 erosion, bush fires, poor plant germination, pests, lower incomes, and deterioration of infrastructure
23 (Mutekwa 2009).

24 In Madagascar, Harvey et al. (2014b) conducted surveyed 600 small farmers and found that chronic
25 food insecurity, physical isolation and lack of access to formal safety nets increased Malagasy
26 farmers' vulnerability to any shocks to their agricultural system, particularly extreme events. In
27 Chitwan, Nepal, occurrence of extreme events and increased variability in temperature has increased
28 the vulnerability of crops to biotic and abiotic stresses and altered the timing of agricultural
29 operations; thereby affecting crop production (Paudel et al. 2014). In Lesotho, a study on subsistence
30 farming found that food crops were the most vulnerable to weather, followed by soil and livestock.
31 Climate variables of major concern were hail, drought and dry spells which reduced crop yields. In
32 the Peruvian Altiplan, Sietz et al. (2012) evaluate smallholders' vulnerability to weather extremes
33 with regard to food security and found the relevance of resource scarcity (livestock, land area),
34 diversification of activities (lack of alternative income, education deprivation) and income restrictions
35 (harvest failure risk) in shaping vulnerability of smallholders. See Section 5.2.2.6 for observed
36 impacts on smallholder pastoral systems.

37 **Projected impacts.** By including regional economic models, integrated methods take into account the
38 potential for yield declines to raise prices and thus livelihoods (up to a certain point) in some climate
39 change scenarios. Regional economic models of farming systems can be used to examine the potential
40 for switching to other crops and livestock, as well as the role that non-farm income can play in
41 adaptation (Valdivia et al. 2015; Antle et al. 2015). On the other hand, lost income for smallholders
42 from climate change-related declines, for example in coffee production, can decrease their food
43 security (Hannah et al. 2017).

44 Farming system methods developed by AgMIP have been used in regional integrated assessments in
45 Sub-Saharan Africa (Kihara et al. 2015), West Africa (Adiku et al. 2015); East Africa (Rao et al.
46 2015), South Africa (Beletse et al. 2015), Zimbabwe (Masikati et al. 2015), South Asia (McDermid et
47 al. 2015), Pakistan (Ahmad et al. 2015), the Indo-Gangetic Basin (Subash et al. 2015), Tamil Nadu

1 (Ponnusamy et al. 2015) and Sri Lanka (Zubair et al. 2015). The assessments found that climate
2 change adds pressure to smallholder farmers across Sub-Saharan Africa and South Asia, with winners
3 and losers within each area studied. Temperatures are expected to increase in all locations, and rainfall
4 decreases are projected for the western portion of West Africa and Southern Africa, while increases in
5 rainfall are projected for eastern West Africa and all study regions of South Asia. The studies project
6 that climate change will lead to yield decreases in most study regions except South India and areas in
7 central Kenya, as detrimental temperature effects overcome the positive effects of CO₂. These studies
8 use AgMIP representative agricultural pathways (RAPs) as a way to involve stakeholders in regional
9 planning and climate resilience (Valdivia et al. 2015). RAPs are consistent with and complement the
10 RCP/SSP approaches for use in agricultural model intercomparisons, improvement, and impact
11 assessments

12 New methods have been developed for improving analysis of climate change impacts and adaptation
13 options for the livestock component of smallholder farming systems in Zimbabwe (Descheemaeker et
14 al. 2018). These methods utilised disaggregated climate scenarios, as well as differentiating farms
15 with larger stocking rates compared to less densely stocked farms. By disaggregating climate
16 scenarios, impacts, and smallholder farmer attributes, such assessments can more effectively inform
17 decision-making towards climate change adaptation.

18 In Central Asia, a study using the bio-economic farm model (BEFM) found large differences in
19 projected climate change impact ranging from positive income gains in large-scale commercial farms
20 in contrast to negative impacts in small-scale farms (Bobojonov and Aw-Hassan 2014). Negative
21 impacts may be exacerbated if irrigation water availability declines due to climate change and
22 increased water demand in upstream regions. In Iran, changes in rainfall and water endowments are
23 projected to significantly impact crop yield and water requirements, as well as income and welfare of
24 farm families (Karimi et al. 2018).

25 Climate change impacts on food, feed and cash crops other than cereals, often grown in smallholder
26 systems or family farms are less often studied, although impacts can be substantial. For example,
27 areas suitable for growing coffee are expected to decrease by 21% in Ethiopia with global warming of
28 2.4°C (Moat et al. 2017) and more than 90% in Nicaragua (Läderach et al. 2017) with 2.2°C local
29 temperature increase.

30 Climate change can modify the relationship between crops and livestock in the landscape, affecting
31 mixed crop-livestock systems in many places. Where crop production will become marginal, livestock
32 may provide an alternative to cropping. Such transitions could occur in up to 3% of the total area of
33 Africa, largely as a result of increases in the probability of season failure in the drier mixed crop-
34 livestock systems of the continent (Thornton et al. 2014).

35 In Mexico, subsistence agriculture is expected to be the most vulnerable to climate change, due to its
36 intermittent production and reliance on maize and beans (Monterroso et al. 2014). Overall, a decrease
37 in suitability and yield is expected in Mexico and Central America for beans, coffee, maize, plantain
38 and rice (Donatti et al. 2018). Municipalities with a high proportional area under subsistence crops in
39 Central America tend to have less resources to promote innovation and action for adaptation
40 (Bouroncle et al. 2017).

41 In summary, smallholder farmers are especially vulnerable to climate change because their livelihoods
42 often depend primarily on agriculture. Further, smallholder farmers often suffer from chronic food
43 insecurity (*high confidence*). Climate change is projected to exacerbate risks of pests and diseases and
44 extreme weather events in smallholder farming systems.

45

1 **5.2.3 Climate change impacts on access**

2 Access to food involves the ability to obtain food, including the ability to purchase food at affordable
3 prices.

4

5 **5.2.3.1 Impacts on prices and risk of hunger**

6 A protocol-based analysis based on AgMIP methods tested a combination of RCPs and SSPs to
7 provide a range of projections for prices, risk of hunger, and land use change (Figure 5.7 and
8 Supplementary Material Table SM5.4.) (Hasegawa et al. 2018). Previous studies have found that
9 decreased agricultural productivity will depress agricultural supply, leading to price increases. Despite
10 different economic models with various representations of the global food system (Valin et al. 2014;
11 Robinson et al. 2014; Nelson et al. 2013; Schmitz et al. 2014), as well as having represented the SSPs
12 in different ways (i.e., technological change, land-use policies, sustainable diets, etc. (Stehfest et al.
13 2019; Hasegawa et al. 2018)), the ensemble of participating models projected a 1-29% cereal price
14 increase in 2050 across SSPs 1, 2, and 3 due to climate change (RCP 6.0), which would impact
15 consumers globally through higher food prices; regional effects will vary. The median cereal price
16 increase was 7%, given current projections of demand. In all cases (across SSPs and global economic
17 models), prices are projected to increase for rice and coarse grains, with only one instance of a price
18 decline (-1%) observed for wheat in SSP1, with price increases projected in all other cases. Animal-
19 sourced foods (ASFs) are also projected to see price increases (1%), but the range of projected price
20 changes are about half those of cereals, highlighting that the climate impacts on ASFs is indirect
21 through the cost and availability of feed, and that there is significant scope for feed substitution within
22 the livestock sector.

1
 2 **Figure 5.7. Implications of climate change by 2050 on land-use, selected agricultural commodity prices,**
 3 **and the population at risk of hunger based on AgMIP Global Economic Model analysis. (A) Projected %**
 4 **change in land-use by 2050 by land type (cropland, grassland, and forest) and SSP. (B) Projected %**
 5 **changes in average world prices by 2050 for cereals (rice, wheat, and coarse grains) and animal sourced**
 6 **foods (ruminant meat, monogastric, and dairy) by SSP. (C) Percentage change by 2050 in the global**
 7 **population at risk of hunger by SSP.**

8 Declining food availability caused by climate change is likely to lead to increasing food cost
 9 impacting consumers globally through higher prices and reduced purchasing power, with low-income
 10 consumers particularly at risk from higher food prices (Nelson et al. 2010; Springmann et al. 2016a;
 11 Nelson et al. 2018). Higher prices depress consumer demand, which in turn will not only reduce
 12 energy intake (calories) globally (Hasegawa et al. 2015; Nelson et al. 2010; Springmann et al. 2016a;
 13 Hasegawa et al. 2018), but will also likely lead to less healthy diets with lower availability of key
 14 micronutrients (Nelson et al. 2018) and increase diet-related mortality in lower and middle-income
 15 countries (Springmann et al. 2016a). These changes will slow progress towards the eradication of
 16 malnutrition in all its forms.

17 The extent that reduced energy intake leads to a heightened risk of hunger varies by global economic
 18 model. However, all models project an increase in the risk of hunger, with the median projection of an

1 increase in the population at risk of insufficient energy intake by 6, 14, and 12 % in 2050 for SSPs 1,
2 2 and 3 respectively compared to a no climate change reference scenario. This median percentage
3 increase would be the equivalent of 8, 24, and 80 million (full range 1-183 million) additional people
4 at risk of hunger due to climate change (Hasegawa et al. 2018).

6 **5.2.3.2 Impacts on land use**

7 Climate change is likely to lead to changes in land use globally (Nelson et al. 2014; Schmitz et al.
8 2014; Wiebe et al. 2015). Hasegawa et al. (2018) found that declining agricultural productivity
9 broadly leads to the need for additional cropland, with 7 of 8 models projecting increasing cropland
10 and the median increase by 2050 projected across all models of 2 % compared to a no climate change
11 reference (Figure 5.7). Not all regions will respond to climate impacts equally, with more uncertainty
12 on regional land-use change across the model ensemble than the global totals might suggest. For
13 example, the median land-use change for Latin America is an increase of cropland by 3 %, but the
14 range across the model ensemble is significant, with 3 models projecting declines in cropland (-25 –-1
15 %) compared to the 5 models projecting cropland increase (0 – 5 %). For further discussion on land
16 use change and food security see Section 5.6.

18 **5.2.4 Climate change impacts on food utilisation**

19 Food utilisation involves nutrient composition of food, its preparation, and overall state of health.
20 Food safety and quality affects food utilisation.

22 **5.2.4.1 Impacts on food safety and human health**

23 Climate change can influence food safety through changing the population dynamics of contaminating
24 organisms due to, for example, changes in temperature and precipitation patterns, and also humidity,
25 increased frequency and intensity of extreme weather events, and changes in contaminant transport
26 pathways. Changes in food and farming systems, e.g., intensification to maintain supply under climate
27 change, may also increase vulnerabilities as the climate changes (Tirado et al. 2010). Climate-related
28 changes in the biology of contaminating organisms include changing the activity of mycotoxin-
29 producing fungi, changing the activity of micro-organisms in aquatic food chains that cause disease
30 (e.g., dinoflagellates, bacteria like *Vibrio*), and increasingly heavy rainfall and floods causing
31 contamination of pastures with enteric microbes (like *Salmonella*) that can enter the human food
32 chain. Degradation and spoilage of products in storage and transport can also be affected by changing
33 humidity and temperature outside of cold chains, notably from microbial decay but also from potential
34 changes in the population dynamics of stored product pests (e.g., mites, beetles, moths) (Moses et al.
35 2015).

36 Mycotoxin-producing fungi occur in specific conditions of temperature and humidity, so climate
37 change will affect their range, increasing risks in some areas (such as mid-temperate latitudes) and
38 reducing them in others (e.g., the tropics) (Paterson and Lima 2010). There is *robust evidence* from
39 process-based models of particular species (*Aspergillus*/Aflatoxin B1, *Fusarium*/deoxynivalenol) with
40 projections of future climate that show that aflatoxin contamination of maize in southern Europe will
41 increase significantly (Battilani et al. 2016), and deoxynivalenol contamination of wheat in north-west
42 Europe will increase by up to 3 times (van der Fels-Klerx et al. 2012b,a). Whilst the downscaled
43 climate models make any specific projection for a given geography uncertain (Van der Fels-Klerx et
44 al. 2013), experimental evidence on the small scale suggests that the combination of rising CO₂ levels,
45 affecting physiological processes in photosynthetic organisms, and temperature changes, can be
46 significantly greater than temperature alone (Medina et al. 2014). Risks related to aflatoxins are likely

1 to change, but detailed projections are difficult because they depend on local conditions (Vaughan et
2 al. 2016).

3 Foodborne pathogens in the terrestrial environment typically come from enteric contamination (from
4 humans or animals), and can be spread by wind (blowing contaminated soil) or flooding – the
5 incidence of both of which are likely to increase with climate change (Hellberg and Chu 2016).
6 Furthermore, water stored for irrigation, which may be increased in some regions as an adaptation
7 strategy, can become an important route for the spread of pathogens (as well as other pollutants);
8 contaminated water and diarrheal diseases are acute threats to food security (Bond et al. 2018). Whilst
9 there is little direct evidence (in terms of modelled projections) the results of a range of reviews, as
10 well as expert groups, suggest that risks from foodborne pathogens are likely to increase through
11 multiple mechanisms (Tirado et al. 2010; van der Spiegel et al. 2012; Liu et al. 2013; Kirezieva et al.
12 2015; Hellberg and Chu 2016).

13 An additional route to climate change impacts on human health can arise from the changing biology
14 of plants altering human exposure levels. This may include climate changing how crops sequester
15 heavy metals (Rajkumar et al. 2013), or how they respond to changing pest pressure (e.g., cassava
16 produces hydrogen cyanide as a defence against herbivore attack).

17 All of these factors will lead to regional differences regarding food safety impacts (Paterson and Lima
18 2011). For instance, in Europe it is expected that most important food safety-related impacts will be
19 mycotoxins formed on plant products in the field or during storage; residues of pesticides in plant
20 products affected by changes in pest pressure; trace elements and/or heavy metals in plant products
21 depending on changes in abundance and availability in soils; polycyclic aromatic hydrocarbons in
22 foods following changes in long-range atmospheric transport and deposition; and presence of
23 pathogenic bacteria in foods following more frequent extreme weather, such as flooding and heat
24 waves (Miraglia et al. 2009).

25 In summary, there is *medium evidence*, with *high agreement* that food utilisation via changes in food
26 safety (and potentially food access from food loss) will be impacted by climate change, mostly by
27 increasing risks, but there is *low confidence*, exactly how they may change for any given place.

28

29 **5.2.4.2 Impacts on food quality**

30 There are two main routes by which food quality may change. First, the direct effects of climate
31 change on plant and animal biology, such as through changing temperatures changing the basic
32 metabolism of plants. Secondly, by increasing carbon dioxide's effect on biology through CO₂
33 fertilisation.

34 *Direct effects on plant and animal biology.* Climate affects a range of biological processes, including
35 the metabolic rate in plants and ectothermic animals. Changing these processes can change growth
36 rates, and therefore yields, but can also cause organisms to change relative investments in growth vs
37 reproduction, and therefore change the nutrients assimilated. This may decrease protein and mineral
38 nutrient concentrations, as well as alter lipid composition (DaMatta et al. 2010). For example, apples
39 in Japan have been exposed to higher temperatures over 3–4 decades and have responded by
40 blooming earlier. This has led to changes in acidity, firmness, and water content, reducing quality
41 (Sugiura et al. 2013). In other fruit, such as grapes, warming-induced changes in sugar composition
42 affect both colour and aroma (Mira de Orduña 2010). Changing heat stress in poultry can affect yield
43 as well as meat quality (by altering fat deposition and chemical constituents), shell quality of eggs,
44 and immune systems (Lara and Rostagno 2013).

45 *Effects of rising CO₂ concentrations.* Climate change is being driven by rising concentrations of
46 carbon dioxide and other greenhouse gases in the atmosphere. As plants use CO₂ in photosynthesis to

1 form sugar, rising CO₂ levels, all things being equal, enhances the process unless limited by water or
2 nitrogen availability. This is known as “CO₂ fertilisation”. Furthermore, increasing CO₂ allows the
3 stomata to be open for a shorter period for gas exchange, reducing water loss through transpiration.
4 These two factors affect the metabolism of plants, and, as with changing temperatures, affects plant
5 growth rates, yields and their nutritional quality. Studies of these effects include meta-analyses,
6 modelling, and small-scale experiments (Franzaring et al. 2013; Mishra and Agrawal 2014; Myers et
7 al. 2014; Ishigooka et al. 2017; Zhu et al. 2018; Loladze 2014; Yu et al. 2014)

8 In regard to nutrient quality, a meta-analysis from seven Free-Air Carbon dioxide Enrichment
9 (FACE), (with elevated atmospheric CO₂ concentration of 546–586 ppm) experiments (Myers et al.
10 2014), found that wheat grains had 9.3% lower zinc (CI 5.9–12.7%), 5.1% lower iron (CI 3.7–6.5%)
11 and 6.3% lower protein (CI 5.2–7.5%), and rice grains had 7.8% lower protein content (CI 6.8–8.9%).
12 Changes in nutrient concentration in field pea, soybean and C4 crops such as sorghum and maize were
13 small or insignificant. Zhu et al. (2018) report a meta-analysis of FACE trials on a range of rice
14 cultivars. They show that protein declines by an average of 10% under elevated CO₂, iron and zinc
15 decline by 8% and 5% respectively. Furthermore, a range of vitamins show large declines across all
16 rice cultivars, including B1 (-17%), B2 (-17%), B5 (-13%) and B9 (-30%), whereas Vitamin E
17 increased. As rice underpins the diets of many of the world’s poorest people in low-income countries,
18 especially in Asia, Zhu et al. (2018) estimate that these changes under high CO₂ may affect the
19 nutrient status of about 600 million people.

20 Decreases in protein concentration with elevated CO₂ are related to reduced nitrogen concentration
21 possibly caused by nitrogen uptake not keeping up with biomass growth, an effect called
22 ‘carbohydrate dilution’ or ‘growth dilution’, and by inhibition of photorespiration which can provide
23 much of the energy used for assimilating nitrate into proteins (Bahrami et al. 2017). Other
24 mechanisms have also been postulated (Feng et al. 2015; Bloom et al. 2014; Taub and Wang 2008).
25 Together, the impacts on protein availability may take as many as 150 million people into protein
26 deficiency by 2050 (Medek et al. 2017). Legume and vegetable yields increased with elevated CO₂
27 concentration of 250 ppm above ambient by 22% (CI 11.6–32.5%), with a stronger effect on leafy
28 vegetables than on legumes and no impact for changes in iron, vitamin C or flavonoid concentration
29 (Scheelbeek et al. 2018).

30 Increasing concentrations of atmospheric CO₂ lower the content of zinc and other nutrients in
31 important food crops. Dietary deficiencies of zinc and iron are a substantial global public health
32 problem (Myers et al. 2014). An estimated two billion people suffer these deficiencies (FAO 2013a),
33 causing a loss of 63 million life-years annually (Myers et al. 2014). Most of these people depend on
34 C3 grain legumes as their primary dietary source of zinc and iron. Zinc deficiency is currently
35 responsible for large burdens of disease globally, and the populations who are at highest risk of zinc
36 deficiency receive most of their dietary zinc from crops (Myers et al. 2015). The total number of
37 people estimated to be placed at new risk of zinc deficiency by 2050 is 138 million. The people likely
38 to be most affected live in Africa and South Asia, with nearly 48 million residing in India alone.
39 Differences between cultivars of a single crop suggest that breeding for decreased sensitivity to
40 atmospheric CO₂ concentration could partly address these new challenges to global health (Myers et
41 al. 2014).

42 In summary, while increased CO₂ is projected to be beneficial for crop productivity at lower
43 temperature increases, it is projected to lower nutritional quality (e.g., less protein, zinc, and iron)
44 (*high confidence*).

45

1 **5.2.5 Climate change impacts on food stability**

2 Food stability is related to people's ability to access and use food in a steady way, so that there not
3 intervening periods of hunger. Increasing extreme events associated with climate change can disrupt
4 food stability. (See Section 5.8.1 for assessment of food price spikes.)

5

6 **5.2.5.1 Impacts of extreme events**

7 FAO et al. (2018) conducted an analysis of prevalence of undernourishment (PoU) and found that in
8 2017, the average of the prevalence of undernourishment (PoU) was 15.4% for all countries exposed
9 to climate extremes (See Supplementary Material Figure SM5.2). At the same time, the PoU was 20%
10 for countries that additionally show high vulnerability of agriculture production/yields to climate
11 variability, or 22.4% for countries with high PoU vulnerability to severe drought. When there is both
12 high vulnerability of agriculture production/yields and high PoU sensitivity to severe drought, the
13 PoU is 9.8 points higher (25.2%). These vulnerabilities were found to be higher when countries had a
14 high dependence on agriculture as measured by the number of people employed in the sector.
15 Bangkok experienced severe flooding in 2011-2012 with large-scale disruption of the national food
16 supply chains since they were centrally organised in the capital city (Allen et al. 2017).

17 The IPCC projects that frequency, duration, and intensity of some extreme events will increase in the
18 coming decades (IPCC 2018a, 2012). To test these effects on food security, Tigchelaar et al. (2018)
19 showed rising instability in global grain trade and international grain prices, affecting especially the
20 about 800 million people living in extreme poverty who are most vulnerable to food price spikes (see
21 Section 5.8.1). They used global datasets of maize production and climate variability combined with
22 future temperature projections to quantify how yield variability will change in the world's major
23 maize-producing and -exporting countries under 2°C and 4°C of global warming.

24 Tesfaye et al. (2017) projected that the extent of heat-stressed areas in South Asia could increase by
25 up to 12% in 2030 and 21% in 2050 relative to the baseline (1950–2000). Another recent study found
26 that drier regions are projected to dry earlier, more severely and to a greater extent than humid
27 regions, with the population of sub-Saharan Africa most vulnerable (Lickley and Solomon 2018).

28

29 **5.2.5.2 Food aid**

30 Food aid plays an important role in providing food security and saving lives after climate disasters. In
31 2015, 14.5 million people were assisted through disaster-risk reduction, climate change and/or
32 resilience building activities (WFP 2018). However, there is no agreement on how to better use
33 emergency food aid, since it can come with unintended consequences for individuals, groups, regions,
34 and countries (Barrett 2006). These may include negative dependency of food recipients (Lentz et al.
35 2005) or price increases, among others.

36 Some authors state that tied food aid provided as “in kind” by the donor country hampers local food
37 production (Clay 2006), although others found no evidence of this (Ferrière and Suwa-Eisenmann
38 2015). Untied cash aid can be used to buy food locally or in neighbouring countries, which is cheaper
39 and can contribute to improving the livelihoods of local farmers (Clay 2006).

40 Ahlgren et al. (2014) found that food aid dependence of Marshall Islands due to climate change
41 impacts can result in poor health outcomes due to the poor nutritional quality of food aid, which may
42 result in future increases of chronic diseases. In this regard, Mary et al. (2018) showed that nutrition-
43 sensitive aid can reduce the prevalence of undernourishment.

44 In summary, based on AR5 and SR15 assessments that the likelihood that extreme weather will
45 increase, (e.g., increases in heatwaves, droughts, inland and coastal flooding due to sea level rise

1 depending on region) in both frequency and magnitude, decreases in food stability and thus increases
2 in food insecurity will likely rise as well (*medium evidence, high agreement*).

4 **5.3 Adaptation options, challenges, and opportunities**

5 This section assesses the large body of literature on food system adaptation to climate change,
6 including increasing extreme events, within a framework of autonomous, incremental, and
7 transformational adaptation. It focuses primarily on regional and local considerations and adaptation
8 options for both the supply side (production, storage, transport, processing, and trade) and the demand
9 side (consumption and diets) of the food system. Agroecological, social, and cultural contexts are
10 considered throughout. Finally, the section assesses the role of institutional measures at global,
11 regional (multiple countries), national, and local scales and capacity-building.

13 **5.3.1 Challenges and opportunities**

14 By formulating effective adaptation strategies, it is possible to reduce or even avoid some of the
15 negative impacts of climate change on food security (See Section 5.2). However, if unabated climate
16 change continues, limits to adaptation will be reached (SR15). In the food system, adaptation actions
17 involve any activities designed to reduce vulnerability and enhance resilience of the system to climate
18 change. In some areas, expanded climate envelopes will alter agro-ecological zones, with opportunity
19 for expansion towards higher latitudes and altitudes, soil and water resources permitting (Rosenzweig
20 and Hillel 2015).

21 More extreme climatic events are projected to lead to more agro-meteorological disasters with
22 associated economic and social losses. There are many options for adapting the food system to
23 extreme events reported in IPCC (2012), highlighting measures that reduce exposure and vulnerability
24 and increase resilience, even though risks cannot fully be eliminated (IPCC 2012). Adaptation
25 responses to extreme events aim to minimise damages, modify threats, prevent adverse impacts, or
26 share losses, thus making the system more resilient (Harvey et al. 2014a).

27 With current and projected climate change (higher temperature, changes in precipitation, flooding and
28 extremes events), achieving adaptation will require both technological (e.g., recovering and improving
29 orphan crops, new cultivars from breeding or biotechnology) and non-technological (e.g., market,
30 land management, diet change) solutions. Climate interacts with other factors such as market supplies
31 over longer distances and policy drivers (Mbow et al. 2008; Howden et al. 2007), as well as local
32 agricultural productivity to determine access to food locally.

33 Given the site-specific nature of climate change impacts on food system components together with
34 wide variation in agroecosystems types and management, and socio-economic conditions, it is widely
35 understood that adaptation strategies are linked to environmental and cultural contexts at the regional
36 and local levels (*high confidence*). Developing systemic resilience that integrates climate drivers with
37 social and economic drivers would reduce the impact on food security, particularly in developing
38 countries. For example, in Africa, improving food security requires evolving food systems to be
39 highly climate resilient, while supporting the need for increasing yield to feed the growing population
40 (Mbow et al. 2014b) (Box 5.2).

41 Adaptation involves producing more food where needed, moderating demand, reducing waste, and
42 improving governance (Godfray and Garnett 2014) (see Section 5.6 for the significant synergies
43 between adaptation and mitigation through specific practices, actions and strategies.).

1 **Box 5.2 Sustainable solutions for food systems and climate change in Africa**

2 Climate change, land use change, and food security are important aspects of sustainability policies in
 3 Africa. According to the McKinsey Global Institute (2010), Africa has around 60% of the global
 4 uncultivated arable land; thus the continent has a high potential for transformative change in food
 5 production. With short and long-term climate change impacts combined with local poverty conditions,
 6 land degradation and poor farming practices, Africa cannot grow enough food to feed its rapidly
 7 growing population. Sustainable improvement of productivity is essential, even as the impacts of
 8 climate change on food security in Africa are projected to be plural and severe.

9 Sustainable Land Management (SLM) of farming systems is important to address climate change
 10 while dealing with these daunting food security needs and the necessity to improve access to
 11 nutritious food to maintain healthy and active lives in Africa (AGRA 2017). SLM has functions
 12 beyond the production of food, such as delivery of water, protection against disease (especially
 13 zoonotic diseases), the delivery of energy, fibre and building materials.

14 Commodity-based systems—driven by external markets—are increasing in Africa (cotton, cocoa,
 15 coffee, oil palm, groundnuts) with important impacts on the use of land and climate. Land
 16 degradation, decreasing water resources, loss of biodiversity, excessive use of synthetic fertilisers and
 17 pesticides are some of the environmental challenges that influence preparedness to adapt to climate
 18 change (Pretty and Bharucha 2015).

19 A balanced strategy on African agriculture can be based on SLM and multifunctional land use
 20 approaches combining food production, cash crops, ecosystem services, biodiversity conservation,
 21 and ecosystem services delivery, and indigenous and local knowledge.

22 Thus, sustainable food systems in Africa entail multiple dimensions as shown in Figure 5.7.

24
 25 **Figure 5.7 Factors influencing sustainable food systems in Africa**

26 With rapid urbanisation, it is important to use combined land goals (e.g., zero-carbon energy, smart
 27 irrigation systems, and climate-resilient agriculture) to minimise the negative side effects of climate
 28 change while securing quality food for a growing population.

29 Building resilience into productivity and production can be based on simultaneous attention to the
 30 following five overarching issues:

31 1) Closing yield gaps through adapted cultivars, sustainable land management, that
 32 combine production and preservation of ecosystems essential functions such as sustainable

1 intensification approaches based on conservation agriculture and community-based adaptation with
2 functioning support services and market access (Mbow et al. 2014a).

3 2) Identifying Sustainable Land Management practices (agroecology, agroforestry, etc.)
4 addressing different ecosystem services (food production, biodiversity, reduction of GHG emissions,
5 soil carbon sequestration) for improved land-based climate change adaptation and mitigation (Sanz et
6 al. 2017; Francis 2016).

7 3) Paying attention to the food-energy-water nexus, especially water use and
8 reutilisation efficiency but also management of rain water (Albrecht et al. 2018).

9 4) Implementing institutional designs focused on youth, women through new economic
10 models that help access credit and loans to support policies that balance cash and food crops.

11 5) Build on and use of local knowledge, culture and traditions while seeking innovations
12 for food waste reduction and transformation of agricultural products.

13 These aspects suppose both incremental and transformational adaptation that may stem from better
14 infrastructure (storage and food processing), adoption of harvest and post-harvest technologies that
15 minimise food waste, and development of new opportunities for farmers to respond to environmental,
16 economic and social shocks that affect their livelihoods (Morton 2017).

17 Agriculture in Africa offers a unique opportunity for merging adaptation to and mitigation of climate
18 change with sustainable production to ensure food security (CCAFS 2012; FAO 2012). Initiatives
19 throughout the food system on both the supply and demand sides can lead to positive outcomes.

21 **5.3.2 Adaptation framing and key concepts**

22 **5.3.2.1 Autonomous, incremental, and transformational adaptation**

23 Framing of adaptation in this section categorises and assesses adaptation measures as autonomous,
24 incremental, and transformational (See Glossary and Table 5.3). Adaptation responses can be reactive
25 or anticipatory.

26 *Autonomous.* Autonomous adaptation in food systems does not constitute a conscious response to
27 climatic stimuli but is triggered by changes in agroecosystems, markets, or welfare changes. It is also
28 referred to as spontaneous adaptation (IPCC 2007). Examples of autonomous adaptation of rural
29 populations have been documented in the Sahel (IRD 2017). In India, farmers are changing sowing
30 and harvesting timing, cultivating short duration varieties, inter-cropping, changing cropping patterns,
31 investing in irrigation, and establishing agroforestry. These are considered as passive responses or
32 autonomous adaptation, because they do not acknowledge that these steps are taken in response to
33 perceived climatic changes (Tripathi and Mishra 2017).

34 *Incremental.* Incremental adaptation maintains the essence and integrity of a system or process at a
35 given scale (Park et al. 2012). Incremental adaptation focuses on improvements to existing resources
36 and management practices. The central aim of incremental adaptation is to maintain the essence and
37 integrity of a system or process at a given scale (IPCC 2014a).

38 *Transformational.* Transformational adaptation changes the fundamental attributes of a socio-
39 ecological system either in anticipation of or in response to climate change and its impacts (IPCC
40 2014a). Transformational adaptation seeks alternative livelihoods and land use strategies needed to
41 develop new farming systems (Termeer et al. 2016). For example, limitations in incremental
42 adaptation among smallholder rice farmers in Northwest Costa Rica led to a shift from rice to
43 sugarcane production due to decreasing market access and water scarcity (Warner et al. 2015).
44 Migration from the Oldman River Basin has been described as a transformational adaptation to climate

1 change in the Canadian agriculture sector (Hadarits et al. 2017). If high-end scenarios of climate
 2 change eventuate, the food security of farmers and consumers will depend on how transformational
 3 change in food systems is managed. An integrated framework of adaptive transition – management of
 4 socio-technical transitions and adaptation to socio-ecological changes – may help build
 5 transformational adaptive capacity (Mockshell and Kamanda 2018; Pant et al. 2015). Rippke et al.
 6 (2016) has suggested overlapping phases of adaptation needed to support transformational change in
 7 Africa.

8
 9 **Table 5.3 Synthesis of food security related adaptation options to address various climate risks (IPCC**
 10 **2014b; Vermeulen et al. 2013, 2018; Burnham and Ma 2016; Bhatta and Aggarwal 2016)**

Key climate drivers and risks	Incremental adaptation	Transformational adaptation	Enabling conditions
<p>Extreme events and short-term climate variability</p> <p>Stress on water resources, drought stress, dry spells, heat extremes, flooding, shorter rainy seasons, pests</p>	<ul style="list-style-type: none"> - Change in variety, water management, water harvesting, supplemental irrigation during dry spells, - Planting dates, pest control, feed banks, - Transhumance, Other sources of revenue (e.g. charcoal, wild fruits, wood, temporary work) - Soil management, composting, 	<ul style="list-style-type: none"> - Early Warning Systems - Use of planning and prediction at seasonal to intra-seasonal climate risk to transition to a food safer condition. - Abandonment of monoculture, diversification - Crop and livestock insurance - Alternate cropping, intercropping -Erosion control 	<ul style="list-style-type: none"> - Establishment of climate services - Integrated water management policies, integrated land and water governance - Seed banks, seed sovereignty and seed distribution policies - Capacity building and extension programs
<p>Warming trend, drying trend</p> <p>Reduced crop productivity due to persistent heat, long drought cycles, deforestation and land degradation with strong adverse effects on food production and nutrition quality, increased pest and disease damage</p>	<ul style="list-style-type: none"> - Strategies to reduce effects of recurring food challenges - Sustainable intensification, agroforestry, conservation agriculture, SLM - Adoption of existing drought-tolerant crop and livestock species - Counter season crop production, - Livestock fattening - New ecosystem-based adaptation (e.g. bee keeping, woodlots) 	<ul style="list-style-type: none"> - Climate services for new agricultural programs, e.g., sustainable irrigation districts) - New technology, e.g., new farming systems, new crops and livestock breeds - Switches between cropping and transhumant livelihoods, replacement of pasture or forest to irrigated/rainfed crops - Shifting to small ruminants or drought resistant livestock or fish 	<ul style="list-style-type: none"> - Climate information in local development policies. - Stallholders' access to credit and production resources, - National food security program based on increased productivity, diversification, transformation and trade - Strengthening (budget, capacities, expertise) of local and national institutions to support agriculture and

	<ul style="list-style-type: none"> - Farmers management of natural resources - Labor redistribution (e.g., mining, development projects, urban migration) - Adjustments to markets and trade pathways already in place 	<ul style="list-style-type: none"> farming Food storage infrastructures, food transformation - Changes in cropping area, land rehabilitation (enclosures, afforestation) perennial farming - New markets and trade pathways 	<ul style="list-style-type: none"> livestock breeding - Devolution to local communities, women empowerment, market opportunities - Incentives for establishing new markets and trade pathways
--	---	---	--

1

2 **5.3.2.2 Risk management**

3 Climate risks affect all pillars of food security, particularly stability because extreme events lead to
4 strong variation to food access. The notion of risk is widely treated in IPCC reports (IPCC 2014c) (see
5 also Chapter 7 in this report). With food systems, many risks co-occur or reinforce each other and this
6 can limit effective adaptation planning as they require a comprehensive and dynamic policy approach
7 covering a range of drivers and scales. For example, from the understanding by farmers of change in
8 risk profiles to the establishment of efficient markets that facilitate response strategies will require
9 more than systemic reviews of risk factors (Howden et al. 2007).

10 Integration of Climate Change Adaptation (CCA) and Disaster Risk Reduction (DRR) helps to
11 minimise the overlap and duplication of projects and programs (Nalau et al. 2016). Recently,
12 countries started integrating the concept of DRR and CCA. For instance, The Philippines has
13 introduced legislation calling for CCA and DRR integration as current policy instruments were largely
14 unsuccessful in combining agencies and experts across the two areas (Leon and Pittock 2016).

15 Studies reveal that the amplitude of interannual growing-season temperature variability is in general
16 larger than that of long-term temperature change in many locations. Responding better to seasonal
17 climate-induced food supply shocks therefore increases society's capability to adapt to climate
18 change. Given these backgrounds, seasonal crop forecasting and early response recommendations,
19 based on seasonal climate forecasts, are emerging to strengthen existing operational systems for
20 agricultural monitoring and forecasting (FAO 2016a; Ceglar et al. 2018; Iizumi et al. 2018).

21 While adaptation and mitigation measures are intended to reduce the risk from climate change
22 impacts in food systems, they can also be sources of risk themselves (e.g. investment risk, political
23 risk) (IPCC 2014b). Climate-related hazards are a necessary element of risks related to climate
24 impacts but may have little or nothing to do with risks related to some climate policies/responses

25 Adoption of agroecological practices could provide resilience for future shocks, spread farmer risk
26 and mitigate the impact of droughts (Niles et al. 2018) (See Section 5.3.2.3). Traditionally, risk
27 management is performed through multifunctional landscape approaches in which resource utilisation
28 is planned across wide areas and local agreements on resource access. Multifunctionality permits
29 vulnerable communities to access various resources at various times and under various risk conditions
30 (Minang et al. 2015).

31 In many countries, governmental compensation for crop-failure and financial losses are used to
32 protect against risk of severe yield reductions. Both public and private sector groups develop
33 insurance markets and improve and disseminate index-based weather insurance programs.

1 Catastrophe bonds, microfinance, disaster contingency funds, and cash transfers are other available
2 mechanisms for risk management.

3 In summary, risk management can be accomplished through agro-ecological landscape approaches
4 and risk sharing and transfer mechanisms such as development of insurance markets and improve
5 index-based weather insurance programs (*high confidence*).

6

7 **5.3.2.3 Role of agroecology and diversification**

8 Agro-ecological systems are integrated land-use systems that maintain species diversity in a range of
9 productive niches. Diversified cropping systems and practicing traditional agro-ecosystems of crop
10 production where a wide range of crop varieties are grown in various spatial and temporal
11 arrangements, are less vulnerable to catastrophic loss (Zhu et al. 2011). The use of local genetic
12 diversity, soil organic matter enhancement, multiple-cropping or poly-culture systems, and home
13 gardening, agro-ecological approaches can build resilience against extreme climate events (Altieri and
14 Koohafkan 2008). However, Nie et al. (2016) argued that while integrated crop-livestock systems
15 present some opportunities such as control of weeds, pests and diseases, and environmental benefits,
16 there are some challenges, including yield reduction, difficulty in pasture-cropping, grazing, and
17 groundcover maintenance in high rainfall zones, and development of persistent weeds and pests.
18 Adaptation measures based on agroecology entail enhancement of agrobiodiversity; improvement of
19 ecological processes and delivery of ecosystem services. They also entail strengthening of local
20 communities and recognition of the role and value of indigenous and local knowledge. Such practices
21 can enhance the sustainability and resilience of agricultural systems by buffering climate extremes,
22 reducing degradation of soils, and reversing unsustainable use of resources; outbreak of pests and
23 diseases and consequently increase yield without damaging biodiversity. Increasing and conserving
24 biological diversity such as soil microorganisms can promote high crop yields and sustain the
25 environment (Schmitz et al 2015; Bhattacharyya et al 2016; Garibaldi et al 2017).

26 Diversification of many components of the food system is a key element for increasing performance
27 and efficiency that may translate into increased resilience and reduced risks (integrated land
28 management systems, agrobiodiversity, indigenous and local knowledge, local food systems, dietary
29 diversity, the sustainable use of indigenous fruits, neglected and underutilised crops as a food source)
30 (*medium confidence*) (Makate et al. 2016; Lin 2011; Awodoyin et al. 2015).

31 The more diverse the food systems are, the more resilient they are in enhancing food security in the
32 face of biotic and abiotic stresses. Diverse production systems are important for providing regulatory
33 ecosystem services such as nutrient cycling, carbon sequestration, soil erosion control, reduction of
34 GHG emissions and control of hydrological processes (Chivenge et al. 2015). Further options for
35 adapting to change in both mean climate and extreme events are livelihood diversification (Michael
36 2017; Ford et al. 2015), and production diversity (Sibhatu et al. 2015).

37 Crop diversification, maintaining local genetic diversity, animal integration, soil organic matter
38 management, water conservation, and harvesting the role of microbial assemblages. These types of
39 farm management significantly affect communities in soil, plant structure, and crop growth in terms
40 of number, type, and abundance of species (Morrison-Whittle et al. 2017). Complementary strategies
41 towards sustainable agriculture (ecological intensification, strengthening existing diverse farming
42 systems and investment in ecological infrastructure) also address important drivers of pollinator
43 decline (IPBES 2016).

44 Evidence also shows that, together with other factors, on-farm agricultural diversity can translate into
45 dietary diversity at the farm level and beyond (Pimbert and Lemke 2018; Kumar et al. 2015; Sibhatu
46 et al. 2015). Dietary diversity is important but not enough as an adaptation option, but results in

1 positive health outcomes by increasing the variety of healthy products in people's diets and reducing
2 exposure to unhealthy environments.

3 Locally developed seeds and the concept of seed sovereignty can both help protect local
4 agrobiodiversity and can often be more climate resilient than generic commercial varieties (Watt
5 2016; Coomes et al., 2015; van Niekerk and Wynberg 2017; Vasconcelos et al. 2013). Seed exchange
6 networks and banks protect local agrobiodiversity and landraces, and can provide crucial lifelines
7 when crop harvests fail (Coomes et al. 2015; van Niekerk and Wynberg 2017; Vasconcelos et al.
8 2013).

9 Related to locally developed seeds, neglected and underutilised species (NUS) can play a key role in
10 increasing dietary diversity (*high confidence*) (Baldermann et al. 2016; van der Merwe et al. 2016;
11 Kahane et al. 2013; Muhanji et al. 2011) (see Box 5.3). These species can also improve nutritional and
12 economic security of excluded social groups, such as tribals (Nandal and Bhardwaj 2014; Ghosh-
13 Jerath et al. 2015), indigent (Kucich and Wicht 2016) or rural populations (Ngadze et al. 2017).

14

15 **Box 5.3 Climate change and indigenous food systems in the Hindu-Kush Himalayan** 16 **Region**

17 Diversification of production systems through promotion of Neglected and Underutilised Species
18 (NUS; also known as understudied, neglected, orphan, lost or disadvantaged crops) offers adaptation
19 opportunities to climate change, particularly in mountains. Neglected and Underutilised Species
20 (NUS) have a potential to improve food security and at the same time help protect and conserve
21 traditional knowledge and biodiversity. Scaling-up NUS requires training farmers and other
22 stakeholders on ways to adopt adequate crop management, quality seed, select varieties, farming
23 systems, soil management, development of new products, and market opportunities (Padulosi et al.
24 2013). Farmers in the Rasuwa district, in the mid-hills of Nepal, prefer to cultivate local bean, barley,
25 millet and local maize, rather than commodity crops because they are more tolerant to water stress and
26 extremely cold conditions (Adhikari et al. 2017). Farmers in the high-altitude cold climate of Nepal
27 prefer local barley with its short growing period because of a shorter growing window. Buckwheat is
28 commonly grown in the Hindu-Kush Himalayan (HKH) region mainly because it grows fast and
29 suppresses weeds. In Pakistan, quinoa (*Chenopodium quinoa*) grew and produced well under saline
30 and marginal soil where other crops would not grow (Adhikari et al. 2017).

31 At the same time, in many parts of the HKH region, a substantial proportion of the population is
32 facing malnutrition. Various factors are responsible for this, and lack of diversity in food and nutrition
33 resulting from production and consumption of few crops is one of them. In the past, food baskets in
34 this region consisted of many different edible plant species, many of which are now neglected and
35 underutilised. This is because almost all the efforts of the Green Revolution after 1960 focused on
36 major crops. Four crops viz. rice, wheat, maize and potato account for about 60% of global plant-
37 derived energy supply (Padulosi et al. 2013).

38 While the Green Revolution technologies substantially increased the yield of few crops and allowed
39 countries to reduce hunger, they also resulted in inappropriate and excessive use of agrochemicals,
40 inefficient water use, loss of beneficial biodiversity, water and soil pollution and significantly reduced
41 crop and varietal diversity. With farming systems moving away from subsistence-based to
42 commercial farming, farmers are also reluctant to grow these local crops because of low return, poor
43 market value and lack of knowledge about their nutritional environmental value.

44 However, transition from traditional diets based on local foods to a commercial crop-based diet with
45 high fats, salt, sugar and processed foods, increased the incidence of non-communicable diseases,
46 such as diabetes, obesity, heart diseases and certain types of cancer (Abarca-Gómez et al. 2017; NCD-

1 RisC 2016b, 2017b). This ‘hidden hunger’ – enough calories, but insufficient vitamins - is
2 increasingly evident in mountainous communities including the HKH region.

3 Internationally, there is rising interest nowadays on NUS, not only because they present tremendous
4 opportunities for fighting poverty, hunger and malnutrition, but also because of their role in mitigating
5 climate risk in agricultural production systems. NUS play an important role in mountain agro-
6 ecosystems because mountain agriculture is generally low-input agriculture, for which many NUS are
7 well adapted.

8 In the HKH region, mountains are agro-ecologically suitable for cultivation of traditional food crops,
9 such as barley, millet, sorghum, buckwheat, bean, grams, taro, yam and a vast range of wild fruits,
10 vegetables and medicinal plants. In one study carried out in two villages of mid-hills in Nepal, Khanal
11 et al. (2015) reported 52 indigenous crop species belonging to 27 families with their various uses.
12 Farming communities continue to grow various indigenous crops, albeit in marginal land, because of
13 their value on traditional food and associated culture. Nepal Agricultural Research Council (NARC)
14 has identified a list of indigenous crops based on their nutritional, medicinal, cultural and other
15 values.

16 Many indigenous crops supply essential micronutrients to the human body, and need to be conserved
17 in mountain food systems. Farmers in HKH region are cultivating and maintaining various indigenous
18 crops such as amaranthus, barley, black gram, horse gram, olarum, yam, rayo, sesame, niger, etc.
19 because of their nutritional value. Most of these indigenous crops are comparable with commercial
20 cereals in terms of dietary energy and protein content, but are also rich in micronutrients. For
21 example, pearl millet has higher content of calcium, iron, zinc, fiboflavin and folic acid than rice or
22 maize (Adhikari et al. 2017).

23 NUS can provide both climate resilience and more options for dietary diversity to the farming
24 communities of mountain ecosystems. Some of these indigenous crops have high medical importance.
25 For example, mountain people in the HKH region have been using *jammun* (i.e., *Syzygium cumini*) to
26 treat diabetes. In the Gilgit-Baltistan province of Pakistan, realising the importance of sea-buckthorn
27 for nutritional and medicinal purposes, local communities have expanded its cultivation to larger
28 areas. Many of these crops can be cultivated in marginal and/or fallow land which otherwise remains
29 fallow. Most of these species are drought resistant and can be easily grown in rainfed conditions in
30 non-irrigated land.

31
32 Dietary diversity has also been correlated (*medium evidence, medium agreement*) to agricultural
33 diversity in small-holder and subsistence farms (Ayenew et al. 2018; Jones et al. 2014; Jones 2017;
34 Pimbert and Lemke 2018), including both crops and animals, and has been proposed as a strategy to
35 reduce micronutrient malnutrition in developing countries (Tontisirin et al. 2002). In this regard, the
36 capacity of subsistence farming to supply essential nutrients in reasonable balance to the people
37 dependent on them has been considered as a means of overcoming their nutrient limitations in sound
38 agronomic and sustainable ways (Graham et al. 2007).

39 *Ecosystem-based adaptation (EbA)*. EbA is a set of nature-based methods addressing climate change
40 adaptation and food security by strengthening and conserving natural functions, goods and services
41 that benefit to people. EbA approaches to address food security provide co-benefits such as
42 contributions to health and improved diet, sustainable land management, economic revenue and water
43 security. EbA practices can reduce greenhouse gas emissions and increase carbon storage (USAID
44 2017).

45 For example, agroforestry systems can contribute to improving food productivity while enhancing
46 biodiversity conservation, ecological balance and restoration under changing climate conditions

1 (Mbow et al. 2014a; Paudela et al. 2017; Newaj et al. 2016; Altieri et al. 2015). Agroforestry systems
2 have been shown to reduce erosion through their canopy cover and their contribution to the micro-
3 climate and erosion control (Sida et al. 2018). Adoption of conservation farming practices such as
4 removing weeds from and dredging irrigation canals, draining and levelling land, and using organic
5 fertilisation were among the popular conservation practices in small-scale paddy rice farming
6 community of northern Iran (Ashoori and Sadegh 2016).

7 Adaptation potential of ecologically-intensive systems includes also forests and rivers ecosystems,
8 where improved resources management such as soil conservation, water cycling and agro-biodiversity
9 support the function of food production affected by severe climate change (Muthee et al. 2017). The
10 use of non-crop plant resources in agro-ecosystems (permaculture, perennial polyculture) can improve
11 ecosystem conservation and may lead to increased crop productivity (Balzan et al. 2016; Crews et al.
12 2018; Toensmeier 2016).

13 In summary, increasing the resilience of the food system through agroecology and diversification is an
14 effective way to achieve climate change adaptation (*robust evidence, high agreement*). Diversification
15 in the food system is a key adaptation strategy to reduce risks (e.g., implementation of integrated
16 production systems at landscape scales, broad-based genetic resources, and heterogeneous diets)
17 (*medium confidence*).

19 **5.3.2.4 Role of cultural values**

20 Food production and consumption are strongly influenced by cultures and beliefs. Culture, values and
21 norms are primary factors in most climate change and food system policies. The benefits of
22 integrating cultural beliefs and indigenous and local knowledge (ILK) into formal climate change
23 mitigation and adaptation strategies can add value to the development of sustainable climate change
24 that are rich in local aspirations, and planned with and for local people (Nyong et al. 2007).

25 Cultural dimensions are important in understanding how societies establish food production systems
26 and respond to climate change, since they help to explain differences in responses across populations
27 to the same environmental risks (Adger et al. 2013). There is an inherent adaptability of indigenous
28 people who are particularly connected to land use, developed for many centuries to produce specific
29 solutions to particular climate change challenges. Acknowledging that indigenous cultures across the
30 world are supporting many string strategies and beliefs that offer sustainable systems with pragmatic
31 solutions will help move forward the food and climate sustainability policies. For instance, in the
32 Sahel, the local populations have developed and implemented various adaptation strategies that
33 sustain their resilience despite many threats (Nyong et al. 2007). There is an increased consideration
34 of these local knowledge and cultural values and norms in the design and implementation of modern
35 mitigation and adaptation strategies.

36 There are some entrenched cultural beliefs and values that may be barriers to climate change
37 adaptation. For instance, culture has been shown to be a major barrier to adaptation for the Fulbe
38 ethnic group of Burkina Faso (Nielsen and Reenberg 2010). Thus, it is important to understand how
39 beliefs, values, practices and habits interact with the behaviour of individuals and collectivities that
40 have to confront climate change (Heyd and Thomas 2008). Granderson (2014) suggests that making
41 sense of climate change and its responses at the community level demands attention to the cultural
42 and political processes that shape how risk is conceived, prioritised and managed. For a discussion of
43 gender issues related to climate change, see Section 5.2.

44 Culturally sensitive risk analysis can deliver a better understanding of what climate change means for
45 society (O'Brien and Wolf 2010; Persson et al. 2015) and thus, how to better adapt. Murphy et al.
46 (2016) stated that culture and beliefs play an important role in adaptive capacity but that they are not

1 static. In the work done by Elum et al. (2017) in South Africa about farmers perception of climate
2 change, they concluded that perceptions and beliefs often have negative effects on adaptation options.

3 Culture is a key issue in food systems and the relation of people with nature. Food is an intrinsically
4 cultural process: food production shapes landscapes, which are in turn linked to cultural heritages and
5 identities (Koohafkan and Altieri 2011; Fuller and Qingwen 2013), and food consumption has a
6 strong cultural dimension. The loss of subsistence practices in modern cultures and its related
7 indigenous and local knowledge, has resulted in a loss of valuable adaptive capacities (Hernández-
8 Morcillo et al. 2014). This is so because these systems are often characterised by livelihood strategies
9 linked to the management of natural resources that that have been evolved to reduce overall
10 vulnerability to climate shocks (‘adaptive strategies’) and to manage their impacts ex-post (‘coping
11 strategies’) (Morton 2007; López-i-Gelats et al. 2016).

13 **5.3.3 Supply-side adaptation**

14 Supply-side adaptation takes place in the production (of crops, livestock, and aquaculture), storage,
15 transport, processing, and trade of food.

17 **5.3.3.1 Crop production**

18 There are many current agricultural management practices that can be optimised and scaled up to
19 advance adaptation. Among the often-studied adaptation options include increased soil organic matter,
20 improved cropland management, increased food productivity, prevention and reversal of soil erosion
21 (see Chapter 6 for evaluation of these practices in regard to desertification and land degradation).
22 Many analyses have demonstrated the effectiveness of soil management and changing sowing date,
23 crop type or variety (Waongo et al. 2015; Bodin et al. 2016; Teixeira et al. 2017; Waha et al. 2013;
24 Zimmermann et al. 2017; Chalise and Naranpanawa 2016; Moniruzzaman 2015; Sanz et al. 2017).
25 Biophysical adaptation options also include pest and disease management (Lamichhane et al. 2015)
26 and water management (Palmer et al. 2015; Korbel'ová and Kohnová 2017).

27 In Africa, Scheba (2017) found that conservation agriculture techniques were embedded in an
28 agriculture setting based on local traditional knowledge, including crop rotation, no or minimum
29 tillage, mulching, and cover crops. Cover cropping and no-tillage also improved soil health in a highly
30 commercialised arid irrigated system in California’s San Joaquin Valley, US (Mitchell et al. 2017).
31 Biofertilisers can enhance rice yields (Kantachote et al. 2016), and Amanullah and Khalid (2016)
32 found that manure and biofertiliser improve maize productivity under semi-arid conditions.

33 Adaptation also involves use of current genetic resources as well as breeding programs for both crops
34 and livestock. More drought, flood and heat-resistant crop varieties (Atlin et al. 2017; Mickelbart et
35 al. 2015; Singh et al. 2017) and improved nutrient and water use efficiency, including overabundance
36 as well as water quality (such as salinity) (Bond et al. 2018) are aspects to factor in to the design of
37 adaptation measures. Both availability and adoption of these varieties is a possible path of adaptation
38 and can be facilitated by new outreach policy and capacity building.

39 Water management is another key area for adaptation. Increasing water availability and reliability of
40 water for agricultural production using different techniques of water harvesting, storage, and its
41 judicious utilisation through farm ponds, dams, and community tanks in rainfed agriculture areas have
42 been presented by Rao et al. (2017) and Rivera-Ferre et al. (2016a). In addition, improved drainage
43 systems (Thiel et al. 2015), and Alternate Wetting and Drying (AWD) techniques for rice cultivation
44 (Howell et al. 2015; Rahman and Bulbul 2015) have been proposed. Efficient irrigation systems have
45 been also analysed and proposed by (Jägermeyr et al. 2016) Naresh et al (2017) (Gunarathna et al.

1 2017; Chartzoulakis and Bertaki 2015). Recent innovation includes using farming system with low
2 usage of water such as drip-irrigation or hydroponic systems mostly in urban farming.

3 4 **5.3.3.2 Livestock production systems**

5 Considering the benefits of higher temperature in temperate climate and the increase of pasture with
6 incremental warming in some humid and temperate grasslands, as well as potential negative effects,
7 can be useful in planning adaptation strategies to future climate change. Rivera-Ferre et al. (2016b)
8 characterize adaptation for different livestock systems as managerial, technical, behavioural and
9 policy-related options. Managerial included production adjustments (e.g., intensification, integration
10 with crops, shifting from grazing to browsing species, multispecies herds, mobility, soil and nutrient
11 management, water management, pasture management, corralling, feed and food storage, farm
12 diversification or cooling systems); and changes in labor allocation (diversifying livelihoods, shifting
13 to irrigated farming, labor flexibility). Technological options included breeding strategies and
14 information technology research. Behavioral options are linked to cultural patterns and included
15 encouraging social collaboration and reciprocity, e.g., livestock loans, communal planning, food
16 exchanges. and information sharing. Policy options are discussed in Section 5.7 and Chapter 7.

17 18 **5.3.3.3 Aquaculture, fisheries, and agriculture interactions**

19 Options may include livelihood diversification within and across sectors of fisheries, aquaculture and
20 agriculture. Thus, adaptation options need to provide management approaches and policies that build
21 the livelihood asset base, reducing vulnerability to multiple stressors with a multi-sector perspective
22 (Badjeck et al. 2010). In Bangladesh fishing pressure on post-larval prawns has increased as displaced
23 farmers have shifted to fishing following salt-water intrusion of agricultural land (Ahmed et al. 2013).
24 In West Africa, strategies to cope with sudden shifts in fisheries are wider-reaching and have included
25 turning to seafood import (Gephart et al. 2017) or terrestrial food production including farming and
26 bush-meat hunting on land (Brashares et al. 2004). Proposed actions for adaptation include effective
27 governance, improved management and conservation, efforts to maximise societal and environmental
28 benefits from trade, increased equitability of distribution and innovation in food production, and the
29 continued development of low-input and low-impact aquaculture (FAO 2018c).

30 Particular adaptation strategies proposed by FAO (2014a) include diverse and flexible livelihood
31 strategies, such as introduction of fish ponds in areas susceptible to intermittent flood/drought periods;
32 flood-friendly small-scale homestead bamboo pens with trap doors allowing seasonal floods to occur
33 without loss of stocked fish; cage fish aquaculture development using plankton feed in reservoirs
34 created by dam building; supporting the transition to different species, polyculture and integrated
35 systems, allowing for diversified and more resilient systems; promotion of rice–fish farming systems
36 reducing overall water needs and providing integrated pest management; and supporting transitions to
37 alternative livelihoods.

38 Risk reduction initiatives include innovative weather-based insurance schemes being tested for
39 applicability in aquaculture and fisheries and climate risk assessments introduced for integrated
40 coastal zone management. For aquaculture’s contribution to building resilient food systems, Troell et
41 al. (2014) found that aquaculture could potentially enhance resilience through improved resource use
42 efficiencies and increased diversification of farmed species, locales of production, and feeding
43 strategies. Yet, given its high reliance on terrestrial crops and wild fish for feeds, its dependence on
44 freshwater and land for culture sites and its environmental impacts reduce this potential. For instance,
45 the increase in aquaculture worldwide may enhance land competition for feed crops, increasing price
46 levels and volatility and worsening food insecurity among the most vulnerable populations.

1 **5.3.3.4 Transport and storage**

2 Fewer studies have been done on adaptation of food system transport and storage compared to the
3 many studies on adaptation to climate in food production.

4 *Transport.* One transport example is found in Bangkok. Between mid-November 2011 and early
5 January 2012, Bangkok, the capital city of Thailand, faced its most dramatic flood in approximately
6 70 years with most transport networks cut-off or destroyed. This caused large-scale disruption of the
7 national food supply chains since they were centrally organised in the capital city (Allen et al. 2017).
8 From this experience, the construction and management of ‘climate-proof’ rural roads and transport
9 networks is argued as one the most important adaptation strategies for climate change and food
10 security in Thailand (Rattanachot et al. 2015).

11 Similarly in Africa, it has been shown that enhanced transportation networks combined with other
12 measures could reduce the impact of climate change on food and nutrition security (Brown et al.
13 2017b). This suggests that strengthening infrastructure and logistics for transport would significantly
14 enhance resilience to climate change while improving food and nutrition security in developing
15 counties.

16 *Storage.* Storage refers to both structures and technologies for storing seed as well as produce.
17 Predominant storage methods used in Uganda are single-layer woven polypropylene bags (popularly
18 called “kavera” locally), chemical insecticides and granaries. Evidence from Omotilewa et al. (2018)
19 showed that the introduction of new storage technology called Purdue Improved Crop Storage (PICS)
20 could contribute to climate change adaptation. PICS is a chemical-free airtight triple-layered
21 technology consisting of two high-density polyethylene inner liners and one outer layer of woven
22 polypropylene bag. Its adoption has increased the number of households planting hybrid maize
23 varieties that are more susceptible to insect pests in storage than traditional lower-yielding varieties.
24 Such innovations could help to protect crops more safely and for longer periods from postharvest
25 insect pests that are projected to increase as result of climate change, thus contributing to food
26 security. In the Indo-Gangetic Plains many different storage structures based on ILK provide reliable
27 and low-cost options made of local materials. For example, elevated grain stores protect from floods,
28 but also provide for air circulation to prevent rot and to control insects and other vermin (Rivera-Ferre
29 et al. 2013).

30

31 **5.3.3.5 Trade and processing**

32 Adaptation measures are also being considered in trade, processing, and packaging, other components
33 of the food system. These will enable availability, stability, and safety of food under changing climate
34 conditions.

35 *Trade.* Brooks & Matthews (2015) found that food trade increases the availability of food by enabling
36 products to flow from surplus to deficit areas, raises incomes and favors access to food, improves
37 utilisation by increasing the diversity of national diets while pooling production risks across
38 individual markets to maintain stability.

39 *Processing.* Growth of spoilage bacteria of red meat and poultry during storage due to increasing
40 temperature has been demonstrated by European Food Safety Authority (EFSA Panel on Biological
41 Hazards 2016). In a recent experiment conducted on the optimisation of processing conditions of
42 Chinese traditional smoke-cured bacon (Larou), Liu et al. (2018a) showed that the use of new natural
43 coating solution composed of lysozyme, sodium alginate, and chitosan during storage period resulted
44 in 99.69% rate of reducing deterioration after 30-day storage. Also, the use of High Hydrostatic
45 Pressure (HHP) technology to inactivate pathogenic, spoilage microorganisms and enzymes with little
46 or no effects on the nutritional and sensory quality of foods have been described by Wang et al.

1 (2016) and Ali et al. (2018) as new advances in processing and packaging fruits, vegetables, meats,
2 seafood, dairy, and egg products.

3 In summary, there are many practices that can be optimised and scaled up to advance supply-side
4 adaptation. On-farm adaptation options include increased soil organic matter and erosion control in
5 cropland, improved livestock and grazing land management, and transition to different species,
6 polyculture and integrated systems in aquaculture. Crop and livestock genetic improvements include
7 tolerance to heat, drought, and pests and diseases. Food transport, storage, trade, and processing will
8 likely play increasingly important roles in adapting to climate change-induced food insecurity.

9

10 **5.3.4 Demand-side adaptation**

11 Adaptation in the demand side of the food system involves consumption practices, diets, and reducing
12 food loss and waste. Recent studies showed that supply-side adaptation measures alone will not be
13 sufficient to sustainably achieve food security under climate change (Springmann et al. 2018b;
14 Swinburn et al. 2019; Bajželj et al. 2014). As noted by Godfray (2015), people with higher income
15 demand more varied diets, and typically ones that are richer in meat and other food types that require
16 more resources to produce. Therefore, both supply-side (production, processing, transport, trade, etc.)
17 and demand-side solutions (changing diets, food loss and waste reduction, etc.) can be effective in
18 adapting to climate change (Creutzig et al. 2016) (see Section **Error! Reference source not found.**
19 or food loss and waste).

20 The implications of dietary choice can have severe consequences for land. For example, Alexander et
21 al. 2016, found that if every country were to adopt the UK's 2011 average diet and meat consumption,
22 95% of global habitable land area would be needed for agriculture – up from 50% of land currently
23 used. For the average US diet, 178% of global land would be needed (relative to 2011) (Alexander et
24 al. 2016); and for “business as usual” dietary trends and existing rates of improvement in yields, 55%
25 more land would be needed above baseline (2009) (Bajželj et al. 2014). Changing dietary habits has
26 been suggested as an effective food route to affect land use (Beheshti et al. 2017) and promote
27 adaptation to climate change through food demand.

28 Most literature has focused on demand-side options that analyse the effects on climate change
29 mitigation by dietary changes. Little focus has been brought on demand-side adaptation measures to
30 adjust the demand to the food challenges related to drivers such as market, climate change, inputs
31 limitations (e.g., fossil fuels, nitrogen, phosphorus), food access, and quality. Adding to that, the high
32 cost of nutritious foods contributes to a higher risk of overweight and obesity (FAO 2018d).
33 Adaptation measures relate also to the implications of easy access to inexpensive, high-calorie, low-
34 nutrition foods which have been shown to lead to malnutrition (Section 5.1). Therefore, adaptation
35 related to diet may be weighed against the negative side-effects on health of current food choices.

36 Reduction in the demand for animal-based food products and increasing proportions of plant-based
37 foods in diets, particularly pulses and nuts; and replacing red meat with other more-efficient protein
38 sources are demand-side adaptation measures (Machovina et al. 2015) (see also Section 5.5.2). For
39 example, replacing beef in the US diet with poultry can meet caloric and protein demands of about
40 120 to 140 million additional people consuming the average American diet (Shepon et al. 2016).
41 Similar suggestions are made for adopting the benefits of moving to plant-based protein, such as
42 beans (Harwatt et al. 2017).

43 The main reason why reducing meat consumption is an adaptation measure is because it reduces
44 pressure on land and water and thus our vulnerability to climate change and inputs limitations
45 (Vanham et al. 2013). For animal feed, ruminants can have positive ecological effects (species
46 diversity, soil carbon) if they are fed extensively on existing grasslands. Similarly, reducing waste at

1 all points along the entire food chain is a significant opportunity for improving demand-side
2 adaptation measures (Godfray 2015).

3 It is important to highlight the opportunities for improving the feed-to-meat conversion considered as
4 a form of food loss. However, the unique capacity of ruminants to produce high-quality food from
5 low-quality forage, in particular from landscapes that cannot be cropped and from cellulosic biomass
6 that humans cannot digest could be seen as an effective way to improve the feed:meat ratio (Cawthorn
7 and Hoffman 2015).

8 In summary, there is potential for demand-side adaptation, such as adoption of diets low in animal-
9 sourced products, in conjunction with reduction in food loss and waste to contribute to reduction in
10 food demand, land sparing, and thus need for adaptation.

11

12 **5.3.5 Institutional measures**

13 To facilitate the scaling up of adaptation throughout the food system, institutional measures are
14 needed at global, regional, national, and local levels (See Section 5.7). Institutional aspects including
15 policies and laws depend on scale and context. International institutions (financial and policies) are
16 driving many aspects of global food systems (e.g., UN agencies, international private sector
17 agribusinesses and retailers). Many others operate at local level and strongly influence livelihoods and
18 markets of smallholder farmers. Hence, differentiation in the roles of the organisations, their missions
19 and outcomes related to food and climate change action need to be clearly mapped and understood.

20 Awareness about the institutional context within which adaptation planning decisions are made is
21 essential for the usability of climate change projection (Lorenz 2017) (Chapter 7 SRCCL). In the
22 planning and operational process of food production, handling and consumption, the environment
23 benefits and climate change goals can be mainstreamed under sustainable management approaches
24 that favor alternative solutions for inputs, energy consumption, transformation and diet. For instance,
25 land use planning would guide current and future decision making and planners in exploring
26 uncertainty to increase the resilience of communities (Berke & Stevens 2016). One of the important
27 policy implications for enhanced food security are the trade-offs between agricultural production and
28 environmental concerns, including the asserted need for global land use expansion, biodiversity and
29 ecological restoration (See Section 5.6) (Meyfroidt 2017).

30 There are a number of adaptation options in agriculture in the form of policy, planning, governance
31 and institutions (Lorenz 2017). For example, early spatial planning action is crucial to guide decision-
32 making processes and foster resilience in highly uncertain future climate change (Brunner and Grêt-
33 Regamey, 2016). Institutions may develop new capacities to empower value chain actors take climate
34 change into account as they develop quality products, promote adoption of improved diet for healthier
35 lifestyles, aid the improvement of livelihoods of communities, and further socioeconomic
36 development (Sehmi et al. 2016). Other adaptation policies include property rights and land tenure
37 security as legal and institutional reforms to ensure transparency and access to land that could
38 stimulate adaptation to climate change Antwi-Agyei et al. (2015).

39

40 **5.3.5.1 Global initiatives**

41 Climate change poses serious wide-ranging risks, requiring a broader approach in fighting the
42 phenomenon. The United Nations Framework Convention on Climate Change (UNFCCC) and its
43 annual Conferences of the Parties (COPs) has been instrumental in ensuring international cooperation
44 in the field of tackling the impacts of climate change in a broader framework (Cléménçon 2016). The
45 National Adaptation Plan (NAP) program under the UNFCCC, was established to: identify vulnerable
46 regions; assess the impacts of climate change on food security; and prioritise adaptation measures for

1 implementation to increase resilience. The National Adaptation Programs of Action (NAPAs) was
2 also established to support least-developed countries (LDCs) address their particular challenges in
3 adaptation, to enhance food security among other priorities. The Paris Agreement (UNFCCC 2015) is
4 a major victory for small island states and vulnerable nations that face climate change-related impacts
5 of floods and droughts resulting in food security challenges. Adaptation and mitigation targets set by
6 the parties through their nationally determined commitments (NDCs) are reviewed internationally to
7 ensure consistency and progress towards actions (Falkner 2016).

8 The Food and Agriculture Organization of the United Nations (FAO) also plays a significant role in
9 designing and coordinating national policies to increase adaptation and food security. The five key
10 strategic objectives of FAO (Help eliminate hunger, food insecurity and malnutrition; Make
11 agriculture, forestry and fisheries more productive and sustainable; Reduce rural poverty; Enable
12 inclusive and efficient agricultural and food systems; and increase the resilience of livelihoods to
13 climate threats) (FAO 2018e), all relate to building resilience and increasing global adaptation to
14 climate variability.

15 In support of the Paris Agreement, FAO launched a global policy, “Tracking Adaptation” with the
16 aim of monitoring the adaptation processes and outcomes of the parties to increase food security, and
17 make available technical information for evaluation by stakeholders. In response to the estimated
18 world population of 9.7 billion by 2050, FAO adopted the Climate Smart Agriculture (CSA) approach
19 to increase global food security without compromising environmental quality (See Section 5.6). FAO
20 supports governments at the national level to plan CSA programs and to seek climate finance to fund
21 their adaptation programs.

22 The Global Commission on Adaptation, co-managed by World Resources Institute (WRI) and the
23 Global Center on Adaptation, seeks to accelerate adaptation action by elevating the political visibility
24 of adaptation and focusing on concrete solutions (Global Commission on Adaptation 2019). The
25 Commission works to demonstrate that adaptation is a cornerstone of better development, and can
26 help improve lives, reduce poverty, protect the environment, and enhance resilience around the world.
27 The Commission is led by Ban Ki-moon, 8th Secretary-General of the United Nations, Bill Gates, co-
28 chair of the Bill & Melinda Gates Foundation, and Kristalina Georgieva, CEO, World Bank. It is
29 convened by 17 countries and guided by 28 commissioners. A global network of research partners and
30 advisors provide scientific, economic, and policy analysis.

32 **5.3.5.2 National policies**

33 The successful development of food systems under climate change conditions requires a national-
34 level management that involves the cooperation of a number of institutions and governance entities to
35 enable more sustainable and beneficial production and consumption practices.

36 For example, Nepal has developed a novel multi-level institutional partnership, under the Local
37 Adaptation Plan of Action (LAPA), which is an institutional innovation that aims to better integrate
38 local adaptation planning processes and institutions into national adaptation processes. That includes
39 collaboration with farmers and other non-governmental organisations (Chhetri et al. 2012). By
40 combining conventional technological innovation process with the tacit knowledge of farmers, this
41 new alliance has been instrumental in the innovation of location-specific technologies thereby
42 facilitating the adoption of technologies in a more efficient manner.

43 National Adaptation Planning of Indonesia was officially launched in 2014 and was an important
44 basis for ministries and local governments to mainstream climate change adaptation into their
45 respective sectoral and local development plans Kawanishi et al. (2016). Crop land use policy to
46 switch from crops that are highly impacted by climate change to those that are less vulnerable were
47 suggested for improving climate change adaptation policy processes and outcomes in Nepal (Chalise

1 and Naranpanawa 2016). Enhancement of representation, democratic and inclusive governance, as
2 well as equity and fairness for improving climate change adaptation policy processes and outcomes in
3 Nepal were also suggested as intuitional measure by Ojha et al. (2015). Further, food, nutrition, and
4 health policy adaptation options such as social safety nets and social protection have been
5 implemented in India, Pakistan, Middle East and North Africa (Devereux 2015; Mumtaz and
6 Whiteford 2017; Narayanan and Gerber 2017).

7 Financial incentives policies at the national scale used as adaptation options include taxes and
8 subsidies; index-based weather insurance schemes; and catastrophe bonds (Zilberman et al. 2018;
9 Linnerooth-Bayer and Hochrainer-Stigler 2015; Ruitter et al. 2017; Campillo et al. 2017).
10 Microfinance, disaster contingency funds, and cash transfers are other mechanisms (Ozaki 2016;
11 Kabir et al. 2016).

12

13 **5.3.5.3 Community-based adaptation**

14 Community-based adaptation (CBA) builds on social organisational capacities and resources to
15 addressing food security and climate change. CBA represents bottom-up approaches and localised
16 adaptation measures where social dynamics serve as the power to respond to the impacts of climate
17 change (Ayers and Forsyth 2009). It identifies, assists, and implements development activities that
18 strengthen the capacity of local people to adapt to living in a riskier and less predictable climate,
19 while ensuring their food security.

20 Klenk et al. (2017) found that mobilisation of local knowledge can inform adaptation decision-making
21 and may facilitate greater flexibility in government-funded research. As an example, rural innovation
22 in terrace agriculture developed on the basis of a local coping mechanism and adopted by peasant
23 farmers in Latin America may serve as an adaptation option to climate change (Bocco and
24 Napoletano, 2017). Clemens et al. (2015) indicated that learning alliances provided social learning
25 and knowledge-sharing in Vietnam through an open dialogue platform that provided incentives and
26 horizontal exchange of ideas.

27 Community-based adaptation generates strategies through participatory processes, involving local
28 stakeholders and development and disaster risk–reduction practitioners. Fostering collaboration and
29 community stewardship is central to the success of CBA (Scott et al. 2017). Preparedness behaviours
30 that are encouraged include social connectedness, education, training, and messaging; CBA also can
31 encompass beliefs that might improve household preparedness to climate disaster risk (Thomas et al.
32 2015). Reliance on social networks, social groups connectivities, or moral economies reflect the
33 importance of collaboration within communities (Reuter 2018; Schramski et al. 2017).

34 Yet, community-based adaptation also needs to consider methods that engage with the drivers of
35 vulnerability as part of community-based approaches, particularly questions of power, culture,
36 identity and practice (Ensor et al. 2018). The goal is to avoid maladaptation or exacerbation of
37 existing inequalities within the communities (Buggy and McNamara 2016). For example, in the
38 Pacific Islands, elements considered in a CBA plan included people’s development aspirations;
39 immediate economic, social and environmental benefits; dynamics of village governance, social rules
40 and protocols; and traditional forms of knowledge that could inform sustainable solutions (Remling
41 and Veitayaki 2016).

42 With these considerations, community-based adaptation can help to link local adaptation with
43 international development and climate change policies (Forsyth 2013). In developing CBA programs,
44 barriers exist that may hinder implementation. These include poor coordination within and between
45 organisations implementing adaptation options, poor skills, poor knowledge about climate change,
46 and inadequate communication among stakeholders (Spires et al. 2014). A rights-based approach has

1 been suggested to address issues of equality, transparency, accountability and empowerment in
2 adaptation to climate change (Ensor et al. 2015).

3 In summary, institutional measures, including risk management, policies, and planning at global,
4 national, and local scales can support adaptation. Advance planning and focus on institutions can aid
5 in guiding decision-making processes and foster resilience. There is evidence that institutional
6 measures can support the scaling up of adaptation and thus there is reason to believe that systemic
7 resilience is achievable.

8

9 **5.3.6 Tools and finance**

10 **5.3.6.1 Early Warning Systems**

11 Many countries and regions in the world have adopted early warning systems (EWS) to cope with
12 climate variability and change as it helps to reduce interruptions and improve response times before
13 and after extreme weather events (Ibrahim and Kruczkiewicz 2016). The Early Warning and Early
14 Action (EW/EA) framework has been implemented in West Africa (Red Cross 2011) and
15 Mozambique (DKNC 2012). Bangladesh has constructed cyclone shelters where cyclone warnings are
16 disseminated and responses organised (Mallick et al. 2013). In Benin, a Standard Operating Procedure
17 is used to issue early warnings through the UNDP Climate Information and Early Warning Systems
18 Project (UNDP 2016).

19 However, there are some barriers to building effective early warning systems in Africa, such as lack
20 of reliable data and distribution systems, lack of credibility, and limited relationships with media and
21 government agencies (UNDP 2016). Mainstreaming early warning systems in adaptation planning
22 could present a significant opportunity for climate disaster risk reduction (Zia and Wagner 2015).
23 Enenkel et al. (2015) suggested that the use of smartphone applications that concentrate on food and
24 nutrition security could help with more frequent and effective monitoring of food prices, availability
25 of fertilisers and drought-resistant seeds, and could help to turn data streams into useful information
26 for decision support and resilience building.

27 GIS and remote sensing technology are used for monitoring and risk quantification for broad-
28 spectrum stresses such as drought, heat, cold, salinity, flooding, and pests (Skakun et al. 2017; Senay
29 et al. 2015; Hossain et al. 2015; Brown 2016), while site-specific applications, such as drones, for
30 nutrient management, precision fertilisers, and residue management can help devise context-specific
31 adaptations (Campbell et al. 2016; Baker et al. 2016). Systematic monitoring and remote sensing
32 options, as argued by Aghakouchak et al. (2015), showed that satellite observations provide
33 opportunities to improve early drought warning. Waldner et al. (2015) found that cropland mapping
34 allows strategic food and nutrition security monitoring and climate modelling.

35 Access to a wide range of adaptation technologies for precipitation change is important, such as
36 rainwater harvesting, wastewater treatment, stormwater management and bioswales, water demand
37 reduction, water-use efficiency, water recycling and reuse, aquifer recharge, inter-basin water transfer,
38 desalination, and surface-water storage (ADB 2014).

39

40 **5.3.6.2 Financial resources**

41 Financial instruments such as micro-insurance, index-based insurance, provision of post-disaster
42 finances for recovery and pre-disaster payment are fundamental means to reduce lower and medium
43 level risks (Linnerooth-Bayer and Hochrainer-Stigler 2014). Fenton & Paavola, 2015; Dowla, 2018).
44 Hammill et al. (2010) found that microfinance services (MFS) are especially helpful for the poor.
45 MFS can provide poor people with the means to diversify, accumulate and manage the assets needed
46 to become less susceptible to shocks and stresses. As a result, MFS plays an important role in

1 vulnerability reduction and climate change adaptation among some of the poor. The provision of
2 small-scale financial products to low-income and otherwise disadvantaged groups by financial
3 institutions can serve as adaptation to climate change. Access to finance in the context of climate
4 change adaptation that focuses on poor households and women in particular is bringing encouraging
5 results (Agrawala and Carraro 2010).

6 In summary, effective adaptation strategies can reduce the negative impacts of climate change. Food
7 security under changing climate conditions depends on adaptation throughout the entire food system –
8 production, supply chain, and consumption/demand, as well as reduction of food loss and waste.
9 Adaptation can be autonomous, incremental, or transformative, and can reduce vulnerability and
10 enhance resilience. Local food systems are embedded in culture, beliefs and values, and indigenous
11 and local knowledge can contribute to enhancing food system resilience to climate change (*high*
12 *confidence*). Institutional and capacity-building measures are needed to scale up adaptation measures
13 across local, national, regional, and global scales.

15 **5.4 Impacts of food systems on climate change**

16 **5.4.1 Greenhouse gas emissions from food systems**

17 This chapter assesses the contributions of the entire food system to greenhouse gas (GHG) emissions.
18 Food systems emissions include CO₂ and non-CO₂ gases, specifically those generated from: i) crop
19 and livestock activities within the farm gate (Table 5.4, category ‘Agriculture’); ii) land use and land
20 use change dynamics associated with agriculture (Table 5.4, category ‘Land Use’); and iii) food
21 processing, retail and consumption patterns, including upstream and downstream processes such as
22 manufacture of chemical fertilisers and fuel (Table 5.4, category ‘Beyond Farm Gate’). The first two
23 categories comprise emissions reported by countries in the AFOLU (Agriculture, Forestry, and Other
24 Land Use) sectors of national GHG inventories; the latter comprises emissions reported in other
25 sectors of the inventory, as appropriate, for instance, industrial processes, energy use, and food loss
26 and waste.

27 The first two components (agriculture and land use) identified above are well quantified and
28 supported by an ample body of literature (Smith et al. 2014). During the period 2007-2016, global
29 agricultural non-CO₂ emissions from crop and livestock activities within the farm gate were 6.2 ± 1.9
30 Gt CO₂-eq yr⁻¹ during 2007-2016, with methane (142 ± 43 Mt CH₄ yr⁻¹, or 4.1 ± 1.2 Gt CO₂-eq yr⁻¹)
31 contributing in CO₂eq about twice as much as nitrous oxide (8.3 ± 2.3 Mt N₂O yr⁻¹, or 2.1 ± 0.6 Gt
32 CO₂-eq yr⁻¹) to this total (see Table 2.2 in Chapter 2). Emissions from land use associated with
33 agriculture in some regions, such as from deforestation and peatland degradation (both processes
34 involved in preparing land for agricultural use), added globally during the same period another $4.8 \pm$
35 2.4 Gt CO₂-eq yr⁻¹ (see Chapter 2). These estimates are associated with uncertainties of about 30%
36 (agriculture) and 50% (land use), as per IPCC AR5 (Smith et al. 2014).

37 Agriculture activities within the farm gate and associated land use dynamics are therefore responsible
38 for about 11.0 ± 3.1 Gt CO₂-eq yr⁻¹, or some 20% of total anthropogenic emissions (Table 5.4),
39 consistent with post-AR5 findings (e.g., Tubiello et al. (2015)). In terms of individual gases, the
40 contributions of agriculture to total emissions by gas are significantly larger. For instance, over the
41 period 2010-2016, methane gas emissions within the farm gate represented about half of the total CH₄
42 emitted by all sectors, while nitrous dioxide gas emissions within the farm gate represented about
43 three-quarters of the total N₂O emitted by all sectors (Tubiello 2019). In terms of carbon, CO₂

1 emissions from deforestation and peatland degradation linked to agriculture contributed about 10% of
2 the CO₂ emitted by all sectors in 2017 (Le Quéré et al. 2018).

3 Food systems emissions beyond the farm gate, such as those upstream from manufacturing of
4 fertilisers, or downstream such as food processing, transport and retail, and food consumption,
5 generally add to emissions from agriculture and land use, but their estimation is very uncertain due to
6 lack of sufficient studies. The IPCC AR5 (Fischedick et al. 2014) provided some information on these
7 other food system components, noting that emissions beyond the farm gate in developed countries
8 may equal those within the farm gate, and cited one study estimating world total food system
9 emissions to be up to 30% of total anthropogenic emissions (Garnett 2011). More recently, Poore and
10 Nemecek (2018), by looking at a database of farms and using a combination of modelling approaches
11 across relevant processes, estimated a total contribution of food systems around 26% of total
12 anthropogenic emissions. Total emissions from food systems may thus account for 25-30% of total
13 GHG emissions (*medium confidence*).

14 Based on the available literature, a break-down of individual contributions of food systems emissions
15 is show in Table 5.4, between those from agriculture within the farm gate (10-12%) (*high confidence*);
16 emissions from land use and land use change dynamics such as deforestation and peatland
17 degradation, which are associated with agriculture in many regions (8-10%) (*high confidence*); and
18 those from food supply chain activities past the farm gate, such as storage, processing, transport, and
19 retail (5-10%) (*limited evidence, medium agreement*). Note that the corresponding lower range of
20 emissions past the farm gate, i.e., 2.5 Gt CO₂-eq yr⁻¹ (Table 5.4), is consistent with recent estimates
21 made by Poore and Nemecek (2018). Contributions from food loss and waste are implicitly included
22 in these estimates of total emissions from food systems (See Section 5.5.2.5). They may account for
23 8–10% of total GHG emissions from agriculture and land use (FAO 2013b) (*low confidence*).

24

25 **Table 5.4 GHG emissions (Gt CO₂eq yr⁻¹) from the food system and their contribution (%) to total**
26 **anthropogenic emissions. Mean of 2007-2016 period.**

Food system component	Emissions (Gt CO ₂ eq yr ⁻¹)	Share in mean total emissions (%)
Agriculture	6.2 ± 1.9 ^a	10-12%
Land use	4.8 ± 2.4 ^a	8-10%
Beyond farm gate	3.8 ± 1.3 ^b	5-10%
Food system (Total)	14.8 ± 3.4	25-30%

27 Notes: Food system emissions are estimated by combining emissions data from a) FAOSTAT (2018) and US
28 EPA (See also Chapter 2) and b) Garnett (2011) and Poore and Nemecek (2018). Percentage shares were
29 computed by using a total emissions value for the period 2007-2016 of nearly 51 Gt CO₂-eq yr⁻¹ (See Chapter 2).
30 GWP values used are those , and by using GWP values of the IPCC AR5 with no climate feedback (GWP-
31 CH4=28; GWP-N2O=265)..

32

33 **5.4.2 Greenhouse gas emissions from croplands and soils**

34 Since AR5, a few studies have quantified separate contributions of crops and soils on the one hand,
35 and livestock on the other, to the total emissions from agriculture and associated land use. For
36 instance, Carlson et al. (2017) estimated emissions from cropland to be in the range of 2–3 GtCO₂-eq

1 yr⁻¹, including methane emissions from rice, CO₂ emissions from peatland cultivation, and N₂O
 2 emissions from fertiliser applications. Data from FAOSTAT (2018), recomputed to use AR5 GWP
 3 values, indicated that cropland emissions from these categories were 3.6 ± 1.2 Gt CO₂-eq yr⁻¹ over the
 4 period 2010–2016; two-thirds of this were related to peatland degradation, followed by N₂O
 5 emissions from synthetic fertilisers and methane emissions from paddy rice fields (Tubiello 2019).
 6 These figures are a subset of the total emissions from agriculture and land use reported in Table 5.4.
 7 Asia, especially India, China and Indonesia accounted for roughly 50% of global emissions from
 8 croplands. Figure 5.8 shows the spatial distribution of emissions from cropland according to Carlson
 9 et al. (2017), not including emissions related to deforestation or changes in soil carbon.

10

11

12 **Figure 5.8 Cropland GHGs consist of CH₄ from rice cultivation, CO₂, N₂O, and CH₄ from peatland**
 13 **draining, and N₂O from N fertiliser application. Total emissions from each grid cell are concentrated in**
 14 **Asia, and are distinct from patterns of production intensity (Carlson et al. 2017).**

15 5.4.3 Greenhouse gas emissions from livestock

16 Emissions from livestock include non-CO₂ gases from enteric fermentation from ruminant animals
 17 and from anaerobic fermentation in manure management processes, as well as non-CO₂ gases from
 18 manure deposited on pastures (Smith et al. 2014). Estimates after the AR5 include those from Herrero
 19 et al. (2016), who quantified non-CO₂ emissions from livestock to be in the range of 2.0–3.6 GtCO₂-
 20 eq yr⁻¹, with enteric fermentation from ruminants being the main contributor. FAOSTAT (2018)
 21 estimates of these emissions, renormalized to AR5 GWP values, were 4.1 ± 1.2 Gt CO₂-eq yr⁻¹ over
 22 the period 2010–2016.

23 These estimates of livestock emissions are for those generated within the farm gate. Adding emissions
 24 from relevant land use change, energy use, and transportation processes, FAO (2014a) and Gerber et
 25 al. (2013) estimated livestock emissions of up to 5.3 ± 1.6 GtCO₂-eq yr⁻¹ circa the year 2010 (data
 26 from original papers, but scaled to SAR global warming potential (GWP) values for methane, for
 27 comparability with previous results).

28 All estimates agree that cattle are the main source of global livestock emissions (65–77%). Livestock
 29 in low and middle-income countries contribute 70% of the emissions from ruminants and 53% from
 30 monogastric livestock (animals without ruminant digestion processes such as sheep, goats, pigs, and
 31 poultry), and these are expected to increase as demand for livestock products increases in these
 32 countries (Figure 5.9). In contrast to the increasing trend in absolute GHG emissions, GHG emissions
 33 intensities, defined as GHG emissions per unit produced, have declined globally and are about 60%
 34 lower today than in the 1960s. This is largely due to improved meat and milk productivity of cattle
 35 breeds (FAOSTAT 2018; Davis et al. 2015).

1 Still, products like red meat remain the most inefficient in terms of emissions per kg of protein
2 produced in comparison to milk, pork, eggs and all crop products (IPCC 2014b). Yet, the functional
3 unit used in these measurements is highly relevant and may produce different results (Salou et al.
4 2017). For instance, metrics based on products tend to rate intensive livestock systems as efficient,
5 while metrics based on area or resources used tend to rate extensive system as efficient (Garnett
6 2011). In ruminant dairy systems, less intensified farms show higher emissions if expressed by
7 product, and lower emissions if expressed by Utilizable Agricultural Land (Gutiérrez-Peña et al. 2019;
8 Salvador et al. 2017; Salou et al. 2017).

9 Furthermore, if other variables are used in the analysis of GHG emissions of different ruminant
10 production systems, such as human-edible grains used to feed animals instead of crop waste and
11 pastures of marginal lands, or C sequestration in pasture systems in degraded lands, then the GHG
12 emissions of extensive systems are reduced. Reductions of 26 and 43% have been shown in small
13 ruminants, such as sheep and goats (Gutiérrez-Peña et al. 2019; Salvador et al. 2017; Batalla et al.
14 2015; Petersen et al. 2013). In this regard, depending on what the main challenge is in different
15 regions (e.g., undernourishment, overconsumption, natural resources degradation), different metrics
16 could be used as reference. Other metrics that consider nutrient density have been proposed because
17 they provide potential for addressing both mitigation and health targets (Doran-Browne et al. 2015).

18 Uncertainty in worldwide livestock population numbers remain the main source of variation in total
19 emissions of the livestock sector, while at the animal level, feed intake, diet regime, and nutritional
20 composition are the main sources of variation through their impacts on enteric fermentation and
21 manure N excretion.

22 Increases in economies of scale linked to increased efficiencies and decreased emission intensities
23 may lead to more emissions, rather than less, an observed dynamic referred to by economists as a
24 'rebound effect.' This is because increased efficiency allows production processes to be performed
25 using fewer resources and often at lower cost. This in turn influences consumer behaviour and product
26 use, increasing demand and leading to increased production. In this way, the expected gains from new
27 technologies that increase the efficiency of resource use may be reduced (i.e., increase in the total
28 production of livestock despite increased efficiency of production due to increased demand for meat
29 sold at lower prices). Thus, in order for the livestock sector to provide a contribution to GHG
30 mitigation, reduction in emissions intensities need to be accompanied by appropriate governance and
31 incentive mechanisms to avoid rebound effects, such as limits on total production.

32

33

34 **Figure 5.9 Global GHG emissions from livestock for 1995-2005 (Herrero et al. 2016a)**

35 Variation in estimates of N₂O emissions are due to differing a) climate regimes, b) soil types, and c)
36 N transformation pathways (Charles et al. 2017; Fitton et al. 2017). It was recently suggested that

Subject to Copy-editing

1 N₂O soil emissions linked to livestock through manure applications could be 20%-40% lower than
2 previously estimated in some regions, for instance in Sub-Saharan Africa and Eastern Europe (Gerber
3 et al. 2016) and from smallholder systems in East Africa (Pelster et al. 2017). Herrero et al. (2016a)
4 estimated global livestock enteric methane to range from 1.6–2.7 Gt CO₂-eq, depending on
5 assumptions of body weight and animal diet.

6 7 **5.4.4 Greenhouse gas emissions from aquaculture**

8 Emissions from aquaculture and fisheries may represent some 10% of total agriculture emissions, or
9 about 0.58 Gt CO₂-eq yr⁻¹ (Barange et al. 2018), with two-thirds being non-CO₂ emissions from
10 aquaculture (Hu et al. 2013; Yang et al. 2015) and the rest due to fuel use in fishing vessels. They
11 were not included in Table 5.4 under agriculture emissions, as these estimates are not included in
12 national GHG inventories and global numbers are small as well as uncertain.

13 Methodologies to measure aquaculture emissions are still being developed (Vasanth et al. 2016). N₂O
14 emissions from aquaculture are partly linked to fertiliser use for feed as well as aquatic plant growth,
15 and depend on the temperature of water as well as on fish production (Paudel et al. 2015). Hu et al.
16 (2012) estimated the global N₂O emissions from aquaculture in 2009 to be 0.028 Gt CO₂-eq yr⁻¹, but
17 could increase to 0.114 Gt CO₂-eq yr⁻¹ (that is 5.72% of anthropogenic N₂O–N emissions) by 2030 for
18 an estimated 7.10% annual growth rate of the aquaculture industry. Numbers estimated by Williams
19 and Crutzen (2010) were around 0.036 Gt CO₂-eq yr⁻¹, and suggested that this may rise to more than
20 0.179 Gt CO₂-eq yr⁻¹ within 20 years for an estimated annual growth of 8.7%. (Barange et al. 2018)
21 assessed the contribution of aquaculture to climate change as 0.38 Gt CO₂-eq yr⁻¹ in 2010, around 7%
22 of those from agriculture.

23 CO₂ emissions coming from the processing and transport of feed for fish raised in aquaculture, and
24 also the emissions associated with the manufacturing of floating cultivation devices (e.g., rafts or
25 floating fish-farms), connecting or mooring devices, artificial fishing banks or reefs, and feeding
26 devices (as well as their energy consumption) may be considered within the emissions from the food
27 system. Indeed, most of the GHG emissions from aquaculture are associated with the production of
28 raw feed materials and secondarily, with the transport of raw materials to mills and finished feed to
29 farms (Barange et al. 2018).

30 31 **5.4.5 Greenhouse gas emissions from inputs, processing, storage, and transport**

32 Apart from emissions from agricultural activities within the farm gate, food systems also generate
33 emissions from the pre- and post-production stages in the form of input manufacturing (fertilisers,
34 pesticides, feed production) and processing, storage, refrigeration, retail, waste disposal, food service,
35 and transport. The total contribution of these combined activities outside the farm gate is not well
36 documented. Based on information reported in the AR5 (Fischedick et al. 2014), we estimated their
37 total contribution to be roughly 15% of total anthropogenic emissions (Table 5.4). There is no post-
38 AR5 assessment at the global level in terms of absolute emissions. Rather, several studies have
39 recently investigated how the combined emissions within and outside the farm gate are embedded in
40 food products and thus associated with specific dietary choices (see next section). Below important
41 components of food systems emissions beyond the farm gate are discussed based on recent literature.

42 Refrigerated trucks, trailers, shipping containers, warehouses, and retail displays that are vital parts of
43 food supply chains all require energy and are direct sources of GHG emissions. Upstream emissions
44 in terms of feed and fertiliser manufacture and downstream emissions (transport, refrigeration) in
45 intensive livestock production (dairy, beef, pork) can account for up to 24–32% of total livestock
46 emissions, with the higher fractions corresponding to commodities produced by monogastric animals

1 (Weiss and Leip 2012). The proportion of upstream/downstream emissions fall significantly for less-
2 intensive and more-localised production systems (Mottet et al. 2017a).

3 *Transport and processing.* Recent globalisation of agriculture has promoted industrial agriculture and
4 encouraged value-added processing and more distant transport of agricultural commodities, all
5 leading to increased GHG emissions. Although greenhouse gas-intensive, food transportation plays an
6 important role in food chains: it delivers food from producers to consumers at various distances,
7 particularly to feed people in food-shortage zones from food-surplus zones. (See Section **Error!**
8 **reference source not found.** for assessment of local food production.)

9 To some extent, processing is necessary in order to make food supplies more stable, safe, long-lived,
10 and in some cases, nutritious (FAO 2007). Agricultural production within the farm gate may
11 contribute 80–86% of total food-related emissions in many countries, with emissions from other
12 processes such as processing and transport being small (Vermeulen et al. 2012). However, in net
13 food-importing countries where consumption of processed food is common, emissions from other
14 parts of the food life cycle generated in other locations are much higher (Green et al. 2015).

15 A study conducted by Wakeland et al. (2012) in the US found that the transportation-related carbon
16 footprint varies from a few percent to more than half of the total carbon footprint associated with food
17 production, distribution, and storage. Most of the GHGs emitted from food processing are a result of
18 the use of electricity, natural gas, coal, diesel, gasoline or other energy sources. Cookers, boilers, and
19 furnaces emit carbon dioxide, and wastewater emits methane and nitrous oxide. The most energy-
20 intensive processing is wet milling of maize, which requires 15% of total US food industry energy
21 (Bernstein et al. 2008); processing of sugar and oils also requires large amounts of energy.

22

23 **5.4.6 Greenhouse gas emissions associated with different diets**

24 There is now an extensive literature on the relationship between food products and emissions,
25 although the focus of the studies has been on high-income countries. Godfray et al. (2018) updated
26 Nelson et al. (2016), a previous systematic review of the literature on environmental impacts
27 associated with food, and concluded that higher consumption of animal-based foods was associated
28 with higher estimated environmental impacts, whereas increased consumption of plant-based foods
29 was associated with estimated lower environmental impact. Assessment of individual foods within
30 these broader categories showed that meat – sometimes specified as ruminant meat (mainly beef) –
31 was consistently identified as the single food with the greatest impact on the environment, most often
32 in terms of GHG emissions and/or land use per unit commodity. Similar hierarchies, linked to well-
33 known energy losses along trophic chains, from roots to beef were found in another recent review
34 focussing exclusively on GHG emissions (Clune et al. 2017), and one on life-cycle assessments
35 (Poore and Nemecek 2018). Poore and Nemecek (2018) amassed an extensive database that specifies
36 both the hierarchy of emissions intensities and the variance with the production context (i.e., by
37 country and farming system).

38 The emissions intensities of red meat mean that its production has a disproportionate impact on total
39 emissions (Godfray et al. 2018). For example, in the US 4% of food sold (by weight) is beef, which
40 accounts for 36% of food-related emissions (Heller and Keoleian 2015). Food-related emissions are
41 therefore very sensitive to the amount and type of meat consumed. However, 100 g of beef has twice
42 as much protein as the equivalent in cooked weight of beans, for example, and 2.5 times more iron.
43 One can ingest only about 2.5 kg of food per day and not all food items are as dense in nutrition.

44 There is therefore *robust evidence with high agreement* that the mixture of foods eaten can have a
45 highly significant impact on per capita carbon emissions, driven particularly through the amount of
46 (especially grain-fed) livestock and products.

1 Given the rising costs of malnutrition in all its forms, a legitimate question is often asked: would a
2 diet that promotes health through good nutrition also be one that mitigates GHG emissions? Whilst
3 sustainable diets need not necessarily provide more nutrition, there is certainly significant overlap
4 between those that are healthier (e.g., via eating more plant-based material and less livestock-based
5 material), and eating the appropriate level of calories. In their systematic review, Nelson et al. (2016)
6 conclude that, in general, a dietary pattern that is higher in plant-based foods, such as vegetables,
7 fruits, whole grains, legumes, nuts, and seeds, and lower in animal-based foods is more health-
8 promoting and is associated with lesser environmental impact (GHG emissions and energy, land, and
9 water use) than is the current average “meat-based” diet.

10 Recent FAO projections of food and agriculture to 2050 under alternative scenarios characterised by
11 different degrees of sustainability, provide global-scale evidence that rebalancing diets is key to
12 increasing the overall sustainability of food and agricultural systems world-wide. A 15% reduction of
13 animal products in the diets of high-income countries by 2050 would contribute to containing the need
14 to expand agricultural output due to upward global demographic trends. Not only would GHG
15 emissions and the pressure on land and water be significantly reduced but the potential for low-
16 income countries to increase the intake of animal-based food, with beneficial nutritional outcomes,
17 could be enhanced (FAO 2018a). Given that higher-income countries typically have higher emissions
18 per capita, results are particularly applicable in such places.

19 However, Springmann et al. (2018a) found that there are locally applicable upper bounds to the
20 footprint of diets around the world, and for lower-income countries undergoing a nutrition transition,
21 adopting “Westernised” consumption patterns (over consumption, large amounts of livestock produce,
22 sugar and fat), even if in culturally applicable local contexts, would increase emissions. The global
23 mitigation potential of healthy but low-emissions diets is discussed in detail in Section **Error!**
24 **reference source not found.**

25 In summary, food system emissions are growing globally due to increasing population, income, and
26 demand for animal-sourced products (*high confidence*). Diets are changing on average toward greater
27 consumption of animal-based foods, vegetable oils and sugar/sweeteners (*high confidence*) (see also
28 Chapter 2), with GHG emissions increasing due to greater amounts of animal-based products in diets
29 (*robust evidence, medium agreement*).

30

31 **5.5 Mitigation options, challenges, and opportunities**

32 The IPCC AR5 WG III concluded that mitigation in agriculture, forestry, and land use (AFOLU) is
33 key to limit climate change in the 21st century, in terms of mitigation of non-CO₂ GHGs, which are
34 predominately emitted in AFOLU, as well as in terms of land-based carbon sequestration. Wollenberg
35 et al. (2016) highlighted the need to include agricultural emissions explicitly in national mitigation
36 targets and plans, as a necessary strategy to meet the 2°C goal of the Paris Agreement. This chapter
37 expands on these key findings to document how mitigation in the entire food system, from farm ate to
38 consumer, can contribute to reaching the stated global mitigation goals, but in a context of improved
39 food security and nutrition. To put the range of mitigation potential of food systems in context, it is
40 worth noting that emissions from crop and livestock are expected to increase by 30-40% from present
41 to 2050, under business-as-usual scenarios that include efficiency improvements as well as dietary
42 changes linked to increased income per capita (FAO 2018a; Tubiello et al. 2014). Using current
43 emissions estimates in this chapter and Chapter 2, these increases translate into projected GHG
44 emissions from agriculture of 8-9 Gt CO₂eq yr⁻¹ by 2050 (*medium confidence*).

45 The AR5 ranked mitigation measures from simple mechanisms such as improved crop and livestock
46 management (Smith et al. 2014) to more complex carbon dioxide reduction interventions, such as

1 afforestation, soil carbon storage and biomass energy projects with carbon capture and storage
2 (BECCS). The AR5 WGIII AFOLU chapter (Smith et al. 2014) identified two primary categories of
3 mitigation pathways from the food system:

4 *Supply side*: Emissions from agricultural soils, land use change, land management, and crop and
5 livestock practices can be reduced and terrestrial carbon stocks can be increased by increased
6 production efficiencies and carbon sequestration in soils and biomass, while emissions from energy
7 use at all stages of the food system can be reduced through improvements in energy efficiency and
8 fossil fuel substitution with carbon-free sources including biomass.

9 *Demand side*: GHG emissions could be mitigated by changes in diet, reduction in food loss and waste,
10 and changes in wood consumption for cooking.

11 In this chapter, supply-side mitigation practices include land use change and carbon sequestration in
12 soils and biomass in both crop and livestock systems. Cropping systems practices include improved
13 land and fertiliser management, land restoration, biochar applications, breeding for larger root
14 systems, and bridging yield gaps (Dooley and Stabinsky 2018). Options for mitigation in livestock
15 systems include better manure management, improved grazing land management, and better feeding
16 practices for animals. Agroforestry also is a supply-side mitigation practice. Improving efficiency in
17 supply chains is a supply-side mitigation measure.

18 Demand-side mitigation practices include dietary changes that lead to reduction of GHG emissions
19 from production and changes in land use that sequester carbon. Reduction of food loss and waste can
20 contribute to mitigation of GHGs on both the supply and demand sides. See Section 5.7 and Chapter 7
21 for the enabling conditions needed to ensure that these food system measures would deliver their
22 potential mitigation outcomes.

23

24 **5.5.1 Supply-side mitigation options**

25 The IPCC AR5 identified options for GHG mitigation in agriculture including cropland management,
26 restoration of organic soils, grazing land management and livestock, with a total mitigation potential
27 of 1.5–4.0 GtCO₂-eq yr⁻¹ by 2030 (compared to baseline emissions in the same year), at carbon prices
28 from 20 to 100 USD/tCO₂-eq (Smith et al. 2014). Reductions in GHG emissions intensity (emissions
29 per unit product) from livestock and animal products can also be a means to achieve reductions in
30 absolute emissions in specific contexts and with appropriate governance (*medium confidence*).
31 Agroforestry mitigation practices include rotational woodlots, long-term fallow, and integrated land
32 use.

33 Emissions from food systems can be reduced significantly by the implementation of practices that
34 reduce carbon dioxide, methane, and nitrous oxide emissions from agricultural activities related to the
35 production of crops, livestock, and aquaculture. These include implementation of more sustainable
36 and efficient crop and livestock production practices aimed at reducing the amount of land needed per
37 output (reductions in GHG emissions intensity from livestock and animal production can support
38 reductions in absolute emissions if total production is constrained), bridging yield gaps, implementing
39 better feeding practices for animals and fish in aquaculture, and better manure management (FAO
40 2019a). Practices that promote soil improvements and carbon sequestration can also play an important
41 role. In the South America region, reduction of deforestation, restoration of degraded pasture areas,
42 and adoption of agroforestry and no-till agricultural techniques play a major role in the nation's
43 voluntary commitments to reduce GHG emissions in the country's mitigation activities (Box 5.4).

44 The importance of supply-side mitigation options is that these can be directly applied by food system
45 actors (farmers, processors, retailers, etc.) and can contribute to improved livelihoods and income
46 generation. Recognising and empowering farming system actors with the right incentives and

1 governance systems will be crucial to increasing the adoption rates of effective mitigation practices
2 and to build convincing cases for enabling GHG mitigation (Section 5.7 and Chapter 7).

4 **Box 5.4 Towards sustainable intensification in South America region**

5 Reconciling the increasing global food demand with limited land resources and low environmental
6 impact is a major global challenge (FAO 2018a; Godfray and Garnett 2014; Yao et al. 2017). South
7 America has been a significant contributor of the world's agricultural production growth in the last
8 three decades (OECD and FAO 2015), driven partly by increased export opportunities for specific
9 commodities, mainly soybeans and meat (poultry, beef and pork).

10 Agricultural expansion, however, has driven profound landscape transformations in the region,
11 particularly between the 1970s and early 2000s, contributing to increased deforestation rates and
12 associated GHG emissions. High rates of native vegetation conversion were found in Argentina,
13 Bolivia, Brazil, Colombia, Ecuador, Paraguay and Peru (FAO 2016b; Graesser et al. 2015),
14 threatening ecologically important biomes, such as the Amazon, the savannas (Cerrado, Chacos and
15 Lannos), the Atlantic Rainforest, the Caatinga, and the Yungas. The Amazon biome is a particularly
16 sensitive biome as it provides crucial ecosystem services including biodiversity, hydrological
17 processes (through evapotranspiration, cloud formation, and precipitation), and biogeochemical cycles
18 (including carbon) (Bogaerts et al. 2017; Fearnside 2015; Beuchle et al. 2015; Grecchi et al. 2014;
19 Celentano et al. 2017; Soares-Filho et al. 2014; Nogueira et al. 2018). Further, deforestation
20 associated with commodity exports has not led to inclusive socioeconomic development, but rather
21 has exacerbated social inequality and created more challenging living conditions for lower-income
22 people (Celentano et al. 2017); nor has it avoided increased hunger of local populations in the last few
23 years (FAO 2018b).

24 In the mid-2000s, governments, food industries, NGOs, and international programs joined forces to
25 put in place important initiatives to respond to the growing concerns about the environmental impacts
26 of agricultural expansion in the region (Negra et al. 2014; Finer et al. 2018). Brazil led regional action
27 by launching the Interministerial Plan of Action for Prevention and Control of Deforestation of the
28 Legal Amazon² (PPCDAm), associated with development of a real-time deforestation warning
29 system. Further, Brazil built capacity to respond to alerts by coordinated efforts of ministries, the
30 federal police, the army and public prosecution (Negra et al. 2014; Finer et al. 2018).

31 Other countries in the region have also launched similar strategies, including a zero-deforestation plan
32 in Paraguay in 2004 (Gasparri and de Waroux 2015), and no-deforestation zones in Argentina in 2007
33 (Garcia Collazo et al. 2013). Peru also developed the National System of Monitoring and Control, led
34 by the National Forest Service and Wildlife Authority (SERFOR), to provide information and
35 coordinate response to deforestation events, and Colombia started producing quarterly warning
36 reports on active fronts of deforestation in the country (Finer et al. 2018).

37 Engagement of the food industry and NGOs, particularly through the Soy Moratorium (from 2006)
38 and Beef Moratorium (from 2009) also contributed effectively to keep deforestation at low historical
39 rates in the regions where they were implemented (Nepstad et al. 2014; Gibbs et al. 2015). In 2012,
40 Brazil also created the national land registry system (SICAR), a georeferenced database, which allows
41 monitoring of farms' environmental liability in order to grant access to rural credit. Besides the

² FOOTNOTE: The Legal Amazon is a Brazilian region of 501.6 Mha (ca. 59% of the Brazilian territory) that contains all the Amazon but also 40% of the Cerrado and 40% of the Pantanal biomes, with a total population of 25.47 million inhabitants.

1 governmental schemes, funding agencies and the Amazon Fund provide financial resources to assist
2 smallholder farmers to comply with environmental regulations (Jung et al. 2017).

3 Nevertheless, Azevedo et al. (2017) argue that the full potential of these financial incentives has not
4 been achieved, due to weak enforcement mechanisms and limited supporting public policies.
5 Agricultural expansion and intensification have complex interactions with deforestation. While
6 mechanisms have been implemented in the region to protect native forests and ecosystems, control of
7 deforestation rates require stronger governance of natural resources (Ceddia et al. 2013; Oliveira and
8 Hecht 2016), including monitoring programs to evaluate fully the results of land use policies in the
9 region.

10 Public and private sector actions resulted in a reduction of the Brazilian legal Amazon deforestation
11 rate from 2.78 Mha yr⁻¹ in 2004, to about 0.75 Mha yr⁻¹ (ca. 0.15%) in 2009 (INPE 2015), oscillating
12 from 0.46 Mha and 0.79 Mha (2016) since then (INPE 2018; Boucher and Chi 2018). The
13 governmental forest protection scheme was also expanded to other biomes. As a result, the Brazilian
14 Cerrado deforestation was effectively reduced from 2.9 Mha yr⁻¹ in 2004 to an average of 0.71 Mha
15 yr⁻¹ in 2016-2017 (INPE 2018).

16 Overall, deforestation rates in South America have declined significantly, with current deforestation
17 rates being about half of rates in the early 2000s (FAOSTAT 2018). However, inconsistent
18 conservation policies across countries (Gibbs et al. 2015) and recent hiccups (Curtis et al. 2018)
19 indicate that deforestation control still requires stronger reinforcement mechanisms (Tollefson 2018).
20 Further, there are important spill-over effects that need coordinated international governance. Curtis et
21 al. (2018) and Dou et al. (2018) point out that, although the Amazon deforestation rate decreased in
22 Brazil, it has increased in other regions, particularly in Southern Asia, and in other countries in South
23 America, resulting in nearly constant deforestation rates worldwide.

24 Despite the reduced expansion rates into forest land, agricultural production continues to rise steadily
25 in South America, relying on increasing productivity and substitution of extensive pastureland by
26 crops. The average soybean and maize productivity in the region increased from 1.8 and 2.0 t ha⁻¹ in
27 1990 to 3.0 and 5.0 t ha⁻¹, respectively, in 2015 (FAOSTAT 2018). Yet, higher crop productivity was
28 not enough to meet growing demand for cereals and oilseeds and cultivation continued to expand,
29 mainly on grasslands (Richards 2015). The reconciliation of this expansion with higher demand for
30 meat and dairy products was carried out through the intensification of livestock systems (Martha et al.
31 2012). Nevertheless, direct and indirect deforestation still occurs, and recently deforestation rates have
32 increased (INPE 2018), albeit they remain far smaller than observed in the 2000-2010 period.

33 The effort towards sustainable intensification has also been incorporated in agricultural policies. In
34 Brazil, for instance, the reduction of deforestation, the restoration of degraded pasture areas, the
35 adoption of integrated agroforestry systems³ and no-till agricultural techniques play a major role in
36 the nation's voluntary commitments to reduce GHG emissions in the country's NAMAs (Mozzer
37 2011) and NDCs (Silva Oliveira et al. 2017; Rochedo et al. 2018). Such commitment under the
38 UNFCCC is operationalised through the Low Carbon Agriculture Plan (ABC)⁴, which is based on low
39 interest credit for investment in sustainable agricultural technologies (Mozzer 2011). Direct pasture
40 restoration and integrated systems reduce area requirements (Strassburg et al. 2014), and increase
41 organic matter (Gil et al. 2015; Bungenstab 2012; Maia et al. 2009), contributing to overall life cycle

³ FOOTNOTE: Integrated agroforestry systems are agricultural systems that strategically integrate two or more components among crops, livestock and forestry. The activities can be in consortium, succession or rotation in order to achieve overall synergy.

⁴ FOOTNOTE: ABC - *Agricultura de Baixo Carbono* in Portuguese.

1 emissions reduction (Cardoso et al. 2016; de Oliveira Silva et al. 2016). Also, increased adoption of
2 supplementation and feedlots, often based on agro-industrial co-products and agricultural crop
3 residues are central to improve productivity and increase climate resilience of livestock systems
4 (Mottet et al. 2017a; van Zanten et al. 2018).

5 Despite providing clear environmental and socio-economic co-benefits, including improved resource
6 productivity, socio-environmental sustainability and higher economic competitiveness,
7 implementation of the Brazilian Low Carbon Agriculture Plan is behind schedule (Köberle et al.
8 2016). Structural inefficiencies related to the allocation and distribution of resources need to be
9 addressed to put the plan on track to meet its emissions reduction targets. Monitoring and verification
10 are fundamental tools to guarantee the successful implementation of the plan.

11 Overall, historical data and projections show that South America is one of the regions of the world
12 with the highest potential to increase crop and livestock production in the coming decades in a
13 sustainable manner (Cohn et al. 2014), increasing food supply to more densely populated regions in
14 Asia, Middle East and Europe. However, a great and coordinated effort is required from governments,
15 industry, traders, scientists and the international community to improve planning, monitoring and
16 innovation to guarantee sustainable intensification of its agricultural systems, contribution to GHG
17 mitigation, and conservation of the surrounding environment (Negra et al. 2014; Curtis et al. 2018;
18 Lambin et al. 2018).

19 20 **5.5.1.1 Greenhouse gas mitigation in croplands and soils**

21 The mitigation potential of agricultural soils, cropland and grazing land management has been the
22 subject of much research and was thoroughly summarised in the AR5 (Smith et al. 2014) (See also
23 Chapter 2 Section 2.5.1 and Chapter 6 Section 6.3.1). Key mitigation pathways are related to practices
24 reducing nitrous oxide emissions from fertiliser applications, reducing methane emissions from paddy
25 rice, reducing both gases through livestock manure management and applications, and sequestering
26 carbon or reducing its losses, with practices for improving grassland and cropland management
27 identified as the largest mitigation opportunities. Better monitoring reporting and verification (MRV)
28 systems are currently needed for reducing uncertainties and better quantifying the actual mitigation
29 outcomes of these activities.

30 New work since AR5 has focused on identifying pathways for the reductions of GHG emissions from
31 agriculture to help meet Paris Agreement goals (Paustian et al. 2016; Wollenberg et al. 2016). Altieri
32 and Nicholls (2017) have characterised mitigation potentials from traditional agriculture. Zomer et al.
33 (2017) have updated previous estimates of global carbon sequestration potential in cropland soils.
34 Mayer et al. (2018) converted soil carbon sequestration potential through agricultural land
35 management into avoided temperature reductions. Fujisaki et al. (2018) identify drivers to increase
36 soil organic carbon in tropical soils. For discussion of integrated practices such as sustainable
37 intensification, conservation agriculture and agroecology, see Section 5.6.4.

38 Paustian et al. (2016) developed a decision-tree for facilitating implementation of mitigation practices
39 on cropland and described the features of key practices. They observed that most individual mitigation
40 practices will have a small effect per unit of land, and hence they need to be combined and applied at
41 large scales for their impact to be significant. Examples included aggregation of cropland practices
42 (e.g., organic amendments, improved crop rotations and nutrient management and reduced tillage) and
43 grazing land practices (e.g., grazing management, nutrient and fire management and species
44 introduction) that could increase net soil C stocks while reducing emissions of N₂O and CH₄.
45 However, it is well-known that the portion of projected mitigation from soil C stock increase (about
46 90% of the total technical potential) is impermanent, i.e., it would be effective for only 20–30 years
47 due to saturation of the soil capacity to sequester carbon, whereas non-CO₂ emission reductions could

1 continue indefinitely. “Technical potential” is the maximum amount of GHG mitigation achievable
2 through technology diffusion.

3 Biochar application and management towards enhanced root systems are mitigation options that have
4 been highlighted in recent literature (Dooley and Stabinsky 2018; Hawken 2017; Paustian et al. 2016;
5 Woolf et al. 2010; Lenton 2010).

6

7 **5.5.1.2 Greenhouse gas mitigation in livestock systems**

8 The technical options for mitigating GHG emissions in the livestock sector have been the subject of
9 recent reviews (Mottet et al., 2017b; Hristov et al. 2013a,b; Smithers 2015; Herrero et al. 2016a;
10 Rivera-Ferre et al. 2016b) (Figure 5.11). They can be classified as either targeting reductions in
11 enteric methane; reductions in nitrous oxide through manure management; sequestering carbon in
12 pastures; implementation of best animal husbandry and management practices, which would have an
13 effect on most GHG; and land use practices that also help sequester carbon. Excluding land use
14 practices, these options have a technical mitigation potential ranging 0.2-2.4 GtCO₂-eq yr⁻¹ (Herrero et
15 al. 2016a; FAO 2007). See also Chapters 2 and 6 in this report.

16 The opportunities for carbon sequestration in grasslands and rangelands may be significant (Conant
17 2010), for instance, through changes in grazing intensity or manure recycling aimed at maintaining
18 grassland productivity (Hirata et al. 2013). Recent studies have questioned the economic potential of
19 such practices, i.e., whether they could implement at scale for economic gain (Garnett et al. 2017;
20 Herrero et al. 2016a; Henderson et al. 2015). For instance, Henderson et al. (2015) found economic
21 potentials below 200 MtCO₂-eq yr⁻¹. Carbon sequestration can occur in situations where grasslands
22 are highly degraded (Garnett 2016). Carbon sequestration linked to livestock management could thus
23 be considered as a co-benefit of well-managed grasslands, as well as a mitigation practice.

24 Different production systems will require different strategies, including the assessment of impacts on
25 food security, and this has been the subject of significant research (e.g., Rivera-Ferre et al. 2016b).
26 Livestock systems are heterogeneous in terms of their agro-ecological orientation (arid, humid or
27 temperate/highland locations), livestock species (cattle, sheep, goats, pigs, poultry and others),
28 structure (grazing only, mixed-crop-livestock systems, industrial systems, feedlots and others), level
29 of intensification, and resource endowment (Robinson 2011).

30 The implementation of strategies presented in **Error! Reference source not found.** builds on this
31 differentiation, providing more depth compared to the previous AR5 analysis. Manure management
32 strategies are more applicable in confined systems, where manure can be easily collected, such as in
33 pigs and poultry systems or in smallholder mixed crop–livestock systems. More intensive systems,
34 with strong market orientation, such as dairy in the US, can implement a range of sophisticated
35 practices like feed additives and vaccines, while many market-oriented dairy systems in tropical
36 regions can improve feed digestibility by improving forage quality and adding larger quantities of
37 concentrate to the rations. Many of these strategies can be implemented as packages in different
38 systems, thus maximising the synergies between different options (Mottet et al. 2017b).

39 See the Supplementary Material Section SM5.5 for detailed description of livestock mitigation
40 strategies; synergies and trade-offs with other mitigation and adaptation options are discussed in
41 Section 5.6.

42

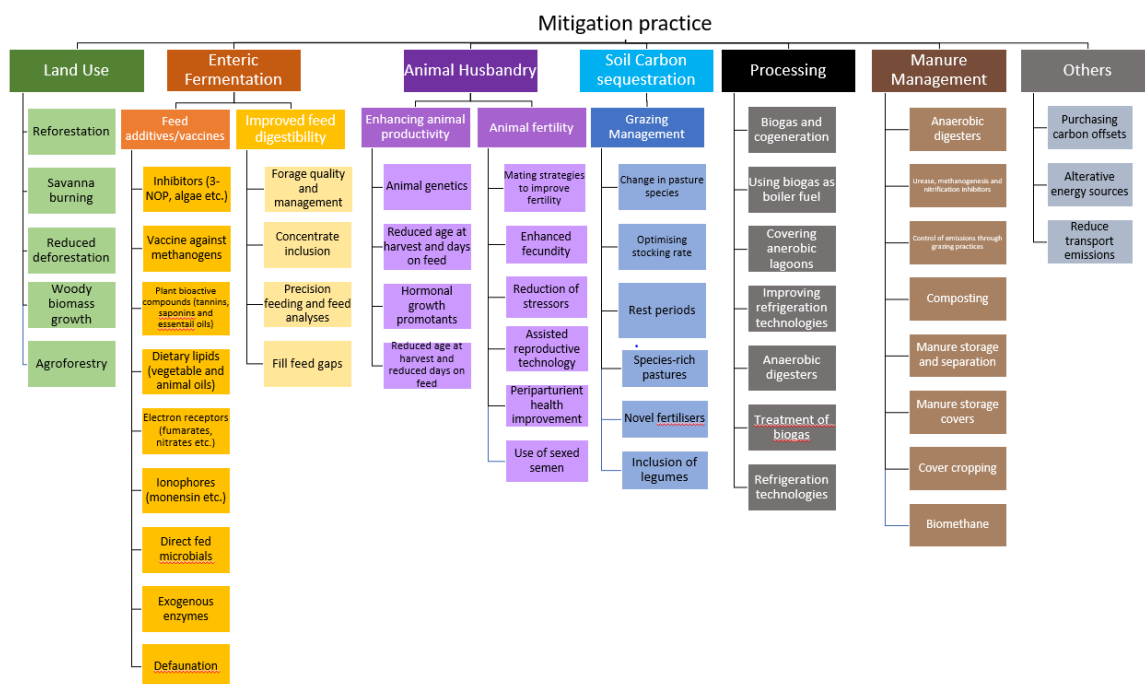

Figure 5.10 Technical supply-side mitigation practices in the livestock sector (adapted from Hristov et al. 2013b; Herrero et al. 2016b; Smith et al. 2014)

5.5.1.3 Greenhouse gas mitigation in agroforestry

Agroforestry can curb GHG emissions of CO₂, CH₄, and N₂O in agricultural systems in both developed and developing countries (See Glossary for definition) (see Chapter 2, Section 2.5.1 and Figure 2.24). Soil carbon sequestration, together with biological N fixation, improved land health and underlying ecosystem services may be enhanced through agricultural lands management practices used by large-scale and smallholder farmers, such as incorporation of trees within farms or in hedges (manure addition, green manures, cover crops, etc.), whilst promoting greater soil organic matter and nutrients (and thus soil organic carbon) content and improve soil structure (Mbow et al. 2014b) (Table 5.5). The tree cover increases the microbial activity of the soil and increases the productivity of the grass under cover. CO₂ emissions are furthermore lessened indirectly, through lower rates of erosion due to better soil structure and more plant cover in diversified farming systems than in monocultures. There is great potential for increasing above ground and soil C stocks, reducing soil erosion and degradation, and mitigating GHG emissions.

These practices can improve food security through increases in productivity and stability since they contribute to increased soil quality and water-holding capacity. Agroforestry provides economic, ecological, and social stability through diversification of species and products. On the other hand, trade-offs are possible when cropland is taken out of production mainly as a mitigation strategy.

Table 5.5 Carbon sequestration potential for agroforestry (Mbow et al. 2014b)

Source	Carbon sequestration (tCO ₂ km ⁻² yr ⁻¹) (range)	C stock (tCO ₂ km ⁻²) (range)	Max rotation period (years)
Dominant parklands	183 (73–293)	12,257 (2,091–25,983)	50
Rotational woodlots ^a	1,431 (807–2,128)	6,789 (4,257–9,358)	5

Tree planting-windrows-home gardens	220.2 (146–293)	6,973 (-)	25
Long term fallows, regrowth of woodlands in abandoned farms^b	822 (80–2,128)	5,761 (-)	25
Integrated land use	1,145 (367–2,458)	28,589 (4,404–83,676)	50
Soil carbon	330 (91–587)	33,286 (4,771–110,100)	-

^a May be classified as forestry on forest land, depending on the spatial and temporal characteristics of these activities.

^b This is potentially not agro-forestry, but forestry following abandonment of agricultural land.

Meta-analyses have been done on carbon budgets in agroforestry systems (Zomer et al. 2016; Chatterjee et al. 2018). In a review of 42 studies, (Ramachandran Nair et al. 2009) estimated C sequestration potentials of differing agroforestry systems. These include sequestration rates in ranging from 954 (semi-arid); to 1,431 (temperate); 2,238 (sub-humid) and 3,670 tCO₂ km⁻² yr⁻¹ (humid). The global technical potential for agroforestry is 0.1–5.7 Gt CO₂e yr⁻¹ (Griscom et al. 2017; Zomer et al. 2016; Dickie et al. 2014) (see Chapter 2, Section 2.5.1). Agroforestry-based carbon sequestration can be used to offset N₂O and CO₂ emissions from soils and increase methane sink strength compared to annual cropping systems (Rosenstock et al. 2014).

Agroforestry systems with perennial crops, such as coffee and cacao, may be more important carbon sinks than those that combine trees with annual crops. Brandt et al. (2018) showed that farms in semi-arid region (300–600 mm precipitation) were increasing in tree cover due to natural regeneration and that the increased application of agroforestry systems were supporting production and reducing GHG emissions.

5.5.1.4 Integrated approaches to crop and livestock mitigation

Livestock mitigation in a circular economy. Novel technologies for increasing the integration of components in the food system are being devised to reduce GHG emissions. These include strategies that help decoupling livestock from land use. Work by van Zanten et al. (2018) shows that 7–23 g of animal protein per capita per day could be produced without livestock competing for vital arable land. This would imply a contraction of in the land area utilised by the livestock sector, but also a more efficient use of resources, and would lead to land sparing and overall emissions reductions.

Pikaar et al. (2018) demonstrated the technical feasibility of producing microbial protein as a feedstuff from sewage that could replace use of feed crops such as soybean. The technical potential of this novel practice could replace 10–19% of the feed protein required, and would reduce cropland demand and associated emissions by 6-7%. These practices are, however, not economically feasible nor easily upscalable in most systems. Nonetheless, significant progress in Japan and South Korea in the reduction and use of food waste to increase efficiencies in livestock food chains has been achieved, indicating a possible pathway to progress elsewhere (FAO 2017; zu Ermgassen et al. 2016). Better understanding of biomass and food and feed wastes, value chains, and identification of mechanisms for reducing the transport and processing costs of these materials is required to facilitate larger-scale implementation.

Waste streams into energy. Waste streams from manure and food waste can be used for energy generation and thus reduction in overall GHG emissions in terms of recovered methane (for instance

1 through anaerobic digestion) production (De Clercq et al. 2016) or for the production of microbial
2 protein (Pikaar et al. 2018). Second-generation biorefineries, once the underlying technology is
3 improved, may enable the generation of hydro-carbon from agricultural residues, grass, and woody
4 biomass in ways that do not compete with food and can generate, along with biofuel, high-value
5 products such as plastics (Nguyen et al. 2017). Second-generation energy biomass from residues may
6 constitute a complementary income source for farmers that can increase their incentive to produce.
7 Technologies include CHP (combined heat and power) or gas turbines, and fuel types such as bio-
8 diesel, bio-pyrolysis (i.e., high temperature chemical transformation of organic material in the absence
9 of oxygen), torrefaction of biomass, production of cellulosic bio-ethanol and of bio-alcohols produced
10 by other means than fermentation, and the production of methane by anaerobic fermentation. (Nguyen
11 et al. 2017).

12 *Technology for reducing fossil fuel inputs.* Besides biomass and bioenergy, other forms of renewable
13 energy substitution for fossil fuels (e.g., wind, solar, geothermal, hydro) are already being applied on
14 farms and throughout the supply chain. Energy efficiency measures are being developed for
15 refrigeration, conservation tillage, precision farming (e.g., fertiliser and chemical application and
16 precision irrigation.

17 *Novel technologies.* Measures that can reduce livestock emissions given continued research and
18 development include methane and nitrification inhibitors, methane vaccines, targeted breeding of
19 lower-emitting animals, and genetically modified grasses with higher sugar content. New strategies to
20 reduce methanogenesis include supplementing animal diets with antimethanogenic agents (e.g., 3-
21 NOP, algae, chemical inhibitors such as chloroform) or supplementing with electron acceptors (e.g.,
22 nitrate) or dietary lipids. These could potentially contribute, once economically feasible at scale, to
23 significant reductions of methane emissions from ruminant livestock. A well-tested compound is 3-
24 nitrooxypropanol (3-NOP), which was shown to decrease methane by up to 40% when incorporated in
25 diets for ruminants (Hristov et al. 2015).

26 Whilst these strategies may become very effective at reducing methane, they can be expensive and
27 also impact on animal performance and/or welfare (Llonch et al. 2017). The use of novel fertilisers
28 and/or plant species that secrete biological nitrification inhibitors also have the potential to
29 significantly reduce N₂O emissions from agricultural soils (Subbarao et al. 2009; Rose et al. 2018).

30 *Economic mitigation potentials of crop and livestock sectors.* Despite the large technical mitigation
31 potential of the agriculture sector in terms of crop and livestock activities, its economic potential is
32 relatively small in the short term (2030) and at modest carbon prices (less than USD 20 tC⁻¹). For crop
33 and soil management practices, it is estimated that 1.0–1.5 GtCO₂-eq yr⁻¹ could be a feasible
34 mitigation target at a carbon price of USD 20/tonne of carbon (Frank et al. 2018, 2017; Griscom et al.
35 2016; Smith et al. 2013; Wollenberg et al. 2016). For the livestock sector, these estimates range from
36 0.12–0.25 GtCO₂-eq yr⁻¹ at similar carbon prices (Herrero et al. 2016c; Henderson et al. 2017). But
37 care is needed in comparing crop and livestock economic mitigation potentials due to differing
38 assumptions.

39 Frank et al. (2018) recently estimated that the economic mitigation potential of non-CO₂ emissions
40 from agriculture and livestock to 2030 could be up to four times higher than indicated in the AR5, if
41 structural options such as switching livestock species from ruminants to monogastrics, or allowing for
42 flexibility to relocate production to more efficient regions were implemented, at the same time as the
43 technical options such as those described above. At higher carbon prices (i.e., at about USD 100tC⁻¹),
44 they found a mitigation potential of supply-side measures of 2.6 GtCO₂-eq yr⁻¹.

45 In this scenario, technical options would account for 38% of the abatement, while another 38% would
46 be obtained through structural changes, and a further 24% would be obtained through shifts in
47 consumption caused by food price increases. Key to the achievement of this mitigation potential lay in

1 the livestock sector, as reductions in livestock consumption, structural changes and implementation of
2 technologies in the sector had some of the highest impacts. Regions with the highest mitigation
3 potentials were Latin America, China and Sub-Saharan Africa. The large-scale implementability of
4 such proposed sweeping changes in livestock types and production systems is likely very limited as
5 well as constrained by long-established socio-economic, traditional and cultural habits, requiring
6 significant incentives to generate change.

7 In summary, supply-side practices can contribute to climate change mitigation by reducing crop and
8 livestock emissions, sequestering carbon in soils and biomass, and by decreasing emissions intensity
9 within sustainable production systems (*high confidence*). The AR5 estimated the total economic
10 mitigation potential of crop and livestock activities as 1.5–4.0 GtCO₂-eq yr⁻¹ by 2030 at prices ranging
11 from 20-100 USD/tCO₂eq (*high confidence*). Options with large potential for GHG mitigation in
12 cropping systems include soil carbon sequestration (at decreasing rates over time), reductions in N₂O
13 emissions from fertilisers, reductions in CH₄ emissions from paddy rice, and bridging of yield gaps.
14 Options with large potential for mitigation in livestock systems include better grazing land
15 management, with increased net primary production and soil carbon stocks, improved manure
16 management, and higher-quality feed. Reductions in GHG emissions intensity (emissions per unit
17 product) from livestock can support reductions in absolute emissions, provided appropriate
18 governance structures to limit total production are implemented at the same time (*medium*
19 *confidence*).

21 **5.5.1.5 Greenhouse gas mitigation in aquaculture**

22 Barange et al. (2018) provide a synthesis of effective options for GHG emissions reduction in
23 aquaculture including reduction of emissions from production of feed material, replacement of fish-
24 based feed ingredients with crop-based ingredients; reduction of emissions from feed mill energy use,
25 improvement of feed conversion rates, improvement of input use efficiency, shift of energy supply
26 (from high-carbon fossil fuels to low-carbon fossil fuels or renewables), and improvement of fish
27 health. Conversion of 25% of total aquaculture area to integrated aquaculture-agriculture ponds
28 (greening aquaculture) has the potential to sequester 95.4 millions tonnes carbon per year (Ahmed et
29 al. 2017).

30 Proposed mitigation in aquaculture includes avoided deforestation. By halting annual mangrove
31 deforestation in Indonesia, associated total emissions would be reduced 10-31% of estimated annual
32 emissions from land use sector at present (Murdiyarso et al. 2015). Globally, 25% mangrove
33 regeneration could sequester 0.54–0.65 millions tonnes carbon per year (Ahmed et al. 2017) of which
34 0.17-0.21 could be through integrated or organic shrimp culture (Ahmed et al. 2018).

36 **5.5.1.6 Cellular agriculture**

37 The technology for growing muscle tissue in culture from animal stem cells to produce meat, i.e.,
38 “cultured” or “synthetic” or “in vitro” or “hydroponic” meat could in theory be constructed with
39 different characteristics and be produced faster and more efficiently than traditional meat (Kadim et
40 al. 2015). Cultured meat (CM) is part of so-called cellular agriculture, which includes production of
41 milk, egg white and leather from industrial cell cultivation (Stephens et al. 2018). CM is produced
42 from muscle cells extracted from living animals, isolation of adult skeletal muscle stem cells
43 (myosatellite cells), placement in a culture medium which allow their differentiation into myoblasts
44 and then, through another medium, generation of myocytes which coalesce into myotubes and grow
45 into strands in a stirred-tank bioreactor (Mattick et al. 2015). Current technology enables the creation
46 of beef hamburgers, nuggets, steak chips or similar products from meat of other animals, including
47 wild species, although production currently is far from being economically feasible. Nonetheless, by

1 allowing bioengineering from the manipulation of the stem cells and nutritive culture, CM allows for
2 reduction of harmful fatty acids, with advantages such as reduced GHG emissions, mostly indirectly
3 through reduced land use (Bhat et al. 2015; Kumar et al. 2017b).

4 Tuomisto and de Mattos (2011) made optimistic technological assumptions, relying on cyanobacteria
5 hydrolysate nutrient source, and produced the lowest estimates on energy and land use. Tuomisto and
6 de Mattos (2011) conducted a lifecycle assessment that indicates that cultured meat could have less
7 than 60% of energy use and 1% of land use of beef production and it would have lower GHG
8 emissions than pork and poultry as well. Newer estimates (Alexander et al. 2017; Mattick et al. 2015)
9 indicate a trade-off between industrial energy consumption and agricultural land requirements of
10 conventional and cultured meat and possibly higher GWP than pork or poultry due to higher energy
11 use. The change in proportion of CO₂ vs CH₄ could have important implications in climate change
12 projections and, depending on decarbonisation of the energy sources and climate change targets,
13 cultured meat may be even more detrimental than exclusive beef production (Lynch 2019).

14 Overall, as argued by Stephens et al. (2018), cultured meat is an “as-yet undefined ontological
15 object” and, although marketing targets people who appreciate meat but are concerned with animal
16 welfare and environmental impacts, its market is largely unknown (Bhat et al. 2015; Slade 2018). In
17 this context it will face the competition of imitation meat (meat analogues from vegetal protein) and
18 insect-derived products, which have been evaluated as more environmentally friendly (Alexander et
19 al. 2017) and it may be considered as being an option for a limited resource world, rather than a
20 mainstream solution. Besides, as commercial production process is still largely undefined, its actual
21 contribution to climate change mitigation and food security is largely uncertain and challenges are not
22 negligible. Finally, it is important to understand the systemic nature of these challenges and evaluate
23 their social impacts on rural populations due to transforming animal agriculture into an industrialised
24 activity and its possible rebound effects on food security, which are still understudied in the literature.

25 Studies are needed to improve quantification of mitigation options for supply chain activities.

27 **5.5.2 Demand-side mitigation options**

28 Although population growth is one of the drivers of global food demand and the resulting
29 environmental burden, demand-side management of the food system could be one of the solutions to
30 curb climate change. Avoiding food waste during consumption, reducing over-consumption, and
31 changing dietary preferences can contribute significantly to provide healthy diets for all, as well as
32 reduce the environmental footprint of the food system. The number of studies addressing this issue
33 have increased in the last few years (see also Chapter 2). (See Section 5.6 for synergies and trade-offs
34 with health and Section 5.7 for discussion of Just Transitions).

36 **5.5.2.1 Mitigation potential of different diets**

37 A systematic review found that higher consumption of animal-based foods was associated with higher
38 estimated environmental impact, whereas increased consumption of plant-based foods was associated
39 with an estimated lower environmental impact (Nelson et al. 2016). Assessment of individual foods
40 within these broader categories showed that meat – especially ruminant meat (beef and lamb) – was
41 consistently identified as the single food with the greatest impact on the environment, on a global
42 basis, most often in terms of GHG emissions and/or land use.

43 Figure 5.12 shows the technical mitigation potentials of some scenarios of alternative diets examined
44 in the literature. Stehfest et al. (2009) were among the first to examine these questions. They found
45 that under the most extreme scenario, where no animal products are consumed at all, adequate food
46 production in 2050 could be achieved on less land than is currently used, allowing considerable forest

1 regeneration, and reducing land-based greenhouse gas emissions to one third of the reference
 2 “business-as-usual” case for 2050, a reduction of 7.8 Gt CO₂-eq yr⁻¹. Springmann et al. (2016b)
 3 recently estimated similar emissions reduction potential of 8 Gt CO₂-eq yr⁻¹ from a vegan diet without
 4 animal-sourced foods. This defines the upper bound of the technical mitigation potential of demand
 5 side measures.

6 Herrero et al. (2016a) reviewed available options, with a specific focus on livestock products,
 7 assessing technical mitigation potential across a range of scenarios, including “No animal products”,
 8 “No meat”, “No ruminant meat”, and “Healthy diet” (reduced meat consumption). With regard to
 9 ‘credible low-meat diets,’ where reduction in animal protein intake was compensated by higher intake
 10 of pulses, emissions reductions by 2050 could be in the 4.3–6.4 Gt CO₂-eq yr⁻¹, compared to a
 11 business-as-usual scenario. Of this technical potential, 1–2 GtCO₂-eq yr⁻¹ come from reductions of
 12 mostly non-CO₂ GHG within the farm gate, while the remainder was linked to carbon sequestration
 13 on agricultural lands no longer needed for livestock production. When the transition to a low-meat
 14 diet reduces the agricultural area required, land is abandoned and the re-growing vegetation can take
 15 up carbon until a new equilibrium is reached. This is known as the land-sparing effect.

26 **Figure 5.12 Technical mitigation potential of changing diets by 2050 according to a range of scenarios**
 27 **examined in the literature. Estimates are technical potential only, and include additional effects of carbon**
 28 **sequestration from land-sparing. Data without error bars are from one study only.**

29 All diets need to provide a full complement of nutritional quality, including micronutrients (FAO et al. 2018)

30 Vegan: Completely plant-based (Springmann et al. 2016; Stehfest et al. 2009)

31 Vegetarian: Grains, vegetables, fruits, sugars, oils, eggs and dairy, and generally at most one serving per month
 32 of meat or seafood (Springmann et al. 2016; Tilman and Clark 2014; Stehfest et al. 2009)

33 Flexitarian: 75% of meat and dairy replaced by cereals and pulses; at least 500 g per day fruits and vegetables;
 34 at least 100 g per day of plant-based protein sources; modest amounts of animal-based proteins and limited
 35 amounts of red meat (one portion per week), refined sugar (less than 5% of total energy), vegetable oils high in
 36 saturated fat, and starchy foods with relatively high glycaemic index (Springmann et al. 2018; Hedenus et al.
 37 2014)

38 Healthy diet: Based on global dietary guidelines for consumption of red meat, sugar, fruits and vegetables, and
 39 total energy intake (Springmann et al. 2018; Bajželj et al. 2014)

40 Fair and Frugal: Global daily per-capita calorie intake of 2800 kcal/cap/day (11.7 MJ/cap/day), paired with
 41 relatively low level of animal products (Smith et al. 2013)

42 Pescetarian: Vegetarian diet that includes seafood (Tilman and Clark 2014)

43 Climate carnivore: 75% of ruminant meat and dairy replaced by other meat (Hedenus et al. 2014)

44 Mediterranean: Vegetables, fruits, grains, sugars, oils, eggs, dairy, seafood, moderate amounts of poultry, pork,
 45 lamb and beef (Tilman and Clark 2014)

1 Other studies have found similar results for potential mitigation linked to diets. For instance, Smith et
2 al. (2013) analysed a dietary change scenario that assumed a convergence towards a global daily per-
3 capita calorie intake of 2800 kcal cap⁻¹ day⁻¹ (11.7 MJ cap⁻¹ day⁻¹), paired with a relatively low level of
4 animal product supply, estimated technical mitigation potential in the range 0.7–7.3 Gt CO₂-eq yr⁻¹ for
5 additional variants including low or high-yielding bioenergy, 4.6 Gt CO₂-eq yr⁻¹ if spare land is
6 afforested.

7 Bajželj et al. (2014) developed different scenarios of farm systems change, waste management, and
8 dietary change on GHG emissions coupled to land use. Their dietary scenarios were based on target
9 kilocalorie consumption levels and reductions in animal product consumption. Their scenarios were
10 “Healthy Diet”; Healthy Diet with 2500 kcal cap⁻¹ day⁻¹ in 2050; corresponded to technical mitigation
11 potentials in the range 5.8 and 6.4 Gt CO₂-eq yr⁻¹.

12 Hedenus et al. (2014) explored further dietary variants based on the type of livestock product.
13 “Climate Carnivore”, in which 75% of the baseline-consumption of ruminant meat and dairy was
14 replaced by pork and poultry meat, and “Flexitarian”, in which 75% of the baseline-consumption of
15 meat and dairy was replaced by pulses and cereal products. Their estimates of technical mitigation
16 potentials by 2050 ranged 3.4– 5.2 Gt CO₂-eq yr⁻¹, the high end achieved under the Flexitarian.
17 Finally, Tilman and Clark (2014) used stylised diets as variants that included “Pescetarian”,
18 “Mediterranean”, “Vegetarian”, compared to a reference diet, and estimated technical mitigation
19 potentials within the farm gate of 1.2–2.3 Gt CO₂-eq yr⁻¹, with additional mitigation from carbon
20 sequestration on spared land ranging 1.8–2.4 Gt CO₂-eq yr⁻¹.

21 Studies have defined dietary mitigation potential as, for example, 20kg per person per week CO₂-eq
22 for Mediterranean diet, vs 13kg per person per week CO₂-eq for vegan (Castañé and Antón 2017).
23 Rosi et al. (2017) developed seven-day diets in Italy for about 150 people defined as omnivore 4.0 ±
24 1.0; ovo-lacto-veggie 2.6 ± 0.6; and vegan 2.3 ± 0.5 kg CO₂-eq per capita per day.

25 Importantly, many more studies that compute the economic and calorie costs of these scenarios are
26 needed. Herrero et al. (2016a) estimated that once considerations of economic and calorie costs of
27 their diet-based solutions were included, the technical range of 4.3–6.4 Gt CO₂-eq yr⁻¹ in 2050 was
28 reduced to 1.8–3.4 Gt CO₂-eq yr⁻¹ when implementing a GHG tax ranging from 20–100 USD/tCO₂.
29 While caloric costs were low below 20 USD/tCO₂, they ranged from 27–190 kcal cap⁻¹ day⁻¹ under
30 the higher economic potential, thus indicating possible negative trade-offs with food security.

31 In summary, demand-side changes in food choices and consumption can help to achieve global GHG
32 mitigation targets (*high confidence*). Low-carbon diets on average tend to be healthier and have
33 smaller land footprints. By 2050, technical mitigation potential of dietary changes range from 2.7–6.4
34 GtCO₂-eq yr⁻¹ for assessed diets (*high confidence*). At the same time, the economic potential of such
35 solutions is lower, ranging from 1.8–3.4 Gt CO₂-eq yr⁻¹ at prices of 20–100 USD/tCO₂, with caloric
36 costs up to 190 kcal cap⁻¹ day⁻¹. The feasibility of how to create economically viable transitions to
37 more sustainable and healthy diets that also respect food security requirements needs to be addressed
38 in future research.

39

40 5.5.2.2 *Role of dietary preferences*

41 Food preference is an inherently cultural dimension that can ease or hinder transformations to food
42 systems that contribute to climate change mitigation. Consumer choice and dietary preferences are
43 guided by social, cultural, environmental, and traditional factors as well as economic growth. The
44 food consumed by a given group conveys cultural significance about social hierarchy, social systems
45 and human-environment relationships (Herforth and Ahmed 2015).

1 As suggested by Springmann et al. (2018a), per capita dietary emissions will translate into different
2 realised diets, according to regional contexts including cultural and gendered norms (e.g. among some
3 groups, eating meat is perceived as more masculine (Ruby and Heine 2011). In some cases, women
4 and men have different preferences in terms of food, with women reporting eating healthier food
5 (Imamura et al. 2015; Kiefer et al. 2005; Fagerli and Wandel 1999): these studies found that men tend
6 to eat more meat, while women eat more vegetables, fruits and dairy products (Kanter and Caballero
7 2012).

8 Food preferences can change over time, with the nutrition transition from traditional diets to high-
9 meat, high-sugar, high-saturated fat diets being a clear example of significant changes occurring in a
10 short period of time. Meat consumption per capita consistently responds to income with a saturating
11 trend at high income levels (Sans and Combris 2015; Vranken et al. 2014). Some emerging economies
12 have rapidly increased demand for beef, leading to pressure on natural resources (Bowles et al. 2019).
13 In another example, by reducing beef consumption between 2005 and 2014, Americans avoided
14 approximately 271 million metric tonnes of emissions (CO₂eq) (NRDC 2017). See Section **Error!**
15 **reference source not found.** for quantitative analysis. Attending farmers markets or buying directly
16 from local producers has been shown to change worldviews (Kerton and Sinclair 2010), and food
17 habits towards healthier diets (Pascucci et al. 2011) can be advanced through active learning (Milestad
18 et al. 2010).

19 Regarding the options to reduce meat intake in developed countries, research shows that there is an
20 apparent sympathy of consumers for meat reduction due to environmental impacts (Dagevos and
21 Voordouw 2013) which has not been exploited. Social factors that influence reducing meat
22 consumption in New Zealand include the need for better education or information dispersal regarding
23 perceived barriers to producing meat-reduced/less meals; ensuring there is sensory or aesthetic appeal;
24 and placing emphasis on human health or nutritional benefits (Tucker 2018).

25 Different and complementary strategies can be used in parallel for different consumer's profiles to
26 facilitate step-by-step changes in the amounts and the sources of protein consumed. In the
27 Netherlands, a nationwide sample of 1083 consumers were used to study their dietary choices toward
28 smaller portions of meat, smaller portions using meat raised in a more sustainable manner, smaller
29 portions and eating more vegetable protein, and meatless meals with or without meat substitutes.
30 Results showed that strategies to change meat eating frequencies and meat portion sizes appeared to
31 overlap and that these strategies can be applied to address consumers in terms of their own
32 preferences (de Boer et al. 2014).

34 **5.5.2.3 Uncertainties in demand-side mitigation potential**

35 Both reducing ruminant meat consumption and increasing its efficiency are often identified as main
36 options to reduce greenhouse gases emissions (GHGE) and to lessen pressure on land (Westhoek et al.
37 2014) (See Section 5.6 for synergies and trade-offs with health and Section 5.7 for discussion of Just
38 Transitions). However, analysing ruminant meat production is highly complex because of the extreme
39 heterogeneity of production systems and due to the numerous products and services associated with
40 ruminants (Gerber et al. 2015). See Supplementary Material Section SM5.5 for further discussion of
41 uncertainties in estimates of livestock mitigation technical potential. Further, current market
42 mechanisms are regarded as insufficient to decrease consumption or increase efficiency, and
43 governmental intervention is often suggested to encourage mitigation in both the supply-side and
44 demand-side of the food system (See Section 5.7) (Wirsenius et al. 2011; Henderson et al. 2018).

45 Minimising GHG emissions through mathematical programming with near-minimal acceptability
46 constraints can be understood as a reference or technical potential for mitigation through diet shifts. In
47 this context (Macdiarmid et al. 2012) found up to 36% reduction in emissions in UK with similar diet

1 costs applying fixed lifecycle analyses (LCA) carbon footprints (i.e., no rebound effects considered).
2 Westhoek et al. (2014) found 25-40 % in emissions by halving meat, dairy and eggs intake in EU,
3 applying standard IPCC fixed emission intensity factors. Uncertainty about the consequences of on-
4 the-ground implementation of policies towards low ruminant meat consumption in the food system
5 and their externalities remain noteworthy.

6 Often, all emissions are allocated to only to human edible meat and the boundaries are set only within
7 the farm gate (Henderson et al. 2018; Gerber et al. 2013). However, less than 50% of slaughtered
8 cattle weight is human edible meat, and 1-10% of the mass is lost or incinerated, depending on
9 specified risk materials legislation. The remaining mass provide inputs to multiple industries e.g.
10 clothing, furniture, vehicle coating materials, biofuel, gelatine, soap, cosmetics, chemical and
11 pharmaceutical industrial supplies, pet feed ingredients and fertilisers (Marti et al. 2011; Mogensen et
12 al. 2016; Sousa et al. 2017). This makes ruminant meat production one of the most complex problems
13 for LCA in the food system (Place and Mitloehner 2012; de Boer et al. 2011). There are only a few
14 examples taking into account slaughter byproducts e.g., Mogensen et al. (2016).

16 **5.5.2.4 Insect-based diets**

17 Edible insects are, in general, rich in protein, fat, and energy and can be a significant source of
18 vitamins and minerals (Rumpold and Schlüter 2015). Approximately 1,900 insect species are eaten
19 worldwide, mainly in developing countries (van Huis 2013). The development of safe rearing and
20 effective processing methods are mandatory for utilisation of insects in food and feed. Some insect
21 species can be grown on organic side streams, reducing environmental contamination and
22 transforming waste into high-protein feed. Insects are principally considered as meat substitutes, but
23 worldwide meat substitute consumption is still very low, principally due to differences in food
24 culture, and will require transition phases such as powdered forms (Megido et al. 2016; Smetana et al.
25 2015). Wider consumer acceptability will relate to pricing, perceived environmental benefits, and the
26 development of tasty insect-derived protein products (van Huis et al. 2015; van Huis 2013). Clearly
27 increasing share of insect-derived protein has the potential to reduce GHG emissions otherwise
28 associated with livestock production. No study to date however has quantified such potential.

30 **5.5.2.5 Food loss and waste, food security, and land use**

31 Food loss and waste impacts food security by reducing global and local food availability, limiting
32 food access due to increase in food price and decrease of producer income, and affecting future food
33 production due to unsustainable use of natural resources (HLPE 2014). Food loss is defined as the
34 reduction of edible food during production, postharvest, and processing, whereas food discarded by
35 consumers is considered as food waste (FAO 2011b). Combined food loss and waste amount to a third
36 of global food production (*high confidence*). During 2010-2016, global food loss and waste equalled
37 8–10% of total GHG emissions (*medium confidence*); and cost about USD 1 trillion per year (FAO
38 2014b) (*low confidence*).

39 A large share of produced food is lost in developing countries due to poor infrastructure, while a large
40 share of produced food is wasted in developed countries (Godfray et al. 2010). Changing consumer
41 behaviour to reduce per capita overconsumption offers substantial potential to improve food security
42 by avoiding related health burdens (Alexander et al. 2017; Smith 2013) and reduce emissions
43 associated with the extra food (Godfray et al. 2010). In 2007, around 20% of the food produced went
44 to waste in Europe and North America, while around 30% of the food produced was lost in sub-
45 Saharan Africa (FAO 2011b). During the last 50 years, the global food loss and waste increased from
46 around 540 Mt in 1961 to 1630 Mt in 2011 (Porter et al. 2016).

1 In 2011, food loss and waste resulted in about 8–10% of the total anthropogenic greenhouse gas
2 emissions of the entire food system. The mitigation potential of reduced food loss and waste from a
3 full life-cycle perspective, i.e., considering both food supply chain activities and land use change, was
4 estimated as 4.4 Gt CO₂-eq yr⁻¹ (FAO 2015a, 2013b). At a global scale, loss and waste of milk,
5 poultry meat, pig meat, sheep meat, and potatoes are associated with 3% of the global agricultural
6 N₂O emissions (more than 200 Gg N₂O-N yr⁻¹ or 0.06 Gt CO₂-eq yr⁻¹) in 2009 (Reay et al. 2012). For
7 the United States, 35% of energy use, 34% of blue water use, 34% of GHG emissions, 31% of land
8 use, and 35% of fertiliser use related to an individual's food-related resource consumption were
9 accounted for as food waste and loss in 2010 (Birney et al. 2017).

10 Similar to food waste, overconsumption, defined as food consumption in excess of nutrient
11 requirements, leads to GHG emissions (Alexander et al. 2017). In Australia for example,
12 overconsumption accounts for about 33% GHGs associated with food (Hadjikakou 2017). In addition
13 to GHG emissions, overconsumption also can lead to severe health conditions such as obesity or
14 diabetes. Over-eating was found to be at least as large a contributor to food system losses (Alexander
15 et al. 2017). Similarly, food system losses associated with consuming resource-intensive animal-based
16 products instead of nutritionally-comparable plant-based alternatives are defined as 'opportunity food
17 losses.' These were estimated to be 96, 90, 75, 50, and 40% for beef, pork, dairy, poultry, and eggs,
18 respectively, in the US (Shepon et al. 2018).

19 Avoiding food loss and waste will contribute to reducing emissions from the agriculture sector. By
20 2050, agricultural GHG emissions associated with production of food that might be wasted may
21 increase to 1.9–2.5 Gt CO₂-eq yr⁻¹ (Hiç et al. 2016). When land use change for agriculture expansion
22 is also considered, halving food loss and waste reduces the global need for cropland area by around
23 14% and GHG emissions from agriculture and land use change by 22–28% (4.5 Gt CO₂-eq yr⁻¹)
24 compared to the baseline scenarios by 2050 (Bajželj et al. 2014). The GHG emissions mitigation
25 potential of food loss and waste reduction would further increase when life cycle analysis accounts for
26 emissions throughout food loss and waste through all food system activities.

27 Reducing food loss and waste to zero might not be feasible. Therefore, appropriate options for the
28 prevention and management of food waste can be deployed to reduce food loss and waste and to
29 minimise its environmental consequences. Papargyropoulou et al. (2014) proposed the 3Rs (i.e.,
30 reduction, recovery and recycle) options to prevent and manage food loss and waste. A wide range of
31 approaches across the food supply chain is available to reduce food loss and waste, consisting of
32 technical and non-technical solutions (Lipinski et al. 2013). However, technical solutions (e.g.,
33 improved harvesting techniques, on-farm storage, infrastructure, packaging to keep food fresher for
34 longer, etc.) include additional costs (Rosegrant et al. 2015) and may have impacts on local
35 environments (FAO 2018b). Additionally, all parts of food supply chains need to become efficient to
36 achieve the full reduction potential of food loss and waste (Lipinski et al. 2013).

37 Together with technical solutions, approaches (i.e, non- technical solutions) to changes in behaviours
38 and attitudes of a wide range of stakeholders across the food system will play an important role in
39 reducing food loss and waste. Food loss and waste can be recovered by distributing food surplus to
40 groups affected by food poverty or converting food waste to animal feed (Vandermeersch et al. 2014).
41 Unavoidable food waste can also be recycled to produce energy based on biological, thermal and
42 thermochemical technologies (Pham et al. 2015). Additionally, strategies for reducing food loss and
43 waste also need to consider gender dynamics with participation of females throughout the food supply
44 chain (FAO 2018f).

45 In summary, reduction of food loss and waste can be considered as a climate change mitigation
46 measure that provides synergies with food security and land use (*robust evidence, medium*
47 *agreement*). Reducing food loss and waste reduces agricultural GHG emissions and the need for
48 agricultural expansion for producing excess food. Technical options for reduction of food loss and

1 waste include improved harvesting techniques, on-farm storage, infrastructure, and packaging.
2 However, the beneficial effects of reducing food loss and waste will vary between producers and
3 consumers, and across regions. Causes of food loss (e.g., lack of refrigeration) and waste (e.g.,
4 behaviour) differ substantially in developed and developing countries (*robust evidence, medium*
5 *agreement*). Additionally, food loss and waste cannot be avoided completely.

7 **5.5.2.6 Shortening supply chains**

8 Encouraging consumption of locally produced food and enhancing efficiency of food processing and
9 transportation can in some cases minimise food loss, contribute to food security, and reduce GHG
10 emissions associated with energy consumption and food loss. For example, Michalský and Hooda
11 (2015), through a quantitative assessment of GHG emissions of selected fruits and vegetables in the
12 UK, reported that increased local production offers considerable emissions savings. They also
13 highlighted that when imports are necessary, importing from Europe instead of the Global South can
14 contribute to considerable GHG emissions savings. Similar results were found by Audsley et al.
15 (2010), with exceptions for some foods, such as tomatoes, peppers or sheep and goat meat. Similarly,
16 a study in India shows that long and fragmented supply chains, which lead to disrupted price signals,
17 unequal power relations perverse incentives and long transport time, could be a key barrier to
18 reducing post-harvest losses (CIPHET 2007).

19 In other cases, environmental benefits associated with local food can be offset by inefficient
20 production systems with high emission intensity and resource needs, e.g., water, due to local
21 conditions. For example, vegetables produced in open fields can have much lower GHG emissions
22 than locally produced vegetables from heated greenhouses (Theurl et al. 2014). Whether locally
23 grown food has a lower carbon footprint depends on the on-farm emissions intensity as well as the
24 transport emissions. In some cases, imported food may have a lower carbon footprint than locally
25 grown food because some distant countries can produce food at much lower emissions intensity. For
26 example, Avetisyan et al. (2014) reported that regional variation of emission intensities associated
27 with production of ruminant products have large implications for emissions associated with local
28 food. They showed that consumption of local livestock products can reduce emissions due to short
29 supply chains in countries with low emission intensities; however, this might not be the case in
30 countries with high emission intensities.

31 In addition to improving emission intensity, efficient distribution systems for local food are needed
32 for lowering carbon footprints (Newman et al. 2013). Emissions associated with food transport
33 depend on the mode of transport, for example, emissions are lower for rail rather than truck (Brodt et
34 al. 2013). Tobarra et al. (2018) reported that emissions saving from local food may vary across
35 seasons and regions of import. They highlighted that in Spain local production of fruits and vegetables
36 can reduce emissions associated with imports from Africa but imports from France and Portugal can
37 save emissions in comparison to production in Spain. Additionally, local production of seasonal
38 products in Spain reduces emissions, while imports of out-of-season products can save emissions
39 rather than producing them locally.

40 In summary, consuming locally grown foods can reduce GHG emissions, if they are grown efficiently
41 (*high confidence*). The emissions reduction potential varies by region and season. Whether food with
42 shorter supply chains has a lower carbon footprint depends on both the on-farm emissions intensity as
43 well as the transport emissions. In some cases, imported food may have a lower carbon footprint
44 because some distant agricultural regions can produce food at lower emissions intensities.

1 **5.6 Mitigation, Adaptation, Food Security, and Land Use – Synergies,** 2 **Trade-Offs, and Co-Benefits**

3 Food systems will need to adapt to changing climates and also to reduce their greenhouse gas (GHG)
4 emissions and sequester carbon if Paris Agreement goals are to be met (Springmann et al. 2018a; van
5 Vuuren et al. 2014). The synergies and trade-offs between the food system mitigation and adaptation
6 options described in Sections 5.3 and 5.5 are of increasing importance in both scientific and policy
7 communities because of the necessity to ensure food security, i.e., provision of nutritious food for the
8 growing population, while responding to climate change (Rosenzweig and Hillel 2015) A special
9 challenge involves interactions between land-based non-food system mitigation, such as negative
10 emissions technologies, and food security. Response options for the food system have synergies and
11 trade-offs between climate change mitigation and adaptation (Figure 5.13; Chapter 6).

12 Tirado et al. (2013) suggest an integrated approach to address the impacts of climate change to food
13 security that considers a combination of nutrition-sensitive adaptation and mitigation measures,
14 climate-resilient and nutrition-sensitive agricultural development, social protection, improved
15 maternal and child care and health, nutrition-sensitive risk reduction and management, community
16 development measures, nutrition-smart investments, increased policy coherence, and institutional and
17 cross-sectoral collaboration. These measures are a meansto achieve both short-term and long-term
18 benefits in poor and marginalised groups.

19 This section assesses the synergies and trade-offs for land-based atmospheric carbon dioxide removal
20 measures, effects of mitigation measures on food prices, and links between dietary choices and human
21 health. It then evaluates a range of integrated agricultural systems and practices that combine
22 mitigation and adaptation measures, including the role of agricultural intensification. The roles of
23 women’s empowerment and urban agriculture are examined, as well as interactions between SDG2
24 (Zero Hunger) and SDG 13 (Climate Action).

25

Food system response options

Figure 5.13 Response options related to food system and their potential impacts on mitigation and adaptation. Many response options offer significant potential for both mitigation and adaptation.

5.6.1 Land-based carbon dioxide removal (CDR) and bioenergy

Large-scale deployment of negative emission technologies (NETs) in emission scenarios has been identified as necessary for avoiding unacceptable climate change (IPCC 2018b). Among the available NETs, carbon dioxide removal (CDR) technologies are receiving increasing attention. Land-based CDRs include afforestation and reforestation (AR), sustainable forest management, biomass energy with carbon capture and storage (BECCS), and biochar (BC) production (Minx et al. 2018). Most of the literature on global land-based mitigation potential relies on CDRs, particularly on BECCS, as a major mitigation action (Kraxner et al. 2014; Larkin et al. 2018; Rogelj et al. 2018, 2015, 2011). BECCS is not yet deployable at a commercial scale, as it faces challenges similar to fossil fuel carbon capture and storage (CCS) (Fuss et al. 2016; Vaughan and Gough 2016; Nemet et al. 2018). Regardless, the effectiveness of large-scale BECCS to meet Paris Agreement goals has been questioned and other pathways to mitigation have been proposed (Anderson and Peters 2016; van Vuuren et al. 2017, 2018; Grubler et al. 2018; Vaughan and Gough 2016).

Atmospheric CO₂ removal by storage in vegetation depends on achieving net organic carbon accumulation in plant biomass over decadal time scales (Kemper 2015) and, after plant tissue decay, in soil organic matter (Del Grosso et al. 2019). AR, BECCS and BC differ in the use and storage of

1 plant biomass. In BECCS, biomass carbon from plants is used in industrial processes (e.g., for
2 electricity, hydrogen, ethanol, and biogas generation), releasing CO₂, which is then captured and
3 geologically stored (Greenberg et al. 2017; Minx et al. 2018).

4 Afforestation and reforestation result in long-term carbon storage in above and belowground plant
5 biomass on previously unforested areas, and is effective as a carbon sink during the AR
6 establishment period, in contrast to thousands of years for geological C storage (Smith et al. 2016).

7 Biochar is produced from controlled thermal decomposition of biomass in absence of oxygen
8 (pyrolysis), a process that also yields combustible oil and combustible gas in different proportions.
9 Biochar is a very stable carbon form, with storage on centennial timescales (Lehmann et al. 2006)
10 (See also Chapter 4). Incorporated in soils, some authors suggest it may lead to improved water-
11 holding capacity, nutrient retention, and microbial processes (Lehmann et al. 2015). There is
12 however considerable uncertainty about the benefits and risks of this practice (The Royal Society
13 2018).

14 Land-based CDRs require high biomass-producing crops. Since not all plant biomass is harvested
15 (e.g., roots and harvesting losses), it can produce co-benefits related to soil carbon sequestration, crop
16 productivity, crop quality, as well improvements in air quality, but the overall benefits strongly
17 depend on the previous land use and soil management practices (Smith et al. 2016; Wood et al. 2018).
18 In addition, CDR effectiveness varies widely depending on type of biomass, crop productivity, and
19 emissions offset in the energy system. Importantly, its mitigation benefits can be easily lost due to
20 land-use change interactions (Harper et al. 2018; Fuss et al. 2018; Daioglou et al. 2019).

21 Major common challenges of implementing these large-scale CDR solutions, as needed to stabilise
22 global temperature “well-below” 2°C by the end of the century, are the large investments and the
23 associated significant changes in land use required. Most of the existing scenarios estimate the
24 global area required for BECCS alone in the range of 109-990 Mha (IPCC 2018a), most commonly
25 around 380–700 Mha (Smith et al. 2016), reaching rates of net area expansion rates up to 23.7 M
26 ha yr⁻¹ (IPCC 2018b). The upper limit implies unprecedented rates of area expansion for crops and
27 forestry observed historically, for instance as reported by FAO since 1961 (FAOSTAT 2018). By
28 comparison, the sum of recent worldwide rates of expansion in harvested area of soybean and
29 sugarcane has not exceeded 3.5 M ha yr⁻¹ on average. Even at this rate, they have been the source
30 of major concerns for their possible negative environmental and food security impacts (Boerema et
31 al. 2016; Popp et al. 2014).

32 Most land area available for CDR is currently pasture, estimated at 3,300 Mha globally (FAOSTAT
33 2018). However, there is *low confidence* about how much low-productivity land is actually available
34 for CDR (Lambin et al. 2013; Gibbs and Salmon 2015). There is also *low confidence* and *low*
35 *agreement* if the transition to BECCS will take place directly on low-productivity grasslands
36 (Johansson and Azar 2007), and uncertainty on the governance mechanisms required to avoid
37 unwanted spill-over effects, for instance causing additional deforestation (Keles et al. 2018).

38 Further, grasslands and rangelands may often occur in marginal areas, in which case they may be
39 exposed to climate risks, including periodic flooding. Grasslands and especially rangelands and
40 savannahs tend to predominate in less-developed regions, often bordering areas of natural vegetation
41 with little infrastructure available for transport and processing of large quantities of CDR-generated
42 biomass (O’Mara 2012; Beringer et al. 2011; Haberl et al. 2010; Magdoff 2007).

43 CDR-driven reductions in available pastureland area is a scenario of constant or increasing global
44 animal protein output as proposed by (Searchinger et al. 2018). However, despite the recent reduction
45 in meat consumption in western countries, this will require productivity improvements (Cohn et al.
46 2014; Strassburg et al. 2014). It would also result in lower emission intensities and create conditions
47 for increased soil carbon stocks (de Oliveira Silva et al. 2016; Searchinger et al. 2018; Soussana et al.

1 2019, 2013). At the same time, food security may be threatened if land-based mitigation displaced
2 crops elsewhere, especially if to regions of lower productivity potential, higher climatic risk, and
3 higher vulnerability.

4 There is *low agreement* about what are the more competitive regions of the world for CDRs. Smith et
5 al. (2016) and Vaughan et al. (2018) identify as candidates relatively poor countries in Latin America,
6 Africa and Asia (except China and India). Others indicate those regions may be more competitive for
7 food production, placing Europe as a major BECCS exporter (Muratori et al. 2016). Economically
8 feasible CDR investments are forecast to be directed to regions with high biomass production
9 potential, demand for extra energy production, low leakage potential for deforestation and low
10 competition for food production (Vaughan et al. 2018). Latin America and Africa, for instance,
11 although having high biomass production potential, still have low domestic energy consumption (589
12 and 673 MTOE – 24.7 and 28.2 EJ, respectively), with about 30% of primary energy from renewable
13 sources (reaching 50% in Brazil), mainly hydropower and traditional biomass.

14 There is *high confidence* that deployment of BECCS will require ambitious investments and policy
15 interventions (Peters and Geden 2017) with strong regulation and governance of bioenergy production
16 to ensure protection of forests, maintain food security and enhance climate benefits (Burns and
17 Nicholson 2017; Vaughan et al. 2018; Muratori et al. 2016), and that such conditions may be
18 challenging for developing countries. Increased value of bioenergy puts pressure on land, ecosystem
19 services, and the prices of agricultural commodities, including food (*high confidence*).

20 There is *medium confidence* for the impact of CDR technologies on increased food prices and reduced
21 food security, as these depend on several assumptions. Nevertheless, those impacts could be strong,
22 with food prices doubling under certain scenario combinations (Popp et al. 2017). The impacts of
23 land-mitigation policies on the reduction of dietary energy availability alone, i.e., without climate
24 change impacts, is estimated at over 100 kcal.person⁻¹ day⁻¹ by 2050, with highest regional impacts in
25 south Asia and sub-Saharan Africa (Hasegawa et al. 2018) (See Section 5.2). However, only limited
26 pilot BECCS projects have been implemented to date (Lenzi et al. 2018). Integrated assessment
27 models (IAMs) use theoretical data based on high-level studies and limited regional data from the few
28 on-the-ground BECCS projects.

29 Furthermore, it has been suggested that several BECCS IAM scenarios rely on unrealistic
30 assumptions regarding regional climate, soils and infrastructure suitability (Anderson and Peters
31 2016), as well as international bioenergy trade (Lamers et al. 2011). Current global IAMs usually
32 consider major trends in production potential and projected demand, overlooking major challenges for
33 the development of a reliable international market. Such a market will have to be created from scratch
34 and overcome a series of constraints, including trade barriers, logistics, and supply chains, as well as
35 social, ecological and economic impacts (Matzenberger et al. 2015).

36 In summary, there is *high agreement* that better assessment of BECCS mitigation potential would
37 need to be based on increased regional, bottom-up studies of biomass potentials, socio-economic
38 consequences (including on food security), and environmental impacts in order to develop more
39 realistic estimates (IPCC 2018a).

40

41 **5.6.2 Mitigation, food prices, and food security**

42 Food prices are the result of supply, demand and trade relations. Earlier studies (e.g., (Nelson et al.
43 2009)) showed that recent climate impacts that reduced crop productivity led to higher prices and
44 increased trade of commodities between regions, with asymmetric impacts on producers and
45 consumers. In terms of published scenario analyses, the most affected regions tend to be Sub-Saharan
46 Africa and parts of Asia, but there is significant heterogeneity in results between countries. Relocation

1 of production to less affected areas buffers these impacts to a certain extent, as well as potential for
2 improvements in food production technologies (Hasegawa et al. 2018; van Meijl et al. 2017; Wiebe et
3 al. 2015; Lotze-Campen et al. 2014; Valin et al. 2014; Robinson et al. 2014).

4 A newer, less studied impact of climate change on prices and their impacts on food security is the
5 level of land-based mitigation necessary to stabilise global temperature. Hasegawa et al. (2018), using
6 an ensemble of seven global economic models across a range of greenhouse gas emissions pathways
7 and socioeconomic trajectories, suggested that the level of mitigation effort needed to reduce
8 emissions can have a more significant impact on prices than the climate impacts themselves on
9 reduced crop yields (Figure 5.14). This occurs because in the models, taxing GHG emissions leads to
10 higher crop and livestock prices, while land-based mitigation leads to less land availability for food
11 production, potentially lower food supply, and therefore food price increases.

12 Price increases in turn lead to reduced consumption, especially by vulnerable groups, or to shifts
13 towards cheaper food, which are often less nutritious. This leads to significant increases in the number
14 of malnourished people. Frank et al. (2017) and Fujimori et al. (2017) arrived at the same conclusions
15 for the 1.5°C mitigation scenario using the IAM Globiom and ensembles of AgMIP global economic
16 models. While the magnitude of the response differs between models, the results are consistent
17 between them. In contrast, a study based on five global agro-economic models highlights that the
18 global food prices may not increase much when the required land for bioenergy is accessible on the
19 margin of current cropland, or the feedstock does not have a direct competition with agricultural land
20 (Lotze-Campen et al. 2014).

21 These studies highlight the need for careful design of emissions mitigation policies in upcoming
22 decades—for example, targeted schemes encouraging more productive and resilient agricultural
23 production systems and the importance of incorporating complementary policies (such as safety-net
24 programmes for poverty alleviation) that compensate or counteract the impacts of the climate change
25 mitigation policies on vulnerable regions (Hasegawa et al. 2018). Fujimori et al. (2018) showed how
26 an inclusive policy design can avoid adverse side-effects on food security through international aid,
27 bioenergy taxes, or domestic reallocation of income. These strategies can shield impoverished and
28 vulnerable people from the additional risk of hunger that would be caused by the economic effects of
29 policies narrowly focussing on climate objectives only.

1

2

3 **Figure 5.14 Regional impacts of climate change and mitigation on food price (top), population (pop) at**
 4 **risk of hunger or undernourishment (middle), greenhouse gas emissions (bottom) in 2050 under different**
 5 **socio-economic scenarios (SSP1, SSP2 and SSP3). Values indicate changes from no climate change and**
 6 **no climate change mitigation scenario. MAGPIE, a global land use allocation model, is excluded due to**

1 **inelastic food demand. The value of India includes that of Other Asia in MAGNET, a global general**
2 **equilibrium model (Hasegawa et al. 2018)**

3 In summary, food security will be threatened through increasing numbers of malnourished people if
4 land-based mitigation raises prices, unless other policy mechanisms reduce its impact (*high*
5 *confidence*). Inclusive policy design can avoid adverse side-effects on food security by shielding
6 vulnerable people from the additional risk of hunger that would be caused by the economic effects of
7 policies narrowly focusing on climate objectives (*medium confidence*).

8

9 **5.6.3 Environmental and health effects of adopting healthy and sustainable diets**

10 Two key questions arise from the potentially significant mitigation potential of dietary change: 1) Are
11 ‘low-GHG emission diets’ likely to be beneficial for health? and 2) Would changing diets at scale
12 provide substantial benefits? In short, what are the likely synergies and trade-offs between low-GHG
13 emissions diets and food security, health, and climate change? See Supplementary Material Section
14 SM5.6 for further discussion.

15 *Are “low GHG emission diets” healthy?* Consistent evidence indicates that, in general, a dietary
16 pattern that is higher in plant-based foods, such as vegetables, fruits, whole grains, legumes, nuts, and
17 seeds, and lower in animal-based foods, is more health-promoting and associated with lower
18 environmental impact (GHG emissions and energy, land, and water use) than either the current global
19 average diets (Swinburn et al. 2019; Willett et al. 2019; Springmann et al. 2016b), or the current
20 average US diet (Nelson et al. 2016). Another study (Van Mierlo et al. 2017) showed that
21 nutritionally-equivalent diets can substitute plant-based foods for meat and provide reductions in
22 GHG emissions.

23 There are several studies that estimate health adequacy and sustainability and conclude that healthy
24 sustainable diets are possible. These include global studies (e.g., (Willett et al. 2019; Swinburn et al.
25 2019)), as well as localised studies (e.g., (Van Dooren et al. 2014). For example, halving
26 consumption of meat, dairy products and eggs in the European Union would achieve a 40% reduction
27 in ammonia emissions, 25–40% reduction in non-CO₂ GHG emissions (primarily from agriculture)
28 and 23% per capita less use of cropland for food production, with dietary changes lowering health
29 risks (Westhoek et al. 2014). In China, diets were designed that could meet dietary guidelines while
30 creating significant reductions in GHG emissions (between 5% and 28%, depending on scenario)
31 (Song et al. 2017). Changing diets can also reduce non-dietary related health issues caused by
32 emissions of air pollutants; for example, specific changes in diets were assessed for their potential to
33 mitigate PM_{2.5} in China (Zhao et al. 2017b).

34 A range of studies are starting to estimate both health and environmental benefits from dietary shifts.
35 For example, (Farchi et al. 2017) estimate health (colorectal cancer, cardio-vascular disease) and
36 GHG reductions of “Mediterranean” diets, low in meat, in Italy, finding the potential to reduce deaths
37 from colorectal cancer of 7-10% and CVD from 9-10%, and potential savings of up to 263 CO₂-
38 eq.person⁻¹.yr⁻¹. In the US, Hallström et al. (2017) found that adoption of healthier diets (consistent
39 with dietary guidelines, and reducing amounts of red and processed meats) could reduce relative risk
40 of coronary heart disease, colorectal cancer, and type 2 diabetes by 20–45%, US health care costs by
41 USD 77–93 billion per year, and direct GHG emissions by 222–826 kg CO₂-eq/capita yr⁻¹ (69–84 kg
42 from the health care system, 153–742 kg from the food system). Broadly similar conclusions were
43 found for the Netherlands (Biesbroek et al. 2014); and the UK (Friel et al. 2009; Milner et al. 2015).

44 Whilst for any given disease, there are a range of factors, including diet, that can affect it, and
45 evidence is stronger for some diseases than others, a recent review found that an overall trend toward
46 increased cancer risk was associated with unhealthy dietary patterns, suggesting that diet-related

1 choices could significantly affect the risk of cancer (Grosso et al. 2017). Tilman and Clark (2014)
 2 found significant benefits in terms of reductions in relative risk of key diseases: type 2 diabetes,
 3 cancer, coronary mortality and all causes of mortality (Figure 5.11).

5.6.3.1 Can dietary shifts provide significant benefits?

6 Many studies now indicate that dietary shifts can significantly reduce GHG emissions. For instance,
 7 several studies highlight that if current dietary trends are maintained, this could lead to emissions
 8 from agriculture of approximately 20 Gt CO₂-eq yr⁻¹ by 2050, creating significant mitigation potential
 9 (Pradhan et al. 2013b; Bajželj et al. 2014; Hedenus et al. 2014; Bryngelsson et al. 2017). Additionally
 10 in the US, a shift in consumption towards a broadly healthier diet, combined with meeting the USDA
 11 and Environmental Protection Agency's 2030 food loss and waste reduction goals, could increase *per*
 12 *capita* food-related energy use by 12%, decrease blue water consumption by 4%, decrease green
 13 water use by 23%, decrease GHG emissions from food production by 11%, decrease GHG emissions
 14 from landfills by 20%, decrease land use by 32%, and increase fertiliser use by 12% (Birney et al.
 15 2017). This study, however, does not account for all potential routes to emissions, ignoring, for
 16 example, fertiliser use in feed production. Similar studies have been conducted, for China (Li et al.
 17 2016), where adoption of healthier diets and technology improvements have the potential to reduce
 18 food systems GHG emissions by >40% relative to those in 2010; and India (Green et al. 2017; Vetter
 19 et al. 2017), where alternative diet scenarios can affect emissions from the food system by -20 to
 20 +15%.

22
 23 **Figure 5.11 Diet and health effects of different consumption scenarios (Tilman and Clark 2014) (* reflects**
 24 **data from a single study, hence no error bars)**

25 Springmann et al (2018a) modelled the role of technology, waste reduction and dietary change in
 26 living within planetary boundaries (Rockström et al. 2009), with the climate change boundary being a
 27 66% chance of limiting warming to less than 2°C. They found that all are necessary for achievement
 28 of a sustainable food system. Their principal conclusion is that only by adopting a “flexitarian diet”,
 29 as a global average, would climate change be limited to under two degrees. Their definition of a
 30 flexitarian diet is fruits and vegetables, plant-based proteins, modest amounts of animal-based
 31 proteins, and limited amounts of red meat, refined sugar, saturated fats, and starchy foods.

1 Healthy and sustainable diets address both health and environmental concerns (Springmann et al.
2 2018b). There is high agreement that there are significant opportunities to achieve both objectives
3 simultaneously. Contrasting results of marginal GHG emissions, i.e. variations in emissions as a result
4 of variation in one or more dietary components, are found when comparing low to high emissions
5 self-selected diets (diets freely chosen by consumers). (Vieux et al. 2013) found self-selected
6 healthier diets with higher amounts of plant-based food products did not result in lower emissions,
7 while (Rose et al. 2019) found that the lowest emission diets analysed were lower in meat but
8 higher in oil, refined grains and added sugar. (Vieux et al. 2018) concluded that setting nutritional
9 goals with no consideration for the environment may increase GHG emissions (GHGE).

10 Tukker et al. (2011) also found a slight increase in emissions by shifting diets towards the European
11 dietary guidelines, even with lower meat consumption. Heller and Keoleian (2015) found a 12%
12 increase in GHGE when shifting to iso-caloric diets, i.e., diets with the same caloric intake of diets
13 currently consumed, following the US guidelines and a 1% decrease in GHGE when adjusting caloric
14 intake to recommended levels for moderate activity. There is scarce information on the marginal
15 GHGE that would be associated with following dietary guidelines in developing countries.

16 Some studies have found a modest mitigation potential of diet shifts when economic and biophysical
17 systems effects are taken into account in association with current dietary guidelines. Tukker et al.
18 (2011), considering economic rebound effects of diet shifts (i.e., part of the gains would be lost due to
19 increased use at lower prices), found maximum changes in emissions of the EU food system of 8%
20 (less than 2% of total EU emissions) when reducing meat consumption by 40 to 58%. Using an
21 economic optimisation model for studying carbon taxation in food but with adjustments of
22 agricultural production systems and commodity markets in Europe (Zech and Schneider 2019) found
23 a reduction of 0.41% in GHG emissions at a tax level of 50 USDt⁻¹CO₂eq. They estimate a leakage of
24 43% of the greenhouse gas emissions reduced by domestic consumption, (i.e., although reducing
25 emissions due to reducing consumption, around 43% of the emissions would not be reduced because
26 part of the production would be directed to exports).

27 Studying optimised beef production systems intensification technologies in a scenario of no
28 grasslands area expansion (de Oliveira Silva et al. 2016) found marginal GHG emissions to be
29 negligible in response to beef demand in the Brazilian Cerrado. This was because reducing
30 productivity would lead to increased emission intensities, cancelling out the effect of reduced
31 consumption.

32 In summary, there is significant potential mitigation (*high confidence*) arising from the adoption of
33 diets in line with dietary recommendations made on the basis of health. These are broadly similar
34 across most countries. These are typically capped by at the number of calories and higher in plant-
35 based foods, such as vegetables, fruits, whole grains, legumes, nuts and seeds, and lower in animal-
36 sourced foods, fats and sugar. Such diets have the potential to be both more sustainable and healthy
37 than alternative diets (but healthy diets are not necessarily sustainable and vice versa). The extent to
38 which the mitigation potential of dietary choices can be realised requires both climate change and
39 health being considered together. Socio-economic (prices, rebound effects), political, and cultural
40 contexts would require significant consideration to enable this mitigation potential to be realised.

41

42 **5.6.4 Sustainable integrated agricultural systems**

43 A range of integrated agricultural systems are being tested to evaluate synergies between mitigation
44 and adaptation and lead to low-carbon and climate-resilient pathways for sustainable food security
45 and ecosystem health (*robust evidence, medium agreement*). Integration refers to the use of practices
46 that enhance an agroecosystem's mitigation, resilience, and sustainability functions. These systems
47 follow holistic approaches with the objective of achieving biophysical, socio-cultural, and economic

1 benefits from land management systems (Sanz et al. 2017). These integrated systems may include
2 agroecology (FAO et al. 2018; Altieri et al. 2015), climate smart agriculture (FAO 2011c; Lipper et
3 al. 2014; Aggarwal et al. 2018), conservation agriculture (Aryal et al. 2016; Sapkota et al. 2015), and
4 sustainable intensification (FAO 2011d; Godfray 2015), among others.

5 Many of these systems are complementary in some of their practices, although they tend to be based
6 on different narratives (Wezel et al. 2015; Lampkin et al. 2015; Pimbert 2015). They have been tested
7 in various production systems around the world (Dinesh et al. 2017; Jat et al. 2016; Sapkota et al.
8 2015; Neufeldt et al. 2013). Many technical innovations, e.g., precision nutrient management
9 (Sapkota et al. 2014) and precision water management (Jat et al. 2015), can lead to both adaptation
10 and mitigation outcomes and even synergies; although negative adaptation and mitigation outcomes
11 (i.e., trade-offs) are often overlooked. Adaptation potential of ecologically intensive systems includes
12 crop diversification, maintaining local genetic diversity, animal integration, soil organic management,
13 water conservation and harvesting the role of microbial assemblages (See Section 5.3). Technical
14 innovations may encompass not only inputs reduction, but complete redesign of agricultural systems
15 (Altieri et al. 2017) and how knowledge is generated (Levidow et al. 2014), including social and
16 political transformations.

17

18 **5.6.4.1 Agroecology**

19 Agroecology (see Glossary) (Francis et al. 2003; Gliessman and Engles 2014; Gliessman 2018),
20 provides knowledge for their design and management, including social, economic, political, and
21 cultural dimensions (Dumont et al. 2016). It started with a focus at the farm level but has expanded to
22 include the range of food system activities (Benkeblia 2018). Agroecology builds systems resilience
23 through knowledge-intensive practices relying on traditional farming systems and co-generation of
24 new insights and information with stakeholders through participatory action research (Menéndez et al.
25 2013). It provides a multidimensional view of food systems within ecosystems, building on
26 indigenous and local knowledge (ILK) and co-evolving with the experiences of local people, available
27 natural resources, access to these resources, and ability to share and pass on knowledge among
28 communities and generations, emphasising the inter-relatedness of all agroecosystem components and
29 the complex dynamics of ecological processes (Vandermeer 1995).

30 At the farm level, agroecological practices recycle biomass and regenerate soil biotic activities. They
31 strive to attain balance in nutrient flows to secure favorable soil and plant growth conditions,
32 minimise loss of water and nutrients, and improve use of solar radiation. Practices include efficient
33 microclimate management, soil cover, appropriate planting time and genetic diversity. They seek to
34 promote ecological processes and services such as nutrient cycling, balanced predator/prey
35 interactions, competition, symbiosis, and successional changes. The overall goal is to benefit human
36 and non-human communities in the ecological sphere, with fewer negative environmental or social
37 impacts and fewer external inputs (Vandermeer et al. 1998; Altieri et al. 1998). From a food system
38 focus, agroecology provides management options in terms of commercialisation and consumption
39 through the promotion of short food chains and healthy diets (Pimbert and Lemke 2018; Loconto et al.
40 2018).

41 Agroecology has been proposed as a key set of practices in building climate resilience (FAO et al.
42 2018; Altieri et al. 2015). These can enhance on-farm diversity (of genes, species, and ecosystems)
43 through a landscape approach (FAO 2018g). Outcomes include soil conservation and restoration and
44 thus soil carbon sequestration, reduction of the use of mineral and chemical fertilisers, watershed
45 protection, promotion of local food systems, waste reduction, and fair access to healthy food through
46 nutritious and diversified diets (Pimbert and Lemke 2018; Kremen et al. 2012; Goh 2011; Gliessman
47 and Engles 2014).

1 A principle agroecology is to contribute to food production by smallholder farmers (Altieri 2002).
2 Since climatic events can severely impact smallholder farmers, there is a need to better understand the
3 heterogeneity of small-scale agriculture in order to consider the diversity of strategies that traditional
4 farmers have used and still use to deal with climatic variability. In Africa, many smallholder farmers
5 cope with and even prepare for climate extremes, minimising crop failure through a series of
6 agroecological practices (e.g., biodiversification, soil management, and water harvesting) (Mbow et
7 al. 2014a). Resilience to extreme climate events is also linked to on-farm biodiversity, a typical
8 feature of traditional farming systems (Altieri and Nicholls 2017).

9 Critiques of agroecology refer to its explicit exclusion of modern biotechnology (Kershen 2013) and
10 the assumption that smallholder farmers are a uniform unit with no heterogeneity in power (and thus
11 gender) relationships (Neira and Montiel 2013; Siliprandi and Zuluaga Sánchez 2014).

13 **5.6.4.2 Climate-smart agriculture**

14 ‘Climate-smart agriculture’ (CSA) is an approach developed to tackle current food security and
15 climate change challenges in a joint and synergistic fashion (Lipper et al. 2014; Aggarwal et al. 2018;
16 FAO 2013c). CSA is designed to be a pathway towards development and food security built on three
17 pillars: increasing productivity and incomes, enhancing resilience of livelihoods and ecosystems and
18 reducing, and removing GHG emissions from the atmosphere (FAO 2013c). Climate-smart
19 agricultural systems are integrated approaches to the closely linked challenges of food security,
20 development, and climate change adaptation/mitigation to enable countries to identify options with
21 maximum benefits and those where trade-offs need management.

22 Many agricultural practices and technologies already provide proven benefits to farmers’ food
23 security, resilience and productivity (Dhanush and Vermeulen 2016). In many cases these can be
24 made implemented by changing the suites of management practices. For example, enhancing soil
25 organic matter to improve water-holding capacity of agricultural landscapes also sequesters carbon. In
26 annual cropping systems, changes from conventional tillage practices to minimum tillage can convert
27 the system from one that either provides only adaptation or mitigation benefits or neither types of
28 benefits to one that provides both adaptation and mitigation benefits (Sapkota et al. 2017a; Harvey et
29 al. 2014a).

30 Increasing food production by using more fertilisers in agricultural fields could maintain crop yield in
31 the face of climate change, but may result in greater overall GHG emissions. But increasing or
32 maintaining the same level of yield by increasing nutrient-use-efficiency through adoption of better
33 fertiliser management practices could contribute to both food security and climate change mitigation
34 (Sapkota et al. 2017a).

35 Mixed farming systems integrating crops, livestock, fisheries and agro-forestry could maintain crop
36 yield in the face of climate change, help the system to adapt to climatic risk, and minimise GHG
37 emissions by increasingly improving the nutrient flow in the system (Mbow et al. 2014a; Newaj et al.
38 2016; Bioversity International 2016). Such systems can help diversify production and/or incomes and
39 support efficient and timely use of inputs thus contributing to increased resilience, but require local
40 seed and input systems and extension services. Recent whole farm modelling exercises have shown
41 the economic and environmental (reduced GH emissions, reduced land use) benefits of integrated
42 crop-livestock systems. Gil et al. (2018) compared different soy-livestock systems across multiple
43 economic and environmental indicators, including climate resilience. However it is important to note
44 that potential benefits are very context specific.

45 Although climate-smart agriculture involves a holistic approach, some argue that it narrowly focuses
46 on technical aspects at the production level (Taylor 2018; Newell and Taylor 2018). Studying barriers
47 to the adoption and diffusion of technological innovations for climate-smart agriculture in Europe,

1 Long et al. (2016) found that there was incompatibility between existing policies and climate-smart
2 agriculture objectives, including barriers to the adoption of technological innovations.

3 Climate-smart agricultural systems recognise that the implementation of the potential options will be
4 shaped by specific country contexts and capacities, as well as enabled by access to better information,
5 aligned policies, coordinated institutional arrangements and flexible incentives and financing
6 mechanisms (Aggarwal et al. 2018). Attention to underlying socio-economic factors that affect
7 adoption of practices and access to technologies is crucial for enhancing biophysical processes,
8 increasing productivity, and reducing GHG emissions at scale. The Government of India, for example,
9 has started a program of climate resilient villages (CRV) as a learning platform to design, implement,
10 evaluate and promote various climate-smart agricultural interventions, with the goal of ensuring
11 enabling mechanisms at the community level (Srinivasa Rao et al. 2016).

12

13 **5.6.4.3 Conservation agriculture**

14 Conservation agriculture (CA) is based on the principles of minimum soil disturbance and permanent
15 soil cover combined with appropriate crop rotation (Jat et al. 2014; FAO 2011e). CA has been shown
16 to respond with positive benefits to smallholder farmers under both economic and environmental
17 pressures (Sapkota et al. 2017a, 2015). This agricultural production system uses a body of soil and
18 residues management practices that control erosion (Blanco Sepúlveda and Aguilar Carrillo 2016)
19 and at the same time to improve soil quality, by increasing organic matter content and improving
20 porosity, structural stability, infiltration and water retention (Sapkota et al. 2017a, 2015; Govaerts et
21 al. 2009)

22 Intensive agriculture during the second half of the 20th century led to soil degradation and loss of
23 natural resources and contributed to climate change. Sustainable soil management practices can
24 address both food security and climate change challenges faced by these agricultural systems. For
25 example, sequestration of soil organic carbon (SOC) is an important strategy to improve soil quality
26 and to mitigation of climate change (Lal 2004). CA has been reported to increase farm productivity by
27 reducing costs of production (Aryal et al. 2015; Sapkota et al. 2015; Indoria et al. 2017) as well as to
28 reduce GHG emission (Pratibha et al. 2016).

29 CA brings favourable changes in soil properties that affect the delivery of nature's contribution to
30 people (NCPs) or ecosystem services including climate regulation through carbon sequestration and
31 GHG emissions (Palm et al. 2013; Sapkota et al. 2017a). However, by analysing datasets for soil
32 carbon in the tropics, Powlson et al. (2014, 2016) argued that the rate of SOC increase and resulting
33 GHG mitigation in CA systems, from zero-tillage in particular, has been overstated (see also Chapter
34 2).

35 However, there is unanimous agreement that the gain in SOC and its contribution to GHG mitigation
36 by CA in any given soil is largely determined by the quantity of organic matter returned to the soil
37 (Giller et al. 2009; Virto et al. 2011; Sapkota et al. 2017b). Thus, a careful analysis of the production
38 system is necessary to minimise the trade-offs among the multiple use of residues, especially where
39 residues remain an integral part of livestock feeding (Sapkota et al. 2017b). Similarly, replacing
40 mono-cropping systems with more diversified cropping systems and agroforestry as well as
41 afforestation and deforestation can buffer temperatures as well as increase carbon storage (Mbow et
42 al. 2014a; Bioversity International 2016), and provide diversified and healthy diets in the face of
43 climate change.

44 CA adoption in Africa has been low despite more than three decades of implementation (Giller et al.
45 2009), although there is promising uptake recently in east and southern Africa. This calls for a better
46 understanding of the social and institutional aspects around CA adoption. Brown et al. (2017a) found

1 that institutional and community constraints hampered the use of financial, physical, human and
2 informational resources to implement CA programs.

3 Gender is another variable to consider since at intra-household level, decision-making and benefits
4 distribution. CA interventions have implications for labour requirements, labour allocation, and
5 investment decisions, all of which impacting the roles of men and women (Farnworth et al. 2016) (see
6 also Section 5.1.3). For example, in the global South, CA generally reduces labour and production
7 costs and generally leads to increased returns to family labour (Aryal et al. 2015) although a gender
8 shift of the labour burden to women have also been described (Giller et al. 2009).

9

10 **5.6.4.4 Sustainable intensification**

11 The need to produce about 50% more food by 2050, required to feed the increasing world population
12 (FAO 2018a) may come at the price of significant increases in GHG emissions and environmental
13 impacts, including loss of biodiversity. For instance, land conversion for agriculture is responsible for
14 an estimated 8-10% of all anthropogenic GHG emissions currently (see Section 5.4). Recent calls for
15 sustainable intensification (SI) are based on the premise that damage to the environment through
16 extensification outweighs benefits of extra food produced on new lands (Godfray 2015). However,
17 increasing net production area by restoring already degraded land may contribute to increased
18 production on the one hand and increase carbon sequestration on the other (Jat et al. 2016), thereby
19 contributing to both increased agricultural production and improved natural capital outcomes (Pretty
20 et al. 2018).

21 Sustainable intensification is a goal but does not specify *a priori* how it could be attained, e.g., which
22 agricultural techniques to deploy (Garnett et al. 2013). It can be combined with selected other
23 improved management practices, e.g., conservation agriculture (see above) or agroforestry, with
24 additional economic, ecosystem services, and carbon benefits. Sustainable intensification, by
25 improving nutrient-, water- and other input-use-efficiency, not only helps to close yield gaps and
26 contribute to food security (Garnett et al. 2013), but also reduces the loss of such production inputs
27 and associated emissions (Sapkota et al. 2017c; Wollenberg et al. 2016). Closing yield gaps is a way
28 to become more efficient in use of land per unit production. Currently, most regions in Africa and
29 South Asia have attained less than 40% of their potential crop production (Pradhan et al. 2015).
30 Integrated farming systems (e.g., mixed crop-livestock, crop-aquaculture) are strategies to produce
31 more products per unit land, which in regard to food security, becomes highly relevant.

32 Sustainable intensification acknowledges that enhanced productivity needs to be accompanied by
33 maintenance of other ecosystem services and enhanced resilience to shocks (Vanlauwe et al. 2014). SI
34 in intensively farmed areas may require a reduction in production in favour of increasing
35 sustainability in the broad sense (Buckwell et al. 2014) (see Cross-Chapter Box 6: Agricultural
36 Intensification). Hence, moving towards sustainability may imply lower yield growth rates than those
37 maximally attainable in such situations. For areas that contain valuable natural ecosystems, such as
38 the primary forest in the Congo basin, intensification of agriculture is one of the pillars of the strategy
39 to conserve forest (Vanlauwe et al. 2014). Intensification in agriculture is recognised as one of the
40 pathways to meet food security and climate change adaptation and mitigation goals (Sapkota et al.
41 2017c).

42 However, SI does not always confer co-benefits in terms of food security and climate change
43 adaption/mitigation. For example, in the case of Vietnam, intensified production of rice and pigs
44 reduced GHG emissions in the short term through land sparing, but after two decades, the emissions
45 associated with higher inputs were likely to outweigh the savings from land sparing (Thu Thuy et al.
46 2009). Intensification needs to be sustainable in all components of food system by curbing agricultural

1 sprawl, rebuilding soils, restoring degraded lands, reducing agricultural pollution, increasing water
2 use efficiency, and decreasing the use of external inputs (Cook et al, 2015).

3 A study conducted by Palm et al. (2010) in sub-Saharan Africa, reported that at low population
4 densities and high land availability, food security and climate mitigation goals can be met with
5 intensification scenarios, resulting in surplus crop area for reforestation. In contrast, for high
6 population density and small farm sizes, attaining food security and reducing GHG emissions require
7 use of more mineral fertilisers to make land available for reforestation. However, some forms of
8 intensification in drylands can increase rather than reduce vulnerability due to adverse effects such as
9 environmental degradation and increased social inequity (Robinson et al. 2015).

10 Sustainable intensification has been critiqued for considering food security only from the supply side,
11 whereas global food security requires attention to all aspects of food system, including access,
12 utilisation, and stability (Godfray 2015). Further, adoption of high-input forms of agriculture under
13 the guise of simultaneously improving yields and environmental performance will attract more
14 investment leading to higher rate of adoption but with the environmental component of SI quickly
15 abandoned (Godfray 2015). Where adopted, SI needs to engage with the sustainable development
16 agenda to (i) identify SI agricultural practices that strengthen rural communities, improve smallholder
17 livelihoods and employment, and avoid negative social and cultural impacts, including loss of land
18 tenure and forced migration; (ii) invest in the social, financial, natural, and physical capital needed to
19 facilitate SI implementation; and (iii) develop mechanisms to pay poor farmers for undertaking
20 sustainability measures (e.g., GHG emissions mitigation or biodiversity protection) that may carry
21 economic costs (Garnett et al. 2013).

22 In summary, integrated agricultural systems and practices can enhance food system resilience to
23 climate change and reduce GHG emissions, while helping to achieve sustainability (*high confidence*).

24

25 **Cross-Chapter Box 6: Agricultural intensification: land sparing, land** 26 **sharing and sustainability**

27 Eamon Haughey (Ireland), Tim Benton (United Kingdom), Annette Cowie (Australia), Lennart
28 Olsson (Sweden), Pete Smith (United Kingdom)

29 **Introduction**

30 The projected demand for more food, fuel and fibre for a growing human population necessitates
31 intensification of current land use to avoid conversion of additional land to agriculture and potentially
32 allow the sparing of land to provide other ecosystem services, including carbon sequestration,
33 production of biomass for energy, and the protection of biodiversity (Benton et al. 2018; Garnett et al.
34 2013). Land use intensity may be defined in terms of three components; (i) intensity of system inputs
35 (land/soil, capital, labour, knowledge, nutrients and other chemicals), (ii) intensity of system outputs
36 (yield per unit land area or per specific input) and (iii) the impacts of land use on ecosystem services
37 such as changes in soil carbon or biodiversity (Erb et al. 2013). Intensified land use can lead to
38 ecological damage as well as degradation of soil resulting in a loss of function which underpins many
39 ecosystem services (Wilhelm and Smith 2018); (Smith et al. 2016). Therefore, there is a risk that
40 increased agricultural intensification could deliver short-term production goals at the expense of
41 future productive potential, jeopardising long term food security (Tilman et al. 2011).

42 Agroecosystems which maintain or improve the natural and human capital and services they provide
43 may be defined as sustainable systems, while those which deplete these assets as unsustainable (Pretty
44 and Bharucha 2014). Producing more food, fuel and fibre without the conversion of additional non-
45 agricultural land while simultaneously reducing environmental impacts requires what has been termed

1 sustainable intensification (Godfray et al. 2010; FAO 2011e); see glossary and Cross-Chapter Box 6,
2 Figure 1). Sustainable intensification (SI) may be achieved through a wide variety of means; from
3 improved nutrient and water use efficiency via plant and animal breeding programs, to the
4 implementation of integrated soil fertility and pest management practices, as well as by smarter land
5 use allocation at a larger spatial scale: for example, matching land use to the context and specific
6 capabilities of the land (Benton et al. 2018). However, implementation of SI is broader than simply
7 increasing the technical efficiency of agriculture (“doing more with less”); it sometimes may require a
8 reduction of yields to raise sustainability, and successful implementation can be dependent on place
9 and scale. (Pretty et al. 2018), following (Hill 1985), highlights three elements to SI: (i) increasing
10 efficiency, (ii) substitution of less beneficial or efficient practices for better ones, and (iii) system
11 redesign to adopt new practices and farming systems (see Cross-Chapter Box 6, Table 1).

12 Under a land sparing strategy, intensification of land use in some areas, generating higher productivity
13 per unit area of land, can allow other land to provide other ecosystem services such as increased
14 carbon sequestration and the conservation of natural ecosystems and biodiversity (Balmford et al.
15 2018; Strassburg et al. 2014). Conversely under a land sharing strategy less, or no, land is set aside,
16 but lower levels of intensification are applied to agricultural land, providing a combination of
17 provisioning and other functions such as biodiversity conservation from the same land (Green et al.
18 2005). The two approaches are not mutually exclusive and the suitability of their application is
19 generally system-, scale- and/or location specific (Fischer et al. 2014). One crucial issue for the
20 success of a land sparing strategy is that spared land is protected from further conversion: as the
21 profits from the intensively managed land increase, there is an incentive for conversion of additional
22 land for production (Byerlee et al. 2014). Furthermore, it is implicit that there are limits to the SI of
23 land at a local and also planetary boundary level (Rockström et al. 2009). These may relate to the
24 “health” of soil, the presence of supporting services, such as pollination, local limits to water
25 availability, or limits on air quality. This implies that it may not be possible to meet demand
26 “sustainably” if demand exceeds local and global limits. There are no single global solutions to these
27 challenges and specific in situ responses for different farming systems and locations are required.
28 Bajželj et al. (2014) showed that implementation of SI, primarily through yield gap closure, had better
29 environmental outcomes compared with business as usual trajectories. However, SI alone will not be
30 able to deliver the necessary environmental outcomes from the food system – dietary change and
31 reduced food waste are also required (Springmann et al. 2018a; Bajželj et al. 2014).

32 **Cross-Chapter Box 6, Table 1 Approaches to sustainable intensification of agriculture (Pretty et al. 2018;**
33 **Hill 1985)**

Approach	Sub-category	Examples/notes
Improving efficiency	Precision agriculture	High and low-technology options to optimise resource use.
	Genetic improvements	Improved resource use efficiency through crop or livestock breeding.
	Irrigation technology	Increase production in areas currently limited by precipitation (sustainable water supply required).
	Organisational scale-up	Increasing farm organisational scale (e.g. co-operative schemes) can increase efficiency via facilitation of mechanisation and precision techniques.
Substitution	Green fertiliser	Replacing chemical fertiliser with green manures, compost (including vermicompost), biosolids and digestate (by product of anaerobic digestion) to maintain and improve soil fertility.
	Biological control	Pest control through encouraging natural predators.
	Alternative crops	Replacement of annual with perennial crops reducing the need for soil disturbance and reducing erosion.
	Premium products	Increase farm-level income for less output by producing a premium product.
System redesign	System diversification	Implementation of alternative farming systems: organic, agroforestry and intercropping (including the use of legumes).
	Pest management	Implementing integrated pest and weed management to reduce the quantities of inputs required.
	Nutrient management	Implementing integrated nutrient management by using crop and soil specific nutrient management – guided by soil testing.
	Knowledge transfer	Using knowledge sharing and technology platforms to accelerate the uptake of good agricultural practices.

Improved efficiency – example of precision agriculture

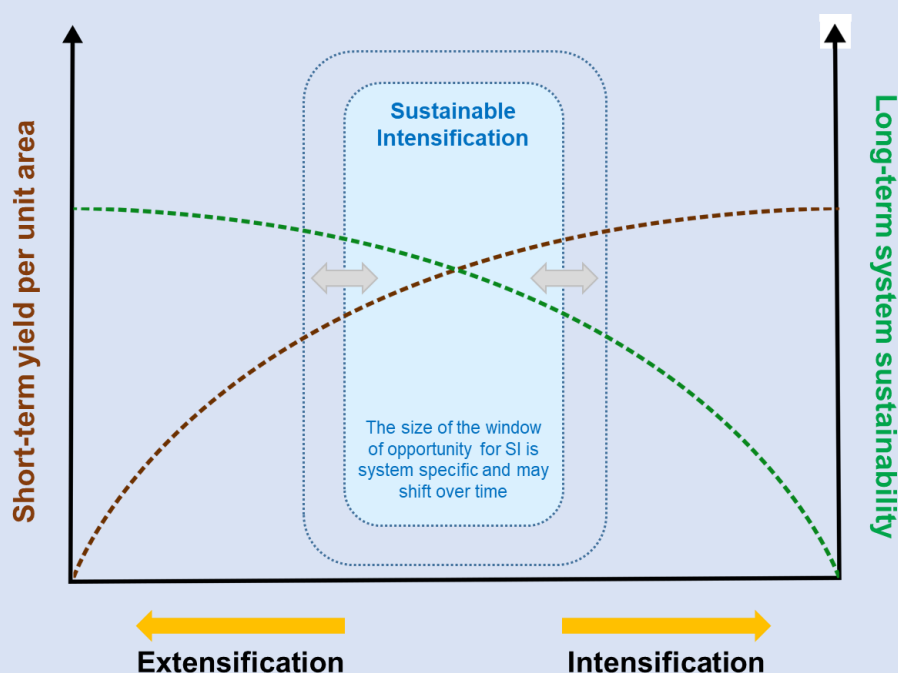

Precision farming usually refers to optimising production in fields through site-specific choices of crop varieties, agrochemical application, precise water management (e.g. in given areas or threshold moistures) and management of crops at a small scale (or livestock as individuals) (Hedley 2015). Precision agriculture has the potential to achieve higher yields in a more efficient and sustainable manner compared with traditional low-precision methods.

Precision agriculture

Precision agriculture is a technologically advanced approach that uses continual monitoring of crop and livestock performance to actively inform management practices. Precise monitoring of crop performance over the course of the growing season will enable farmers to economise on their inputs in terms of water, nutrients and pest management. Therefore, it can contribute to both the food security (by maintaining yields), sustainability (by reducing unnecessary inputs) and land sparing goals associated with SI. The site-specific management of weeds allows a more efficient application of herbicide to specific weed patches within crops (Jensen et al. 2012). Such precision weed control has resulted in herbicide savings of 19 – 22% for winter oilseed rape, 46 – 57% for sugar beet and 60 – 77% for winter wheat production (Gutjahr and Gerhards 2010). The use of on-farm sensors for real time management of crop and livestock performance can enhance farm efficiency (Aqeel-Ur-Rehman et al. 2014). Mapping soil nutrition status can allow for more targeted and therefore effective nutrient management practices (Hedley 2015). Using wireless sensors to monitor environmental conditions such as soil moisture, has the potential to allow more efficient crop irrigation (Srbnovska et al. 2015). Controlled traffic farming, where farm machinery is confined to permanent tracks, using automatic steering and satellite guidance, increases yields by minimising soil compaction. However, barriers to the uptake of many of these high-tech precision agriculture technologies remain. In what is described as the ‘implementation problem’, despite the potential to collect vast quantities of data on crop or livestock performance, applying these data to inform management decisions remains a challenge (Lindblom et al. 2017).

1 *Low-tech precision agriculture*

2 The principle of precision agriculture can be applied equally to low capital-input farming, in the form
 3 of low-tech precision agriculture (Conway 2013). The principle is the same but instead of adopting
 4 capital-heavy equipment (such as sensor technology connected to the ‘internet of things’, or large
 5 machinery and expensive inputs), farmers use knowledge and experience and innovative approaches
 6 often re-purposed, such as a bottle cap as a fertiliser measure for each plant, applied by hand (Mondal
 7 and Basu 2009). This type of precision agriculture is particularly relevant to small-scale farming in
 8 the global South, where capital investment is major limiting factor. For example, the application of a
 9 simple seed priming technique resulted in a 20 to 30% increase in yields of pearl millet and sorghum
 10 in semi-arid West Africa (Aune et al. 2017). Low-tech precision agriculture has the potential to
 11 increase the economic return per unit land area while also creating new employment opportunities.

14 **Cross-Chapter Box 6, Figure 1** There is a need to balance increasing demands for food, fuel and fibre
 15 with long-term sustainability of land use. Sustainable intensification can, in theory, offer a window of
 16 opportunity for the intensification of land use without causing degradation. This potentially allows the
 17 sparing of land to provide other ecosystem services, including carbon sequestration and the protection of
 18 biodiversity. However, the potential for SI is system specific and may change through time (indicated by
 19 grey arrows). Current practice may already be outside of this window and be unsustainable in terms of
 20 negative impacts on the long-term sustainability of the system

21 **Sustainable intensification through farming system redesign**

22 SI requires equal weight to be placed on the sustainability and intensification components (Benton
 23 2016; Garnett et al. 2013), Cross-Chapter Box 6, Figure 1 outlines the trade-offs which SI necessitates
 24 between the intensity of land use against long-term sustainability. One approach to this challenge is
 25 through farming system redesign including increased diversification.

26 *Diversification of intensively managed systems*

27 Incorporating higher levels of plant diversity in agroecosystems can improve the sustainability of
 28 farming systems (Isbell et al. 2017). Where intensive land use has led to land degradation more
 29 diverse land use systems such as intercropping can provide a more sustainable land use option with

1 co-benefits for food security, adaptation and mitigation objectives. For example, in temperate regions,
2 highly productive agricultural grasslands used to produce meat and dairy products are characterised
3 by monoculture pastures with high agrochemical inputs. Multi-species grasslands may provide a route
4 to SI, as even a modest increase in species richness in intensively managed grasslands can result in
5 higher forage yields without increased inputs, such as chemical fertiliser (Finn et al. 2013; Sanderson
6 et al. 2013; Tilman et al. 2011). Recent evidence also indicates multispecies grasslands have greater
7 resilience to drought, indicating co-benefits for adaptation (Hofer et al. 2016; Haughey et al. 2018).

8 *Diversification of production systems*

9 Agroforestry systems (see glossary) can promote regional food security and provide many additional
10 ecosystem services when compared with monoculture crop systems. Co-benefits for mitigation and
11 adaptation include increased carbon sequestration in soils and biomass, improved water and nutrient
12 use efficiency and the creation of favourable micro-climates (Waldron et al. 2017). Silvopasture
13 systems, which combine grazing of livestock and forestry, are particularly useful in reducing land
14 degradation where the risk of soil erosion is high (Murgueitio et al. 2011). Crop and livestock systems
15 can also be combined to provide multiple services. Perennial wheat derivatives produced both high
16 quality forage and substantial volumes of cereal grains (Newell and Hayes 2017), and show promise
17 for integrating cereal and livestock production while sequestering soil carbon (Ryan et al. 2018). A
18 key feature of diverse production systems is the provision of multiple income streams for farming
19 households, providing much needed economic resilience in the face of fluctuation of crop yields and
20 prices.

21 **Landscape Approaches**

22 The land sparing and land sharing approaches which may be used to implement SI are inherently
23 “landscape approaches” (e.g., (Hodgson et al. 2010)). While the term landscape is by no means
24 precise (Englund et al. 2017), landscape approaches, focused for example at catchment scale, are
25 generally agreed to be the best way to tackle competing demands for land (e.g. Sayer et al. 2013), and
26 are the appropriate scale at which to focus the implementation of sustainable intensification. The
27 landscape approach allots land to various uses – cropping, intensive and extensive grazing, forestry,
28 mining, conservation, recreation, urban, industry, infrastructure – through a planning process that
29 seeks to balance conservation and production objectives. With respect to SI, a landscape approach is
30 pertinent to achieving potential benefits for biodiversity conservation, ensuring that land “spared”
31 through SI remains protected, and that adverse impacts of agriculture on conservation land are
32 minimised. Depending on the land governance mechanisms applied in the jurisdiction, different
33 approaches will be appropriate/required. However, benefits are only assured if land use restrictions
34 are devised and enforced.

35 **Summary**

36 Intensification needs to be achieved sustainably, necessitating a balance between productivity today
37 and future potential (*high agreement, medium evidence*). Improving efficiency of agriculture systems
38 can increase production per unit of land through greater resource use efficiency. To achieve SI some
39 intensively managed agricultural systems may have to be diversified as they cannot be further
40 intensified without land degradation. A combination of land sparing and sharing options can be
41 utilised to achieve SI – their application is most likely to succeed if applied using a landscape
42 approach.

44 **5.6.5 Role of urban agriculture**

45 Cities are an important actor in the food system in regard to both demand for food for urban dwellers
46 and production of food in urban and peri-urban areas (see also cross-chapter box 4: Climate Change

1 and Urbanisation in Chapter 2). Both the demand side and supply side roles are important relative to
2 climate change mitigation and adaptation strategies. Urban areas are home to more than half of the
3 world's population, and a minimal proportion of the production; thus, they are important drivers for
4 the development of the complex food systems in place today, in regard to supply chains and dietary
5 preferences.

6 The increasing separation of urban and rural populations with regard to territory and culture is one of
7 the factors favouring the nutrition transition towards urban diets (Weber and Matthews 2008; Neira et
8 al. 2016). These are primarily based on a high diversity of food products, independent of season and
9 local production, and on the extension of the distances that food travels between production and
10 consumption. The transition of traditional diets to more homogeneous diets has also become tied to
11 consumption of animal protein, which has increased GHG emissions globally (see also Section 5.4.6).

12 Cities are becoming key actors in developing strategies of mitigation to climate change, in their food
13 procurement and in sustainable urban food policies alike (McPhearson et al. 2018). These are being
14 developed by big and medium-sized cities in the world, often integrated within climate change
15 policies (Moragues et al. 2013; Calori and Magarini 2015). A review conducted of 100 cities across
16 the world shows that urban food consumption is one of the largest sources of urban material flows,
17 urban carbon footprint, and land footprint (Goldstein et al. 2017). Additionally, the urban poor have
18 limited capacity to adapt to climate-related impacts, which place their food security at risk under
19 climate change (Dubbeling and de Zeeuw 2011).

20 *Urban and peri-urban areas.* In 2010, around 14% of the global population was nourished by food
21 grown in urban and peri-urban areas (Kriewald et al.). A review study on sub-Saharan Africa shows
22 that urban and peri-urban agriculture contributes to climate change adaptation and mitigation (Lwasa
23 et al. 2014, 2015). Urban and peri-urban agriculture reduces food carbon footprint by avoiding long
24 distance food transport and limits GHG emissions by recycling organic waste and wastewater that
25 would otherwise releases methane from landfill and dumping sites (Lwasa et al. 2014). Urban and
26 peri-urban agriculture also contributes in adapting to climate change including extreme events, by
27 reducing urban heat island effect, increasing water infiltration and slowing down run-offs to prevent
28 flooding, etc. (Lwasa et al. 2014, 2015; Kumar et al. 2017a). For example, a scenario analysis shows
29 that urban gardens reduce the surface temperature up to 10°C in comparison to the temperature
30 without vegetation (Tsilini et al. 2015). Urban agriculture can also improve biodiversity and
31 strengthen associated ecosystem services (Lin et al. 2015).

32 Urban and peri-urban agriculture is exposed to climate risks and urban growth that may undermine its
33 long-term potential to address urban food security (Padgham et al. 2015). Therefore, there is a need to
34 better understand the impact of urban sprawl on peri-urban agriculture; the contribution of urban and
35 peri-urban agriculture to food self-sufficiency of cities; the risks posed by pollutants from urban areas
36 to agriculture and vice-versa; the global and regional extent of urban agriculture; and the role that
37 urban agriculture could play in climate resilience and abating malnutrition (Mok et al. 2014; Hamilton
38 et al. 2014). Globally, urban sprawl is projected to consume 1.8–2.4% and 5% of the current
39 cultivated land by 2030 and 2050 respectively, leading to crop calorie loss of 3–4% and 6–7%,
40 respectively (Pradhan et al. 2014; Bren d'Amour et al. 2017). Kriewald et al. shows that the urban
41 growth has the largest impacts in most of the sub-continent (e.g., Western, Middle, and Eastern
42 Africa) while climate change will mostly reduce potential of urban and peri-urban agriculture in
43 Southern Europe and Northern Africa.

44 In summary, urban and peri-urban agriculture can contribute to improving urban food security,
45 reducing greenhouse gas emissions, and adapting to climate change impacts (*robust evidence, medium
46 agreement*).

47

1 5.6.6 Links to the Sustainable Development Goals

2 In 2015, the Sustainable Development Goals (SDGs) and the Paris Agreement were two global major
3 international policies adopted by all countries to guide the world to overall sustainability, within the
4 2030 Sustainable Development Agenda and UNFCCC processes respectively. The 2030 Sustainable
5 Development agenda includes 17 goals and 169 targets, including zero hunger, sustainable agriculture
6 and climate action (United Nations 2015).

7 This section focuses on intra- and inter-linkages of SDG 2 and SDG 13 based on the official SDG
8 indicators (Figure 5.16), showing the current conditions (see (Roy et al. 2018) and Chapter 7 for
9 further discussion). The second goal (Zero Hunger – SDG 2) aims to end hunger and all forms of
10 malnutrition by 2030 and commits to universal access to safe, nutritious and sufficient food at all
11 times of the year. SDG 13 (Climate Action) calls for urgent action to combat climate change and its
12 impacts. Integrating the SDGs into the global food system can provide opportunities for mitigation
13 and adaptation and enhancement of food security.

14
15 **Figure 5.16. Intra and inter-linkages for SDG 2 (*Zero hunger*) and SDG 13 (*Climate action*) at the global**
16 **level using the official indicators of Sustainable Development Goals that consists data for 122 indicators**
17 **for a total of 227 countries between the years 1983 and 2016 (United Nations Statistics Division 2016) and**
18 **applying a statistical approach (Pradhan et al. 2017). Pradhan et al. (2017) defined synergy and trade-offs**
19 **as significant positive ($\rho > 0.6$, red bar) and negative ($\rho < -0.6$, green bar) spearman correlation between**
20 **SDG indicators, respectively. The ρ between 0.6 and -0.6 is considered as nonclassifieds (yellow bar). The**
21 **correlation between unique pairs of indicator time-series is carried based on country data, e.g., between**
22 **“prevalence of undernourishment” (an indicator for SDG 2.1) and “maternalmortality ratio” (an**
23 **indicator for SDG 3.1). The data pairs can belong to the same goal or to two distinct goals. At the global**
24 **level, intra-linkages of SDGs are quantified by the percentage of synergies, trade-offs, and nonclassifieds**
25 **of indicator pairs belonging to the same SDG (here, SDG 2 and SDG 13) for all the countries. Similarly,**
26 **SDG interlinkages are estimated by the percentage of synergies, trade-offs, and nonclassifieds between**
27 **indicator pairs that fall into two distinct goals for all the countries. The grey bar shows insufficient data**
28 **for analysis. The number of data pair used for the analysis is presented in the grey box.**

29 Ensuring food security (SDG 2) shows positive relations (synergies) with most goals (Pradhan et al.
30 2017; International Council for Science (ICSU) 2017), but has trade-offs with SDG 12 (*Responsible*
31 *Consumption and Production*) and SDG 15 (*Life on Land*) under current development paradigms

1 (Pradhan et al. 2017). Sustainable transformation of traditional consumption and production
2 approaches can overcome these trade-offs based on several innovative methods (Shove et al. 2012).
3 For example, sustainable intensification and reduction of food waste can minimise the observed
4 negative relations between SDG 2 and other goals (Obersteiner et al. 2016) (see also Cross-Chapter
5 Box 6 and Section 5.5.2). Achieving the target 12.3 of SDG 12 (Responsible Consumption and
6 Production) “by 2030, to halve per capita global food waste at the retail and consumer levels and
7 reduce food losses along production and supply chains, including post-harvest losses” will contribute
8 to climate change mitigation.

9 Doubling productivity of smallholder farmers and halving food loss and waste by 2030 are targets of
10 SDG 2 and SDG 12, respectively (United Nations Statistics Division 2016). Agroforestry that
11 promotes biodiversity and sustainable land management also contributes to food security (Montagnini
12 and Metzler 2017). Land restoration and protection (SDG 15) can increase crop productivity (SDG 2)
13 (Wolff et al. 2018). Similarly, efficient irrigation practices can reduce water demand for agriculture
14 that could improve health of the freshwater ecosystem (SDG 6 and SDG 15) without reducing food
15 production (Jägermeyr et al. 2017).

16 Climate action (SDG 13) shows negative relations (trade-offs) with most goals and antagonistic to the
17 2030 development agenda under the current development paradigm (Figure 5.16) (Lusseau and
18 Mancini 2019; Pradhan 2019). The targets for SDG 13 have a high focus on climate change
19 adaptation and the data for the SDG 13 indicators are limitedly available. SDG 13 shares two
20 indicators with SDG 1 and SDG 11 (United Nations 2017) and therefore, has mainly positive linkages
21 with these two goals. Trade-offs was observed between SDG 2 and SDG 13 for around 50% of the
22 case (Pradhan et al. 2017).

23 Transformation from current development paradigms and breaking of these lock-in effects can protect
24 climate and achieve food security in future. Sustainable agriculture practices can provide climate
25 change adaptation and mitigation synergies, linking SDG 2 and SDG 13 more positively
26 (International Council for Science (ICSU) 2017). IPCC highlights that most of the current observed
27 trade-offs between SDG 13 and other SDGs can be converted into synergies based on various
28 mitigation options that can be deployed to limit the global warming well below 1.5°C (IPCC 2018b).

29 In summary, there are fundamental synergies that can facilitate the joint implementation of strategies
30 to achieve SDGs and climate action, with particular reference to those climate response strategies
31 related to both supply side (production and supply chains) and demand side (consumption and dietary
32 choices) described in this chapter (*high agreement and medium evidence*).

34 **5.7 Enabling conditions and knowledge gaps**

35 To achieve mitigation and adaptation to climate change in food systems, enabling conditions are
36 needed to scale up the adoption of effective strategies (such as those described in Sections 5.3 to 5.6
37 and Chapter 6). These enabling conditions include multi-level governance and multi-sector
38 institutions (Supplementary Material Section SM5.7) and multiple policy pathways (Section 5.7.1,
39 5.7.2). In this regard, the subnational level is gaining relevance both in food systems and climate
40 change. Just Transitions are needed to address both climate change and food security (Section 5.7.3).
41 Mobilisation of knowledge, education, and capacity will be required (Section 5.7.4) to fill knowledge
42 gaps (Section 5.7.5).

43 Effective governance of food systems and climate change requires the establishment of institutions
44 responsible for coordinating among multiple sectors (education, agriculture, environment, welfare,
45 consumption, economic, health), levels (local, regional, national, global) and actors (governments,
46 CSO, public sector, private sector, international bodies). Positive outcomes will be enegendered by

1 participation, learning, flexibility, and cooperation. See Supplementary Material Section SM5.7 for
2 further discussion.

3

4 **5.7.1 Enabling policy environments**

5 The scope for responses to make sustainable land use inclusive of climate change mitigation and
6 adaptation, and the policies to implement them, are covered in detail in Chapters 6 and 7. Here we
7 highlight some of the major policy areas that have shaped the food system, and might be able to shape
8 responses in future. Although two families of policy – agriculture and trade – have been instrumental
9 in shaping the food system in the past (and potentially have led to conditions that increase climate
10 vulnerability) (Benton and Bailey 2019), a much wider family of policy instruments can be deployed
11 to reconfigure the food system to deliver healthy diets in a sustainable way.

12

13 **5.7.1.1 Agriculture and trade policy**

14 *Agriculture.* The thrust of agricultural policies over the last 50 years has been to increase productivity,
15 even if at the expense of environmental sustainability (Benton and Bailey 2019). For example, in
16 2007-9 46% of OECD support for agriculture was based on measures of output (price support or
17 payments based on yields), 37% of support was based on the current or historical area planted, herd
18 size (or correlated measures of the notional costs of farming), and 13% was payments linked to input
19 prices. In a similar vein, non-OECD countries have promoted productivity growth for their
20 agricultural sectors.

21 *Trade.* Along with agricultural policy to grow productivity, the development of frameworks to
22 liberalise trade (such as the General Agreement on Tariffs and Trade (GATT) Uruguay Round, now
23 incorporated into the World Trade Organisation) have been essential in stimulating the growth of a
24 globalised food system. Almost every country has a reliance on trade to fulfil some or all of its local
25 food needs, and trade networks have grown to be highly complex (Puma et al. 2015; MacDonald et al.
26 2015; Fader et al. 2013; Ercsey-Ravasz et al. 2012). This is because many countries lack the capacity
27 to produce sufficient food due to climatic conditions, soil quality, water constraints, and availability of
28 farmland (FAO 2015b). In a world of liberalised trade, using comparative advantage to maximise
29 production in high-yielding commodities, exporting excess production, and importing supplies of
30 other goods supports economic growth.

31 City states as well as many small island states, do not have adequate farmland to feed their
32 populations, while sub-Saharan African countries are projected experience high population growth as
33 well as to be negatively impacted by climate change, and thus will likely find it difficult to produce all
34 of their own food supplies (Agarwal et al. 2002). One study estimates that some 66 countries are
35 currently incapable of being self-sufficient in food (Pradhan et al. 2014). Estimates of the proportion
36 of people relying on trade for basic food security vary from ~16% to ~22% (Fader et al. 2013;
37 Pradhan et al. 2014), with this figure rising to between 1.5 and 6 billion people by 2050, depending on
38 dietary shifts, agricultural gains, and climate impacts (Pradhan et al. 2014).

39 Global trade is therefore essential for achieving food and nutrition security under climate change
40 because it provides a mechanism for enhancing the efficiency of supply chains, reducing the
41 vulnerability of food availability to changes in local weather, and moving production from areas of
42 surplus to areas of deficit (FAO 2018d). However, the benefits of trade will only be realised if trade is
43 managed in ways that maximise broadened access to new markets while minimising the risks of
44 increased exposure to international competition and market volatility (Challinor et al. 2018; Brown et
45 al. 2017b).

1 As described in Section 5.8.1, trade acts to buffer exposure to climate risks when the market works
 2 well. Under certain conditions – such as shocks, or the perception of a shock, coupled with a lack of
 3 food stocks or lack of transparency about stocks (Challinor et al. 2018; Marchand et al. 2016) – the
 4 market can fail and trade can expose countries to food price shocks.

5 Furthermore, Clapp (2016) showed that trade, often supported by high levels of subsidy support to
 6 agriculture in some countries, can depress world prices and reduce incomes for other agricultural
 7 exporters. Lower food prices that result from subsidy support may benefit urban consumers in
 8 importing countries, but at the same time they may hurt farmers' incomes in those same countries. The
 9 outmigration of smallholder farmers from the agriculture sector across the Global South is
 10 significantly attributed to these trade patterns of cheap food imports (Wittman 2011; McMichael
 11 2014; Akram-Lodhi and others 2013). Food production and trade cartels, as well as financial
 12 speculation on food futures markets, affect low-income market-dependent populations.

13 Food sovereignty is a framing developed to conceptualise these issues (Reuter 2015). They directly
 14 relate to the ability of local communities and nations to build their food systems, based among other
 15 aspects, on diversified crops and indigenous and local knowledge. If a country enters international
 16 markets by growing more commodity crops and reducing local crop varieties, it may get economic
 17 benefits, but may also expose itself to climate risks and food insecurity by increasing reliance on
 18 trade, which may be increasingly disrupted by climate risks. These include a local lack of resilience
 19 from reduced diversity of products, but also exposure to food price spikes, which can become
 20 amplified by market mechanisms such as speculation.

21 In summary, countries must determine the balance between locally produced vs imported food (and
 22 feed) such that it both minimises climate risks and ensures sustainable food security. There is *medium*
 23 *evidence* that trade has positive benefits but also creates exposure to risks (Section 5.3).

24

25 **5.7.1.2 Scope for expanded policies**

26 There are a range of ways that policy can intervene to stimulate change in the food system – through
 27 agriculture, research and development, food standards, manufacture and storage, changing the food
 28 environment and access to food, changing practices to encourage or discourage trade (Table 5.6).
 29 Novel incentives can stimulate the market, for example, through reduction in waste or changes in diets
 30 to gain benefits from a health or sustainability direction. Different contexts with different needs will
 31 require different set of policies at local, regional and national levels. See Supplementary Material
 32 Section SM5.7 for further discussion on expanded policies.

33

34 **Table 5.6 Potential policy “families” for food-related adaptation and mitigation of climate change. The**
 35 **column “scale” refers to scale of implementation: International (I), national (N), sub-national-regional**
 36 **(R), and local (L).**

Family	Sub-family	Scale	Interventions	Examples
Supply-side efficiency	Increasing agricultural efficiency and yields	I, N	Agricultural R&D	Investment in research, innovation, knowledge exchange, e.g., on genetics, yield gaps, resilience
		I, N	Supporting precision agriculture	Agricultural engineering, robotics, big data, remote sensing, inputs
		I, N	Sustainable intensification	Soils, nutrients, capital, labour (see

			projects	Cross-Chapter Box 6)
		N, R	Improving farmer training and knowledge sharing	Extension services, online access, field schools, farmer-to-farmer networks (CABI 2019)
	Land use planning	N, R, L	Land use planning for ecosystem services (remote sensing, indigenous and local knowledge)	Zoning, protected area networks, multifunctional landscapes, “land sparing” (see Cross-Chapter Box 6; Benton et al. 2018; Jones et al. 2013)
		N, R, L	Conservation agriculture programs	Soil and water erosion control, soil quality improvement (Conservation Evidence 2019)
		N	Payment for ecosystem services	Incentives for farmers/landowners to choose lower-profit but environmentally benign resource use, e.g., Los Negros Valley in Bolivia (Ezzine-de-Blas et al. 2016)
	Market approaches	I, N	Mandated carbon cost reporting in supply chains; public/private incentivised insurance products	Carbon and natural capital accounts (CDP 2019), crop insurance (Müller et al. 2017a)
	Trade	I	Liberalising trade flows; green trade	Reduction in GHG emissions from supply chains (Neumayer 2001)
Raising profitability and quality	Stimulating markets for premium goods	N, R	Sustainable farming standards, agroecology projects, local food movements	Regional policy development, public procurement of sustainable food (Mairie de Paris 2015)
Modifying demand	Reducing food waste	I, N, L	Regulations, taxes	‘Pay-As-You-Throw (PAYT)’ schemes; EU Landfill Directives; Japan Food Waste Recycling Law 2008; South Africa Draft Waste Classification and Management Regulations 2010 (Chalak et al. 2016)
		I, N, L	Awareness campaigns, education	FAO Global Initiative on Food Loss and Waste Reduction (FAO 2019b)
		I, N	Funding for reducing food waste	Research and investment for shelf life, processing, packaging, cold storage (MOFPI 2019)
		I, N, L	Circular economy using waste as inputs	Biofuels, distribution of excess food to charities (Baglioni et al. 2017)
	Reducing consumption	I, N, L	Carbon pricing for selected food commodities	Food prices reflective of GHG gas emissions throughout production and

	n of carbon-intensive food			supply chain (Springmann et al. 2017; Hasegawa et al. 2018)
		I, N, L	Changing food choice through education	Nutritional and portion-size labelling, ‘nudge’ strategies (positive reinforcement, indirect suggestion) (Arno and Thomas 2016)
		I, N, L	Changing food choices through money transfers	Unconditional cash transfers; e-vouchers exchanged for set quantity or value of specific, pre-selected goods (Fenn 2018)
		N, L	Changing food environments through planning	Farmers markets, community food production, addressing ‘food deserts’ (Ross et al. 2014)
	Combining carbon and health objectives	I, N, L	Changing subsidies, standards, regulations to healthier and more sustainably produced foods	USDA’s “Smart Snacks for School” regulation mandating nutritional guidelines (USDA 2016) Incentivising production via subsidies (direct to producer based on output or indirect via subsidising inputs)
		N	Preventative vs curative public health care incentives	Health insurance cost reductions for healthy and sustainable diets
		I, N, L	Food system labelling	Organic certification, nutrition labels, blockchain ledgers (Chadwick 2017)
		N, L	Education and awareness campaigns	School curricula; public awareness campaigns
		N, L	Investment in disruptive technologies (e.g., cultured meat)	Tax breaks for R&D, industrial strategies (European Union 2018)
		N, L	Public procurement	For health: Public Procurement of Food for Health (Caldeira et al. 2017) For environment: Paris Sustainable Food Plan 2015-2020 Public Procurement Code (Mairie de Paris 2015)

1

2 In summary, although agriculture is often thought to be shaped predominantly by agriculture and trade
3 policies, there are over twenty families of policy areas that can shape agricultural production directly
4 or indirectly (through environmental regulations or through markets, including by shaping consumer

1 behaviour). Thus, delivering outcomes promoting climate change adaptation and mitigation can arise
2 from policies across many departments, if suitably designed and aligned.

3

4 **5.7.1.3 Health-related policies and cost savings**

5 The co-benefits arising from mitigating climate change through changing dietary patterns, and thus
6 demand, have potentially important economic impacts (*high confidence*). The gross value added from
7 agriculture to the global economy (GVA) was USD 1.9tn (in 2013 (FAO 2015c)), from a global
8 agriculture economy (GDP) of USD 2.7tn (in 2016). In 2013, the FAO estimated an annual cost of
9 USD 3.5tn for malnutrition (FAO 2013a).

10 However, this is likely to be an underestimate of the economic health costs of current food systems
11 for several reasons: (1) Lack of data – for example there is little robust data in the UK on the
12 prevalence of malnutrition in the general population (beyond estimates of obesity and surveys of
13 malnourishment of patients in hospital and care homes, from which estimates over 3 million people in
14 the UK are undernourished (BAPEN 2012)); (2) Lack of robust methodology to determine, for
15 example, the exact relationship between overconsumption of poor diets, obesity and non-
16 communicable diseases like diabetes, cardio-vascular disease, a range of cancers or Alzheimer's
17 disease (Peditizi et al. 2016), (3) Unequal healthcare spending around the world.

18 In the US, the economic cost of diabetes, a disease strongly associated with obesity and affecting
19 about 23 million Americans, is estimated at USD 327bn in 2017 (American Diabetes Association
20 2018), with direct healthcare costs of USD 9,600 per person. By 2025, it is estimated that globally
21 there will be over 700 million people with diabetes (NCD-RisC 2016b), over 30 times the number in
22 the US. Even if a global average cost of diabetes per capita were a quarter of that in the US, the total
23 economic cost of diabetes would be approximately the same as global agricultural GDP. Finally, (4)
24 the role of agriculture in causing ill-health beyond dietary health, such as through degrading air
25 quality (e.g., (Paulot and Jacob 2014)).

26 Whilst data of the healthcare costs associated with the food system and diets are scattered and the
27 proportion of costs directly attributable to diets and food consumption is uncertain, there is potential
28 for more preventative healthcare systems to save significant costs that could incentivise agricultural
29 business models to change what is grown, and how. The potential of moving towards more
30 preventative healthcare is widely discussed in the health economics literature, particularly in order to
31 reduce the life-style-related (including dietary-related) disease component in aging populations (e.g.,
32 (Bloom et al. 2015)).

33

34 **5.7.1.4 Multiple policy pathways**

35 As discussed in more detail in Chapters 6 and 7, there is a wide potential suite of interventions and
36 policies that can potentially enhance the adaptation of food systems to climate change, as well as
37 enhance the mitigation potential of food systems on climate change. There is an increasing number of
38 studies that argue that the key to sustainable land management is not in land management practices
39 but in the factors that determine the demand for products from land (such as food). Public health
40 policy therefore has the potential to affect dietary choice and thus the demand for different amounts
41 of, and types of, food.

42 Obersteiner et al. (2016) show that increasing the average price of food is an important policy lever
43 that, by reducing demand, reduces food waste, pressure on land and water, impacts on biodiversity
44 and through reducing emissions, mitigates climate change and potentially helps to achieve multiple
45 SDGs. Whilst such policy responses – such as a carbon tax applied to goods including food – has the
46 potential to be regressive, affecting the poor differentially (Frank et al. 2017; Hasegawa et al. 2018;

1 Kehlbacher et al. 2016), and increasing food insecurity – further development of social safety nets can
2 help to avoid the regressive nature (Hasegawa et al. 2018). Hasegawa et al. (2018) point out that such
3 safety nets for vulnerable populations could be funded from the revenues arising from a carbon tax.

4 The evidence suggests, as with SR15 (IPCC 2018a) and its multiple pathways to climate change
5 solutions, that there is no single solution that will address the problems of food and climate change,
6 but instead there is a need to deploy many solutions simultaneously adapted to the needs and options
7 available in a given context. For example, Springmann et al. (2018a) indicate that maintaining the
8 food system within planetary boundaries at mid-century, including equitable climate, requires
9 increasing the production (and resilience) of agricultural outputs (i.e., closing yield gaps), reducing
10 waste, and changes in diets towards ones often described as flexitarian (low-meat dietary patterns that
11 are in line with available evidence on healthy eating). Such changes can have significant co-benefits
12 for public health, as well as facing significant challenges to ensure equity (in terms of affordability for
13 those in poverty).

14 Significant changes in the food system require them to be acceptable to the public (“public license”),
15 or they will be rejected. Focus groups with members of the public around the world, on the issue of
16 changing diets, have shown that there is a general belief that the government plays a key role in
17 leading efforts for change in consumption patterns (Wellesley et al. 2015). If governments are not
18 leading on an issue, or indicating the need for it through leading public dialogue, it signals to their
19 citizens that the issue is unimportant or undeserving of concern

20 In summary, there is significant potential (*high confidence*) that, through aligning multiple policy
21 goals, multiple benefits can be realised that positively impact public health, mitigation and adaptation
22 (e.g. adoption of healthier diets, reduction in waste, reduction in environmental impact). These
23 benefits may not occur without the alignment across multiple policy areas (*high confidence*).

25 **5.7.2 Enablers for changing markets and trade**

26 “Demand” for food is not an exogenous variable to the food system but is shaped crucially by its
27 ability to produce, market, and supply food of different types and prices. These market dynamics can
28 be influenced by a variety of factors beyond consumer preferences (e.g., corporate power and
29 marketing, transparency, the food environment more generally), and the ability to reshape the market
30 can also depend on its internal resilience and/or external shocks (Challinor et al. 2018; Oliver et al.
31 2018)).

33 **5.7.2.1 Capital markets**

34 Two areas are often discussed in regard to role of capital markets in shaping the food system. First,
35 investment in disruptive technologies might stimulate climate-smart food systems (WEF/McKinsey &
36 Company 2018; Bailey and Wellesley 2017), including alternative proteins, such as laboratory or
37 “clean meat” (which has significant ability to impact on land use requirements) (Alexander et al.
38 2017) (See Section 5.5.1.6). An innovation environment through which disruptive technology can
39 emerge typically requires the support of public policy, whether in directly financing small and
40 emerging enterprises, or funding research and development via reducing tax burdens.

41 Second, widespread adoption of (and perhaps underpinned by regulation for) natural capital
42 accounting as well as financial accounting are needed. Investors can then be aware of the risk
43 exposure of institutions, which can undermine sustainability through externalising costs onto the
44 environment. The prime example of this in the realm of climate change is the Carbon Disclosure
45 Project, with around 2500 companies voluntarily disclosing their carbon footprint, representing nearly
46 60% of the world’s market capital (CDP 2018).

5.7.2.2 Insurance and re-insurance

The insurance industry can incentivise actors' behaviour towards greater climate mitigation or adaptation, including building resilience. For example, Lloyd's of London analysed the implications of extreme weather for the insurance market, and conclude that the insurance industry needs to examine their exposure to risks through the food supply chain and develop innovative risk-sharing products can make an important contribution to resilience of the global food system (Lloyd 2015).

Many of these potential areas for enabling healthy and sustainable food systems are also knowledge gaps, in that whilst the levers are widely known, their efficacy and the ability to scale-up, in any given context, are poorly understood.

5.7.3 Just transitions to sustainability

Research is limited on how land use transitions would proceed from ruminant production to other socio-ecological farming systems. Ruminants have been associated with humans since the early development of agriculture, and the role of ruminants in many agricultural systems and smallholder communities is substantial. Ruminant production systems have been adapted to a wide range of socioeconomic and environmental conditions in crop, forestry, and food processing settings (Čolović et al. 2019), bioenergy production (de Souza et al. 2019), and food waste recycling (Westendorf 2000). Pasture cultivation in succession to crops is recognised as important to management of pest and diseases cycles and to improve soil carbon stocks and soil quality (Carvalho and Dedieu 2014). Grazing livestock is important as a reserve of food and economic stocks for some smallholders (Ouma et al. 2003).

Possible land-use options for transitions away from livestock production in a range of systems include (a) retain land but reduce investments to run a more extensive production system; (b) change land use by adopting a different production activity; (c) abandon land (or part of the farm) to allow secondary vegetation regrowth (Carvalho et al. 2019; Laue and Arima 2016); and (d) invest in afforestation or reforestation (Baynes et al. 2017). The extensification option could lead to increases rather than decreases in GHG emissions related to reduction in beef consumption. Large-scale abandonment, afforestation, or reforestation would probably have more positive environmental outcomes, but could result in economic and social issues that would require governmental subsidies to avoid decline and migration in some regions (Henderson et al. 2018). Alternative economic use of land, such as bioenergy production, could balance the negative socioeconomic impact of reducing beef output, reduce the tax values needed to reduce consumption, and avoid extensification of ruminant production systems (Wirsenius et al. 2011). However, the analysis of the transition of land use for ruminants to other agricultural production systems is still a literature gap (Cross-Chapter Box 7: Bioenergy and BECCS in mitigation scenarios, in Chapter 6).

Finally, it is important to recognise that, while energy alternatives produce the same function for the consumer, it is questionable that providing the same nutritional value through an optimised mix of dietary ingredients provides the same utility for humans. Food has a central role in human pleasure, socialisation, cultural identity, and health (Röös et al. 2017), including some of the most vulnerable groups, so just transitions and their costs need to be taken into account. Pilot projects are important to provide greater insights for large-scale policy design, implementation, and enforcement.

In summary, more research is needed on how land use transitions would proceed from ruminant production to other farming systems and affect the farmers and other food system actors involved. There is *limited evidence* on what the decisions of farmers under lower beef demand would be.

1 **5.7.4 Mobilising knowledge**

2 Addressing climate change-related challenges and ensuring food security requires all types of
3 knowledge (formal/non-formal, scientific/indigenous, women, youth, technological). Miles et al.
4 (2017) stated that a research and policy feedback that allows transitions to sustainable food systems
5 must have at first a whole system approach. Currently, in transmitting knowledge for food security
6 and land sustainability under climate change there are three major approaches: (1) public technology
7 transfer with demonstration (extension agents); (2) public and private advisory services (for
8 intensification techniques) and; (3) non-formal education with many different variants such as farmers
9 field schools, rural resource centers; facilitation extension where front-line agents primarily work as
10 “knowledge brokers” in facilitating the teaching–learning process among all types of farmers
11 (including women and rural young people), or farmer-to-farmer, where farmers act themselves as
12 knowledge transfer and sharing actors through peer processes.

13

14 **5.7.4.1 Indigenous and local knowledge**

15 Recent discourse has a strong orientation towards scaling-up innovation and adoption by local
16 farmers. However, autonomous adaptation, indigenous knowledge and local knowledge are both
17 important for agricultural adaptation (Biggs et al. 2013) (See Section 5.3). These involve the
18 promotion of farmer participation in governance structures, research, and the design of systems for the
19 generation and dissemination of knowledge and technology, so that farmers needs and knowledge can
20 be taken into consideration. Klenk et al. (2017) found that mobilisation of local knowledge can inform
21 adaptation decision-making and may facilitate greater flexibility in government-funded research. As
22 an example, rural innovation in terrace agriculture developed on the basis of a local coping
23 mechanism and adopted by peasant farmers in Latin America may serve as an adaptation option or
24 starting place for learning about climate change responses (Bocco and Napoletano 2017). Clemens et
25 al. (2015) found that an open dialogue platform enabled horizontal exchange of ideas and alliances for
26 social learning and knowledge-sharing in Vietnam. Improving local technologies in a participatory
27 manner, through on-farm experimentation, farmer-to-farmer exchange, consideration of women and
28 youths, is also relevant in mobilising knowledge and technologies.

29

30 **5.7.4.2 Citizen science**

31 Citizen science has been tested as a useful tool with potential for biodiversity conservation (Schmitz
32 et al. 2015) and mobilising knowledge from society. In food systems, knowledge-holders (e.g.,
33 farmers and pastoralists) are trained to gather scientific data in order to promote conservation and
34 resource management (Fulton et al. 2019) or to conserve and use traditional knowledge in developed
35 countries relevant to climate change adaptation and mitigation through the use of ICT (Calvet-Mir et
36 al. 2018).

37

38 **5.7.4.3 Capacity building and education**

39 Mobilising knowledge may also require significant efforts on capacity building and education to scale
40 up food system responses to climate change. This may involve increasing the capacity of farmers to
41 manage current climate risks and to mitigate and adapt in their local contexts, and of citizens and
42 consumers to understand the links between food demand and climate change emissions and impacts,
43 as well as policy makers to take a systemic view of the issues. Capacity building may also require
44 institutional change. For example, alignment of policies towards sustainable and healthy food systems
45 may require building institutional capacity across policy silos.

1 As a tool for societal transformation, education is a powerful strategy to accelerate changes in the way
2 we produce and consume food. Education refers to early learning and life-long acquisition of skills for
3 higher awareness and actions for solving food system challenges (FAO 2005). Education also entails,
4 vocational training, research and institutional strengthening (Hollinger 2015). Educational focus
5 changes according to the supply side (e.g., crop selection, input resource management, yield
6 improvement, and diversification) and the demand side (nutrition and dietary health implications).
7 Education on food loss and waste spans both the supply and demand sides.

8 In developing countries, extension learning such as Farmer Field Schools – also known as Rural
9 Resources Centers – are established to promote experiential learning on improved production and
10 food transformation (FAO 2016c). While in developed countries, mass education campaigns are rising
11 to reduce food waste, improved diets or acceptable food, and ultimately changes the structure of food
12 industries that is based on the large-scale food products (Heller 2019; UNCCD 2017).

13 The design of new education modules from primary to secondary to tertiary education could help
14 create new jobs in the realm of sustainability (e.g., certification programs). For example, one area
15 could be educating managers of recycling programs for food-efficient cities where food and organic
16 waste are recycled to fertilisers (Jara-Samaniego et al. 2017). Research and education need to be
17 coordinated so that knowledge gaps can be filled and greater trust established in shifting behavior of
18 individuals from conventional options to more sustainable ones. Education campaigns can also
19 influence policy and legislation, and help to advance successful outcomes for climate change
20 mitigation and adaptation in regard to supply-side innovations, technologies, trade, and investment,
21 and demand-side evolution of food choices for health and sustainability, and greater gender equality
22 throughout the entire food system. (Heller 2019).

24 **5.7.5 Knowledge gaps and key research areas**

25 Knowledge gaps around options and solutions and their (co-)benefits and trade-offs are increasingly
26 important now that implementation of mitigation and adaptation measures is scaling up.

27 Research is needed on how a changing climate and interventions to respond to it will affect all aspects
28 of food security, including access, utilisation and stability, not just availability. Knowledge gaps
29 across all the food security pillars are one of the barriers hindering mitigation and adaptation to
30 climate change in the food system and its capacity to deliver food security. The key areas for climate
31 change, food systems, and food security research are enlisted below.

33 **5.7.5.1 Impacts and adaptation**

34 *Climate Services (Food availability).* Agriculture and food security is a priority area for the Global
35 Framework for Climate Services (GFCS) a program of the World Meteorological Organization
36 (WMO). The GFCS enables vulnerable sectors and populations to better manage climate variability
37 and adapt to climate change (Hansen et al. 2018). Global precipitation datasets and remote sensing
38 technologies can be used to detect local to regional anomalies in precipitation as a tool for devising
39 early-warning systems for drought-related impacts, such as famine (Huntington et al. 2017). Crop
40 model improvements are needed for evapotranspiration to guide crop water management in future
41 climate (Cammarano et al. 2016).

42 *Crop and livestock genetics (Food availability, utilisation).* Advances in plant breeding are crucial for
43 enhancing food security under changing climate for a wide variety of crops including fruits and
44 vegetables as well as staples. Genetics improvement is needed in order to breed crops and livestock
45 that can both reduce greenhouse gas emissions, increase drought and heat tolerance (e.g., rice), and
46 enhance nutrition and food security (Nankishore and Farrell 2016; Kole et al. 2015). Many of these

1 characteristics already exist in traditional varieties, including orphan crops and autochthonous breeds,
2 so research is needed to recuperate such varieties and evaluate their potential for adaptation and
3 mitigation.

4 Phenomics-assisted breeding appears to be a promising tool for deciphering the stress responsiveness
5 of crop and animal species (Papageorgiou 2017; Kole et al. 2015; Lopes et al. 2015; Boettcher et al.
6 2015). Initially discovered in bacteria and archaea, CRISPR–Cas9 is an adaptive immune system
7 found in prokaryotes and since 2013 has been used as a genome editing tool in plants. The main use
8 of CRISPR systems is to achieve improved yield performance, biofortification, biotic and abiotic
9 stress tolerance, with rice (*Oryza sativa*) being the most studied crop (Gao 2018; Ricoch et al. 2017).

10 *Climate impact models (Food availability)*. Understanding the full range of climate impacts on staple
11 crops (especially those important in developing countries), fruits and vegetables is missing in the
12 current climate impact models. Further, CO₂ effects on nutrition quality of different crops are just
13 beginning to be parameterised in the models (Müller et al. 2014). Bridging these gap is essential for
14 projecting future dietary diversity, healthy diets, and food security (Bisbis et al. 2018). Crop model
15 improvements are needed for evapotranspiration to guide crop water management in future climate
16 (Cammarano et al. 2016). Similarly, more studies are needed to understand the impacts of climate
17 change on global rangelands and livestock and aquaculture, which have received comparatively less
18 attention than the impacts on crop production.

19 *Resilience to extreme events (Food availability, access, utilisation, and stability)*. On the adaptation
20 side, knowledge gaps include impacts of climate shocks (Rodríguez Osuna et al. 2014) as opposed to
21 impacts of slow-onset climate change, how climate-related harvest failures in one continent may
22 influence food security outcomes in others, impacts of climate change on fruits and vegetables and
23 their nutrient contents.

24

25 **5.7.5.2 Emissions and mitigation**

26 *GHG emissions inventory techniques (Food utilisation)*. Knowledge gaps include food consumption-
27 based emissions at national scales, embedded emissions (overseas footprints) of food systems,
28 comparison of GHG emissions per type of food systems (e.g., smallholder and large-scale commercial
29 food system), and GHG emissions from land-based aquaculture. An additional knowledge gap is the
30 need for more socio-economic assessments of the potential of various integrated practices to deliver
31 the mitigation potential estimated from a biophysical perspective. While studies often project how
32 much CO₂ could theoretically be sequestered in soil, for instance, there is not yet discussion of the
33 potential for this to be effectively monitored, verified, and implemented, once barriers and incentives
34 to adoption of the techniques, practices, and technologies are considered. Thus, future research needs
35 fill the gaps on evaluation of climate actions in the food system.

36 *Food supply chains (Food availability)*. The expansion of the cold chain into developing economies
37 means increased energy consumption and GHG emissions at the consumer stages of the food system,
38 but its net impact on GHG emissions for food systems as a whole is complex and uncertain (Heard
39 and Miller 2016). Further understanding of negative side effects in intensive food processing systems
40 is still needed.

41 Blockchains, as a distributed digital ledger technology which ensures transparency, traceability, and
42 security, is showing promise for easing some global food supply chain management challenges,
43 including the need for documentation of sustainability and the circular economy for stakeholders
44 including governments, communities, and consumers to meet sustainability goals. Blockchain-led
45 transformation of food supply chains is still in its early stages; research is needed on overcoming
46 barriers to adoption (Tripoli and Schmidhuber 2018; Casado-Vara et al. 2018; Mao et al. 2018; Saberi
47 et al. 2019).

1

2 **5.7.5.3 Synergies and trade-offs**

3 *Supply-side and demand-side mitigation and adaptation (Food availability, utilisation).* Knowledge
4 gaps exist on potential and risk associated with novel mitigation technologies on supply side (e.g.,
5 inhibitors, targeted breeding, cellular agriculture, etc.). Additionally, most integrated assessment
6 models (IAMs) currently have limited regional data on BECCS projects because of little BECCS
7 implementation (Lenzi et al. 2018). Hence, several BECCS scenarios seem to rely on unrealistic
8 assumptions regarding regional climate, soils and infrastructure suitability (Köberle et al. 2019) as
9 well as trade of international trade of bioenergy (Lamers et al. 2011).

10 Areas for study include how to incentivise, regulate, and raise awareness on the co-benefits of healthy
11 consumption patterns and climate change mitigation and adaptation; to improve access to healthy
12 diets for vulnerable groups through food assistance programs; and to implement policies and
13 campaigns to reduce food loss and food waste. Knowledge gaps also exist on the role of different
14 policies, and underlying uncertainties, to promote changes in food habits towards climate resilience
15 and healthy diets.

16 *Food systems, land use change, and telecoupling (Food availability, access, utilisation).* The
17 analytical framework of telecoupling has recently been proposed to address this complexity,
18 particularly the connections, flows, and feedbacks characterising food systems (Friis et al. 2016;
19 Easter et al. 2018). For example, how will climate-induced shifts in livestock and crop diseases affect
20 food production and consumption in the future. Investigating the social and ecological consequences
21 of these changes will contribute to decision making under uncertainty in the future. Research areas
22 include food systems and their boundaries, hierarchies, and scales through metabolism studies,
23 political ecology and cultural anthropology.

24 *Food-Energy-Water Nexus (Food availability, utilisation, stability).* Emerging interdisciplinary
25 science efforts are providing new understanding of the interdependence of food, energy, and water
26 systems and these interdependencies are beginning to take into account climate change, food security,
27 and AFOLU assessments (Scanlon et al. 2017; Liu et al. 2017). These science advances, in turn,
28 provide critical information for coordinated management to improve the affordability, reliability, and
29 environmental sustainability of food, energy, and water systems. Despite significant advances within
30 the past decade, there are still many challenges for the scientific community. These include the need
31 for interdisciplinary science related to the food-energy-water nexus; ground-based monitoring and
32 modelling at local-to-regional scales (Van Gaalen et al. 2017); incorporating human and institutional
33 behaviour in models; partnerships among universities, industry, and government to develop policy-
34 relevant data; and systems modelling to evaluate trade-offs associated with food-energy-water
35 decisions (Scanlon et al. 2017). However, the nexus approach, as a conceptual framework, requires
36 the recognition that, although land and the goods and services it provides is finite, potential demand
37 for the goods and services may be greater than the ability to supply them sustainably (Benton et al.
38 2018). By addressing demand-side issues, as well as supply-side efficiencies, it provides a potential
39 route for minimising trade-offs for different goods and services (Benton et al. 2018) and (Section 5.6).

40

41 **5.8 Future challenges to food security**

42 A particular concern in regard to the future of food security is the potential for the impacts of
43 increasing climate extremes on food production to contribute to multi-factored complex events such
44 as food price spikes. In this section, we assess literature on food price spikes and potential strategies
45 for increasing resilience to such occurrences. We then assess the potential for such food system events
46 to affect migration and conflict.

1

2 **5.8.1 Food price spikes**

3 Under average conditions, global food system markets may function well, and equilibrium approaches
4 can estimate demand and supply with some confidence; however, if there is a significant shock, the
5 market can fail to smoothly link demand and supply through price, and a range of factors can act to
6 amplify the effects of the shock, and transmit it across the world (Box 5.5). Given the potential for
7 shocks driven by changing patterns of extreme weather to increase with climate change, there is the
8 potential for market volatility to disrupt food supply through creating food price spikes. This potential
9 is exacerbated by the interconnectedness of the food system (Puma et al. 2015) with other sectors (i.e.,
10 the food system depends on water, energy, transport, etc.) (Homer-Dixon et al. 2015), so the impact of
11 shocks can propagate across sectors and geographies (Homer-Dixon et al. 2015). There is also less
12 spare land globally than there has been in the past, such that if prices spike, there are fewer options to
13 bring new production on stream (Marianela et al. 2016).

14 Increasing extreme weather events can disrupt production and transport logistics. For example, in
15 2012 the US Corn Belt suffered a widespread drought; US corn yield declined 16% compared to 2011
16 and 25% compared to 2009. A record yield loss of 2016 in French that is attributed to a conjunction of
17 abnormal warmth in late autumn and abnormal wet in the following spring (Ben-Ari et al. 2018) is
18 another well-documented example. To the extent that such supply shocks are associated with climate
19 change, they may become more frequent and contribute to greater instability in agricultural markets in
20 the future. Furthermore, analogue conditions of past extremes might create significantly greater
21 impacts in a warmer world. A study simulating analogous conditions to the Dustbowl drought in
22 today's agriculture suggests that Dust-Bowl-type droughts today would have unprecedented
23 consequences, with yield losses about 50% larger than the severe drought of 2012 (Glotter and Elliott
24 2016). Damages at these extremes are highly sensitive to temperature, worsening by about 25% with
25 each degree centigrade of warming. By mid-century, over 80% of summers are projected to have
26 average temperatures that are likely to exceed the hottest summer in the Dustbowl years (1936)
27 (Glotter and Elliott 2016).

28 How a shortfall in production – or an interruption in trade due to an event affecting a logistics choke-
29 point (Wellesley et al. 2017) – of any given magnitude may create impacts depends on many
30 interacting factors (Homer-Dixon et al. 2015; Tadasse et al. 2016; Challinor et al. 2018). The principal
31 route is by affecting agricultural commodity markets, which respond to a perturbation through
32 multiple routes as in Figure 5.17 **Error! Reference source not found.** This includes pressures from
33 other sectors (such as if biofuels policy is incentivising crops for the production of ethanol, as
34 happened in 2007–2008). The market response can be amplified by poor policies, setting up trade and
35 non-trade barriers to exports, from countries seeking to ensure their local food security (Bailey et al.
36 2015). Furthermore, the perception of problems can fuel panic buying on the markets that in turn
37 drives up prices.

38 Thus, the impact of an extreme weather event on markets has both a *trigger* component (the event)
39 and a *risk perception* component (Challinor et al. 2016, 2018). Through commodity markets, prices
40 change across the world because almost every country depends, to a greater or lesser extent, on trade
41 to fulfil local needs. Commodity prices can also affect local market prices by altering input prices,
42 changing the cost of food aid, and through spill-over effects; for example, in 2007–2008 the grain
43 affected by extreme weather was wheat, but there was a significant price spike in rice markets (Dawe
44 2010).

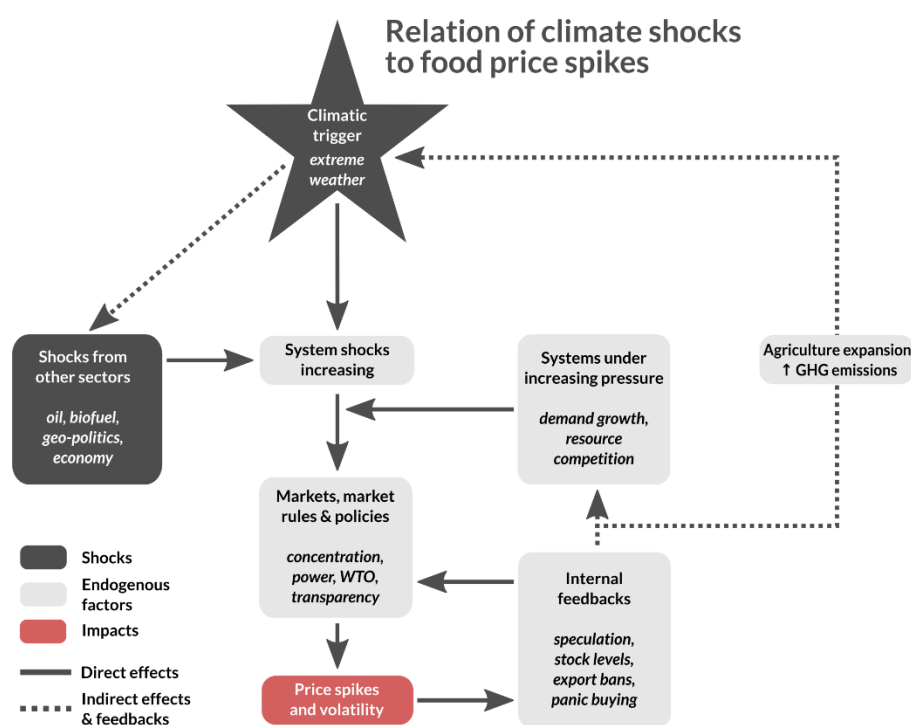

45 As discussed by Bailey et al. (2015), there are a range of adaptation measures that can be put in place
46 to reduce the impact of climate-related production shortfalls. These include (a) ensuring transparency
47 of public and private stocks, as well as improved seasonal forecasting to signal forthcoming yield

1 shortfalls (FAO 2016a; Ceglar et al. 2018; Iizumi et al. 2018), (b) building real or virtual
 2 stockholdings, (c) increasing local productivity and diversity (as a hedge against a reliance on trade)
 3 and (d) ensuring smoother market responses, through, for example, avoiding the imposition of export
 4 bans.

5 In summary, given the likelihood that extreme weather will increase, in both frequency and magnitude
 6 (Hansen et al. 2012; Coumou et al. 2014; Mann et al. 2017; Bailey et al. 2015), and the current state
 7 of global and cross-sectoral interconnectedness, the food system is at increasing risk of disruption
 8 (*medium evidence, medium agreement*), with large uncertainty about how this could manifest. There
 9 is therefore a need to build resilience into international trade as well as local supplies.

10

11

12

13 **Figure 5.17 Underlying processes that affect the development of a food price spike in agricultural**
 14 **commodity markets (Challinor et al. 2018)**

15 **Box 5.5 Market drivers and the consequences of extreme weather in 2010-2011**

16 The 2010–2011 food price spike was initially triggered by the exceptional heat in summer 2010, with
 17 an extent from Europe to the Ukraine and Western Russia (Barriopedro et al. 2011; Watanabe et al.
 18 2013; Hoag 2014). The heatwave in Russia was extreme in both temperature (over 40°C) and duration
 19 (from July to mid-August in 2010). This reduced wheat yields by approximately one third (Wegren
 20 2011; Marchand et al. 2016). Simultaneously, in the Indus Valley in Pakistan, unprecedented rainfall
 21 led to flooding, affecting the lives and livelihoods of 20 million people. There is evidence that these
 22 effects were both linked and made more likely through climate change (Mann et al. 2017).

23 In response to its shortfall in yields, Russia imposed an export ban in order to maintain local food
 24 supplies. Other countries responded in a largely uncoordinated ways, each of them driven by
 25 internal politics as well as national self-interests (Jones and Hiller 2017). Overall, these measures
 26 led to rapid price rises on the global markets (Welton 2011), partly through panic buying, but also
 27 through financial speculation (Spratt 2013).

1 Analysis of responses to higher food prices in the developing world showed that lower-income groups
2 responded by taking on more employment, reducing food intake, limiting expenditures, spending
3 savings (if available), and participating in demonstrations. People often identified their problems as
4 stemming from collusion between powerful incumbent interests (e.g., of politicians and big business)
5 and disregard for the poor (Hossain and Green 2011). This politicised social response helped spark
6 food-related civil protest, including riots, across a range of countries in 2010–2011 (Natalini et al.
7 2017). In Pakistan, food price rises were exacerbated by the economic impacts of the floods, and
8 which further contributed to food-related riots in 2010.

9 Price spikes also impact on food security in the developed world. In the UK, global commodity price
10 inflation influenced local food prices, increasing food-price inflation by ~5 times at the end of 2010.
11 Comparing household purchases over the five year period from 2007 to 2011 showed that the amount
12 of food bought declined, on average, by 4.2%, whilst paying 12% more for it. The lowest income
13 decile spent 17% more by 2011 than they did in 2007 (Holding et al. 2013; Tadasse et al. 2016).
14 Consumers also saved money by trading down for cheaper alternatives. For the poorest, in the
15 extreme situation, food became unaffordable: the Trussell Trust, a charity supplying emergency food
16 handouts for people in crisis, noted a 50% increase in handouts in 2010.

18 **5.8.2 Migration and conflict**

19 Since the IPCC AR5 (Porter et al. 2014; Cramer et al. 2014), new work has advanced multi-factor
20 methodological issues related to migration and conflict (e.g., Kelley et al. 2015, 2017; Werrell et al.
21 2015; Challinor et al. 2018; Pasini et al. 2018). These in particular have addressed systemic risks to
22 food security that result from cascading impacts triggered by droughts and floods and how these are
23 related to a broad range of societal influences.

24 Climate variability and extremes have short-, medium- and long-term impacts on livelihoods and
25 livelihood assets – especially of the poor – contributing to greater risk of food insecurity and
26 malnutrition (FAO et al. 2018). Drought threatens local food security and nutrition and aggravates
27 humanitarian conditions, which can trigger large-scale human displacement and create a breeding
28 ground for conflict (Maystadt and Ecker 2014). There is *medium agreement* that existing patterns of
29 conflict could be reinforced under climate change affecting food security and livelihood opportunities,
30 for example, already fragile regions with ethnic divides such as North and Central Africa as well as
31 Central Asia (Buhaug 2016; Schleussner et al. 2016) (Box 5.6).

32 Challinor et al. (2018) have developed a typology for transboundary and transboundary risk
33 transmission that distinguishes the roles of climate and social and economic systems. To understand
34 these complex interactions, they recommend a combination of methods that include expert judgement;
35 interactive scenario building; global systems science and big data; and innovative use of climate and
36 integrated assessment models; and social science techniques (e.g., surveys, interviews, and focus
37 groups).

39 **5.8.2.1 Migration**

40 There has been a surge in international migration in recent years, with around five million people
41 migrating permanently in 2016 (OECD 2017). Though the initial driver of migration may differ across
42 populations, countries and contexts, migrants tend to seek the same fundamental objective: to provide
43 security and adequate living conditions for their families and themselves. Food insecurity is a critical
44 ‘push’ factor driving international migration, along with conflict, income inequality, and population

1 growth. The act of migration itself causes food insecurity, given the lack of income opportunities and
2 adverse conditions compounded by conflict situations.

3 Warner et al. (2012) found the interrelationships between changing rainfall patterns, food and
4 livelihood security in eight countries in Asia, Africa and Latin America. Several studies in Africa
5 have found that persistent droughts and land degradation contributed to both seasonal and permanent
6 migration (Gray 2011; Gray and Mueller 2012; Hummel 2015; Henry et al. 2004; Folami and Folami
7 2013), worsening contextual vulnerability conditions of different households (Dasgupta et al. 2014).

8 Dependency on rainfed agriculture is from 13% in Mexico to more than 30% in Guatemala,
9 Honduras, and Nicaragua, suggesting a high degree of sensitivity to climate variability and change,
10 and undermined food security (Warner et al. 2009). Studies have demonstrated that Mexican
11 migration (Feng et al. 2010; Nawrotzki et al. 2013) and Central American migration (WFP 2017)
12 fluctuate in response to climate variability. The food system is heavily dependent on maize and bean
13 production and long-term climate change and variability significantly affect the productivity of these
14 crops and the livelihoods of smallholder farmers (WFP 2017). In rural Ecuador, adverse
15 environmental conditions prompt out-migration, although households respond to these challenges in
16 diverse ways resulting in complex migratory responses (Gray and Bilsborrow 2013).

17 Migration patterns have been linked to heat stress in Pakistan (Mueller et al. 2014) and climate
18 variability in the Sundarbans due to decline in food security (Guha and Roy 2016). In Bangladesh, the
19 impacts of climate change have been on the rise throughout the last three decades with increasing
20 migration, mostly of men leaving women and children to cope with increasing effects of natural
21 disasters (Rabbani et al. 2015).

22

23 **Box 5.6 Migration in the Pacific region: Impacts of climate change on food security**

24 Climate change-induced displacement and migration in the Pacific has received wide attention in the
25 scientific discourse (Fröhlich and Klepp 2019). The processes of climate change and their effects in
26 the region have serious implications for Pacific Island nations as they influence the environments that
27 are their 'life-support systems' (Campbell 2014). Climate variability poses significant threats to both
28 agricultural production and food security. Rising temperatures and reductions in groundwater
29 availability, as well as increasing frequency and severity of disaster events translate into substantial
30 impacts on food security causing human displacement, a trend that will be aggravated by future
31 climate impacts (ADB 2017). Declining soil productivity, groundwater depletion, and non-availability
32 of freshwater threatens agricultural production in many remote atolls.

33 Many countries in the Pacific devote a large share of available land area to agricultural production.
34 For example, more than 60% of land area is cultivated in the Marshall Islands and Tuvalu and more
35 than 40% in Kiribati and Tonga. With few options to expand agricultural area, the projected impacts
36 of climate change on food production are of particular concern (ADB 2013, 2017). The degradation of
37 available land area for traditional agriculture, adverse disruptions of agricultural productivity and
38 diminishing livelihood opportunities through climate change impacts leads to increasing poverty and
39 food insecurity, incentivising migration to urban agglomerations (ADB 2017; FAO et al. 2018).

40 Campbell (2014) describe the trends that lead to migration. First, climate change, including sea level
41 rise, affect communities' land security, which is the physical presence on which to live and sustain
42 livelihoods. Second, they impinge on livelihood security (especially food security) of island
43 communities where the productivity of both subsistence and commercial food production systems is
44 reduced. Third, the effects of climate change are especially severe on small-island environments since
45 they result in declining ecological habitat. The effects on island systems are mostly manifested in
46 atolls through erosion and inundation, and on human populations through migration. Population

1 growth and scenarios of climate change is *likely* to further induce food stress as impacts unfolds in
2 coming decades (Campbell 2015).

3 While the populations of several islands and island groups in the Pacific (e.g., Tuvalu, Carteret
4 Islands, and Kiribati) have been perceived as the first probable victims of rising seas so that their
5 inhabitants would become, and in some quarters already are seen to be, the first ‘environmental’ or
6 ‘climate change refugees,’ migration patterns vary. Especially in small islands, the range and nature of
7 the interactions among economic, social, and/or political drivers are complex. For example, in the
8 Maldives, Stojanov et al. (2017) show that while collective perceptions support climate change
9 impacts as being one of the key factors prompting migration, individual perceptions give more
10 credence to other cultural, religious, economic or social factors.

11 In the Pacific, Tuvalu has long been a prime candidate to disappear due to rising sea level, forcing
12 human migration. However, results of a recent study (Kench et al. 2018) challenge perceptions of
13 island loss in Tuvalu, reporting despite sea level rise, a net increase in land area of 73.5 ha. The
14 findings suggest that islands are dynamic features likely to persist as habitation sites over the next
15 century, presenting opportunities for adaptation that embrace the heterogeneity of island types and
16 processes. Farbotko (2010) and Farbotko and Lazrus (2012) present Tuvalu as a site of ‘wishful
17 sinking,’ in the climate change discourse. These authors argue that representations of Tuvalu as a
18 laboratory for global climate change migration are visualisations by non-locals.

19 In Nanumea (Tuvalu), forced displacements and voluntary migrations are complex decisions made
20 by individuals, families and communities in response to discourses on risk, deteriorating
21 infrastructure and other economic and social pressures (Marino and Lazrus 2015). In many atoll
22 nations in western Pacific, migration has increasingly become a sustainable livelihood strategy,
23 irrespective of climate change (Connell 2015).

24 In Lamén Bay, Vanuatu, migration is both a cause and consequence of local vulnerabilities. While
25 migration provides an opportunity for households to meet their immediate economic needs, it limits
26 the ability of the community to foster longer-term economic development. At the same time,
27 migration adversely affects the ability of the community to maintain food security due to lost labour
28 and changing attitudes towards traditional ways of life among community members (Craven 2015).

29 Small islands are very sensitive to climate change impacts (*high confidence*) (Nurse et al. 2014) and
30 impacted by multiple climatic stressors (see (IPCC 2018a) and SROCC). Food security in the Pacific,
31 especially in Micronesia, has worsened in the past half century and climate change is *likely* to further
32 hamper local food production, especially in low-lying atolls (Connell 2016) Migration in small islands
33 (internally and internationally) occurs for multiple reasons and purposes, mostly for better livelihood
34 opportunities (*high confidence*).

35 Beyond sea level rise, effects of increasing frequency and intensity of extreme events such as severe
36 tropical cyclones are *likely* to affect human migration in the Pacific (Connell 2015; Krishnapillai and
37 Gavenda 2014; Charan et al. 2017; Krishnapillai 2017). On Yap Island, extreme weather events are
38 affecting every aspect of atoll communities’ existence, mainly due to islands’ small size, their low
39 elevation, and extensive coastal areas (Krishnapillai 2018). Displaced atoll communities on Yap
40 Island grow a variety of nutritious vegetables and use alternative crop production methods such as
41 small-plot intensive farming, raised bed gardening, as part of a community-based adaptation program
42 (Krishnapillai and Gavenda 2014; Krishnapillai 2018).

43 Recurrences of natural disasters and crises threaten food security through impacts on traditional
44 agriculture, causing the forced migration and displacement of coastal communities to highlands in
45 search of better living conditions. Although considerable differences occur in the physical
46 manifestations of severe storms, such climate stressors threaten the life-support systems of many atoll

1 communities (Campbell et al. 2014). Failure of these systems resulting from climate disasters propel
2 vulnerable atoll communities into poverty traps, and low adaptive capacity could eventually force
3 these communities to migrate.

4 5 **5.8.2.2 Conflict**

6 While climate change will not alone cause conflict, it is often acknowledged as having the potential to
7 exacerbate or catalyse conflict in conjunction with other factors. Increased resource competition can
8 aggravate the potential for migration to lead to conflict. When populations continue to increase,
9 competition for resources will also increase, and resources will become even scarcer due to climate
10 change (Hendrix and Glaser 2007). In agriculture-dependent communities in low-income contexts,
11 droughts have been found to increase the likelihood of violence and prolonged conflict at the local
12 level, which eventually pose a threat to societal stability and peace (FAO et al. 2017). In contrast,
13 conflicts can also have diverging effects on agriculture due to land abandonment, resulting in forest
14 growth, or agriculture expansion causing deforestation, e.g., in Colombia (Landholm et al. 2019).

15 Several studies have explored the causal links among climate change, drought, impacts on agricultural
16 production, livelihoods, and civil unrest in Syria from 2007-2010, but without agreement as to the role
17 played by climate in subsequent migration (Kelley et al. 2015, 2017; Challinor et al. 2018; Selby et al.
18 2017; Hendrix 2018). Contributing factors that have been examined include rainfall deficits,
19 population growth, agricultural policies, and influx of refugees that had placed burdens on the
20 region's water resources (Kelley et al. 2015). Drought may have played a role as a trigger, as this
21 drought was the longest and the most intense in the last 900 years (Cook et al. 2016; Mathbout et al.
22 2018). Some studies linked the drought to widespread crop failure, but the climate hypothesis has
23 been contested (Selby et al. 2017; Hendrix 2018). Recent evidence shows that the severe drought
24 triggered agricultural collapse and displacement of rural farm families with approximately 300,000
25 families going to Damascus, Aleppo and other cities (Kelley et al. 2017).

26 Persistent drought in Morocco during the early 1980s resulted in food riots and contributed to an
27 economic collapse (El-Said and Harrigan 2014). A drought in Somalia that fuelled conflict through
28 livestock price changes, establishing livestock markets as the primary channel of impact (Maystadt
29 and Ecker 2014). Cattle raiding as a normal means of restocking during drought in the Great Horn of
30 Africa led to conflict (ICPAC and WFP 2017) whereas a region-wide drought in northern Mali in
31 2012 wiped out thousands of livestock and devastated the livelihoods of pastoralists, in turn swelling
32 the ranks of armed rebel factions and forcing others to steal and loot for survival (Breisinger et al.
33 2015).

34 On the other hand, inter-annual adjustments in international trade can play an important role in
35 shifting supplies from food surplus regions to regions facing food deficits which emerge as a
36 consequence of extreme weather events, civil strife, and/or other disruptions (Baldos and Hertel
37 2015). A more freely functioning global trading system is tested for its ability to deliver improved
38 long run food security in 2050.

39 In summary, given increasing extreme events and global and cross-sectoral interconnectedness, the
40 food system is at increasing risk of disruption, e.g., via migration and conflict (*high confidence*).
41 {5.2.3, 5.2.4}

43 **Frequently Asked Questions**

44 **FAQ 5.1 How does climate change affect food security?**

1 Climate change negatively affects all four pillars of food security: availability, access, utilisation and
2 stability. Food availability may be reduced by negative climate change impacts on productivity of
3 crops, livestock and fish, for instance due to increases in temperature and changes in rainfall patterns.
4 Productivity is also negatively affected by increased pests and diseases, as well as changing
5 distributions of pollinators under climate change. Food access and its stability may be affected
6 through disruption of markets, prices, infrastructure, transport, manufacture, and retail, as well as
7 direct and indirect changes in income and food purchasing power of low-income consumers. Food
8 utilisation may be directly affected by climate change due to increases in mycotoxins in food and feed
9 with rising temperatures and increased frequencies of extreme events, and indirectly through effects
10 on health. Elevated atmospheric CO₂ concentrations can increase yields at lower temperature
11 increases, but tend to decrease protein content in many crops, reducing their nutritional values.
12 Extreme events, e.g., flooding, will affect the stability of food supply directly through disruption of
13 transport and markets.

14 15 **FAQ 5.2 How can changing diets help address climate change?**

16 Agricultural activities emit substantial amounts of greenhouse gases (GHGs). Food supply chains
17 activities past the farm gate (e.g., transportation, storage, packaging) also emit GHGs, for instance due
18 to consumption of energy. GHG emissions from food production vary across food types. Producing
19 animal-sourced food (i.e., meat and dairy) emits larger amount of GHGs than growing crops,
20 especially in intensive, industrial livestock systems. This is mainly true for commodities produced by
21 ruminant livestock such as cattle, due to enteric fermentation processes that are large emitters of
22 methane. Changing diets towards a lower share of animal-sourced food, once implemented at scale,
23 reduces the need to raise livestock and changes crop production from animal feed to human food. This
24 reduces the need for agricultural land compared to present and thus generates changes in the current
25 food system. From field to consumer this would reduce overall GHG emissions. Changes in consumer
26 behaviour beyond dietary changes can also have, at scale, effects on overall GHG emissions from
27 food systems. Consuming regional and seasonal food can reduce GHG emissions, if they are grown
28 efficiently.

3 *Detection and attribution methods*

4 Observed impacts of climate change on food security have been noted as a cause of concern (HLPE
 5 2012) and assessed in AR5 (Porter et al. 2014; Cramer et al. 2014) and SR15 (IPCC 2018). Assessing
 6 evidence for detection and attribution of observed climate change impacts on the food system remains
 7 a challenge because agriculture is a managed system with practices changing over time. Using AR5
 8 and SR15 findings that observed climate changes attributable to human influence include rising
 9 temperatures, increases in the intensity and frequency of hot days and nights, more areas with
 10 increases than decreases in the frequency, intensity, and or amount of heavy precipitation, and drying
 11 trends in some regions especially in the Mediterranean region (including southern Europe, northern
 12 Africa and the Near East), we assess recent studies of observed climate change impacts on the food
 13 system that utilise IPCC attribution methods (Hegerl et al. 2010), as well as others that depend on
 14 local knowledge from the developing world.

15 New work has addressed observed climate effects on expanded aspects of the food system, including
 16 pastoral systems (Rasul et al. 2019; Abiona et al. 2016), pests, diseases, and pollinators (Bebber et al.
 17 2014; Schweiger et al. 2010), and adaptation (Li et al. 2017) (see Section 5.3). Surveys of farmer
 18 perceptions of climate changes and their impacts are being increasingly utilised in developing
 19 countries for example (Hussain et al. 2016) (Ifeanyi-obi et al. 2016; Onyeneke 2018).

20

21 *Improvements in projection methods since AR5*

22 Since AR5, methods for assessment of future climate change impacts on food systems have improved
 23 in several areas, providing new insights. These methods include greater number of ensembles of
 24 multiple climate, crop, and economic models, with improved characterisation of uncertainty (Wiebe et
 25 al. 2015); further comparison of results from process-based crop models and statistical models (Zhao
 26 et al. 2017); advances in regional integrated assessments (Rosenzweig and Hillel 2015), and new
 27 coordinated global and regional studies (Rosenzweig et al. 2017; Ruane et al. 2018). Temperature
 28 response functions in crop models have been improved (Wang et al. 2017).

1 Expanded meta-analyses of free-air carbon dioxide experiments (FACE) have examined effects of
2 high CO₂ on crop nutrients not just on yield (Smith and Myers 2018; Zhu et al. 2018) (Section
3 5.2.4.2). Recent reviews have confirmed that higher CO₂ concentrations increase crop growth and
4 yield, especially in crops with C3 photosynthetic pathways, but realisation of these direct CO₂ effects
5 depends on nutrient and water availability (Lombardozi et al. 2018; Toreti et al.; Uddin et al. 2018)
6 (*high confidence*). New work has considered future impacts of farming systems, extreme events, fruits
7 and vegetables, rangelands and livestock, and aquaculture, as well as food safety, pests and diseases,
8 and food quality (Section 5.2).

9 However, several sources of uncertainty exist in projection of climate change crop impacts, partly
10 stemming from differences between the models and methods utilised, sparse observations related to
11 current climate trends, and other agro-ecosystem responses (e.g., to CO₂ effects) (Mistry et al. 2017;
12 Li et al. 2015; Bassu et al. 2014; Asseng et al. 2013). The uncertainty in climate simulations is
13 generally larger than, or sometimes comparable to, the uncertainty in crop simulations using a single
14 model (Iizumi et al. 2011), but is less than crop model uncertainty when multiple crop models are
15 used as in AgMIP (Rosenzweig et al. 2014b) and CO₂ is considered (Hasegawa et al. 2018; Müller et
16 al. 2014; Asseng et al. 2013).

17 Most of the work on projected impacts on climate change impacts on crops continues to focus on the
18 major commodities-wheat, maize, rice, and soybean-while areas still lagging are multi-model
19 ensemble approaches for livestock and fruits and vegetables. While the current reliance on the four
20 major commodities makes assessment of climate change impacts on them important, there is a
21 growing recognition that more than caloric intake is required to achieve food security for all and that
22 assessments need to take into account how climate change will affect the 2 billion malnourished
23 people in the current climate and food system.

3**Table SM5.3 Observed climate change impacts on crop production, data sources, and detection and attribution methods**

Climate observations	Climate data source	Observed impacts	Impact method/source	Time period	Region	Detection & Attribution method	Reference	Continent
Warming temperatures	Chinese Meteorological Administration	If 1980 variety was still grown, maize yield would stagnate or decrease; due to adoption of maize varieties with long growth period yield increased by 7-17% per decade.	China Agricultural Database	1980-2009	Heilongjiang Province, Northeast China	Single step attribution	(Meng et al. 2014)	Asia
Warming temperatures	Chinese Meteorological Administration	Changes in winter wheat phenology; observed dates of sowing, emergence, and beginning of winter dormancy were delayed by 1.2, 1.3, and 1.2 days per decade. Dates of regrowth after dormancy, anthesis, and maturity advanced 2.0, 3.7, and 3.1 days per decade. Growth duration, overwintering period, and vegetation phase shortened by 4.3, 3.1, and 5.0 days per decade.	Local agrometeorological experimental stations maintained by Chinese Meteorological Administration	1981-2009	Loess Plateau, Northwest China	Single step attribution	(He 2015)	Asia

Warming temperatures	Central China Meteorological Agency	Advance in sowing and phenological stages advanced by 23-26 days	Agrometeorological experimental station Wulanwusu, China	1981-2010	Northwest China	Statistical relationships for cotton phenologies, seed cotton yields, and climate parameters using Pearson correlation analysis.	(Huang and Ji 2015)	Asia
Warming temperatures	China Meteorological Administration	Changes in temperature, precipitation and solar radiation in past three decades and increased wheat yield in northern China by 0.9-12.9%; reduced wheat yield in southern China by 1.2-10.2 %.	China Meteorological Administration	1981-2009	China	Correlations between annual yields with climate variables. Partial correlations with detrended yields and climate variables.	(Tao et al. 2014)	Asia
Warming temperatures	Pakistan Meteorological Department	Change in phenology of sunflowers. Sowing dates for spring sunflowers 3.4-9.3 days per decade earlier. Sowing dates for autumn sunflower delayed by 2.7-8.4 days per decade.	Punjab Agriculture Department	1980-2016	Punjab, Pakistan	Single step attribution	(Tariq et al. 2018)	Asia

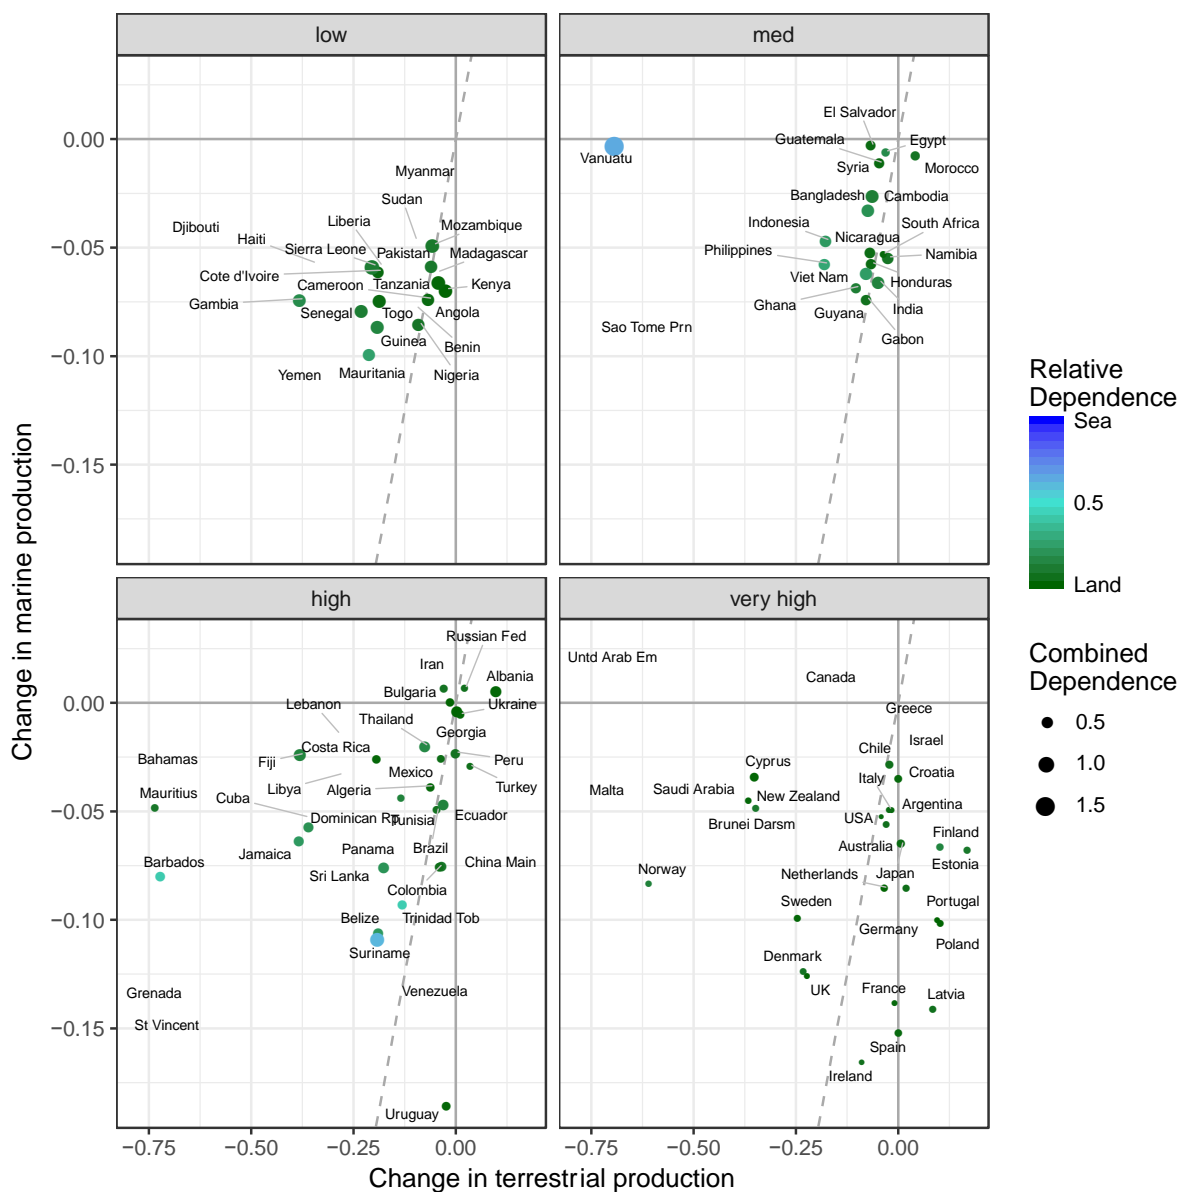

Warming temperatures	Pakistan Meteorological Department	Change in phenology in maize. Sowing dates for spring maize 3.5-5.5 days per decade earlier. Sowing dates for autumn maize 1.5-4.2 days per decade later.	Punjab Agriculture Department	1980-2014	Punjab, Pakistan	Single step attribution	(Abbas et al. 2017)	Asia
Increases in max and min temperatures	India Meteorological Department (IMD)	Reduced wheat yields by 5.2% . 1 degree C increase in maximum temperature lowers yields by 2.3% while same increase in minimum temperature lowers yields by 3.6%.	Indian Harvest Database Centre of Monitoring the Indian Economy (CMIE) and Directorate of Economics, Ministry of Agriculture.	1981-2009	India	Regression analysis between temperature and yield.	(Gupta et al. 2017)	Asia
Reduced rainfall and rising temperatures	Australian Bureau of Meteorology	Stagnated wheat yields. Declines in water-limited yield potential.	Agricultural Commodity Statistics	1965-2015	Australia	Single step attribution	(Hochman et al. 2017)	Australia

Increases in temperature and drought	Czech Hydrometeorological Institute (CHMI), 268 climatological stations, and 774 rain gauge stations	Long-term impacts on fruiting vegetables (+4.9 to 12.2% per degree C) but decreases in stability of traditionally grown root vegetables in warmest areas of country.	Database of 12 field-grown vegetables at district level as reported by Czech Statistical Office.	1961-2014	Czech Republic	Associative pattern attribution	(Potopová et al. 2017)	Europe
Long-term temperature and precipitation trends	Precipitation: 1900-2008 Gridded Monthly Time Series Version 2.01. Available at: http://climate.geog.udel.edu/~climate/ .	Wheat and barley yields declined by 2.5% and 3.8%, and maize and sugar beet yields have increased due to temperature and precipitation changes.	EU Farm Accountancy Data Network (FADN)	1989-2009	Europe	Associative pattern attribution	(Moore and Lobell 2015)	Europe

1 **Notes:** See Hegerl et al. (2010) for full definitions of attribution methods: Single Step: where a model(s) is run with and without a single variable of interest
2 (i.e., temperature) and results compared to observed changes within a system; Multi-Step: Through processes modelling and/or a statistical link, a change in
3 climate is linked to a variable of interest, and then that variable of interest is linked to an observed change; Associative Pattern: Involves the synthesis of
4 multiple observations – and demonstrates a pattern of strong association between these changes and changes in temperatures due to anthropogenic forcing.

Figure SM5.2 Undernourishment is higher when exposure to climate extremes is compounded by high levels of vulnerability in agriculture (FAO et al. 2018).

1 **Section SM5.5**

2 *Livestock mitigation strategies*

3 *Intensification of animal diets.* It is well established that appropriate diet regimes may contribute to
4 reduce the amount of GHG produced per unit of animal product (Gerber et al. 2013b), which, within
5 the appropriate implementation including governance, may lead to mitigation of absolute emissions.
6 This increased efficiency can be achieved through improved supplementation practices or through
7 land use management with practices like improved pasture management, including grazing rotation,
8 fertiliser applications, soil pH modification, development of fodder banks, improved pasture species,
9 use of legumes and other high protein feeds, the use of improved crop by-products and novel feeds
10 (i.e., black soldier fly meal, industrially produced microbial protein (Pikaar et al. 2018).

11 When done through increased feeding of grains, transition to improved diets shifts the contributions of
12 different GHG gases to the total emissions. This is due to the fact that the proportion of methane to
13 total emissions is reduced (due to lower roughage intake), while the proportion of emissions
14 associated with feed manufacture (energy and land use change) increases. Therefore, CO₂ emissions
15 from land use change increase while methane emissions per unit of output decrease (Gill et al. 2010).
16 As a consequence, the quantified benefits of a given strategy will also depend on the assumed GWP of
17 methane.

18 Of the available livestock GHG mitigation options, improved feeding systems are relatively easy to
19 implement at the farm level. A prerequisite for these options to work is that the livestock systems
20 need to be geared towards market-oriented production, as otherwise there is little incentive to improve
21 feeding systems. This in turn implies that costs and benefits to farmers are appropriate to incentivise
22 specific management changes and also assess the impact that market-orientation may have in some
23 societies, such as pastoralists (López-i-Gelats et al. 2016). Examples of where this option could be
24 applicable are smallholder dairy-crop mixed systems in Africa and Asia, dual-purpose and dairy
25 production in Latin America and beef cattle operations, where significant mitigation opportunities
26 exist. Other mitigation options include manipulation of rumen microflora, breeding for lower methane
27 production, and the use of feed additives (Hristov et al. 2013).

28 The largest GHG efficiency gaps are observed in livestock systems where the quality of the diet is the
29 poorest (i.e., grassland-based and some arid and humid mixed systems in the developing world). The
30 highest marginal gains of improving animal diets through simple feeding practices, both biologically
31 and economically, are in these systems (FAO, 2013; Herrero et al. 2013).

32 *Control of animal numbers, shifts in breeds, and improved management.* Increases in animal numbers
33 are one of the biggest factors contributing directly to GHG emissions (Tubiello, 2019). Regions with
34 intensive animal production, such as concentrated animal feeding operations (CAFOs), can control
35 animal numbers, conduct breeding programs for efficient animals, and improve feeding management.
36 In the developing world, many low-producing animals could be replaced by fewer but better-fed
37 cross-bred animals of a higher potential, with improved grazing management (i.e., attention to feed,
38 herbage availability, and allowances) playing an important role. In both developed and developing
39 countries these practices are able to reduce total emissions while maintaining or increasing the supply
40 of livestock products.

41 However, attention must be paid to synergies and trade-offs between livelihoods and specific
42 mitigation strategies, such as controlling animal numbers, recognising the multiple objectives that
43 livestock raising may contribute to within specific settings, especially in low-input systems.
44 Improvements in animal health can also significantly reduce emissions intensity by improved yields
45 and fertility per animal and reductions in mortality (ADAS 2015).

46 *Changes in livestock species.* Switching species to better suit particular environments is a strategy that
47 could yield higher productivity per animal for the resources available. At the same time, structural

1 changes in the livestock sector from beef to sheeps and goats, or mainly from ruminants to
2 monogastrics (e.g., from beef to pig or poultry production) could lead to reduced methane emissions
3 and higher efficiency gains. Assessment done using integrated assessment models (IAMs) have shown
4 that these practices could lead to reductions in land use change and its associated emissions (Havlik et
5 al. 2014; Frank et al. 2018).

6 *Managing nitrous oxide emissions from manure.* In the developing world, large amounts of nutrients
7 are lost due to poor manure management. In currently adopted feeding systems, large amounts of
8 nutrients and carbon are lost in connection with manure storage (e.g., Herrero et al. 2013). In many
9 places pig manure is not recycled; considered a waste, it is often discharged to water bodies or left to
10 accumulate unused. Yet these farming systems can be highly N and P limited. This practice creates
11 serious problems especially in urban and peri-urban systems by contributing to water and air
12 pollution. Research in intensive African ruminant livestock systems, for instance, has shown that up to
13 70% of the manure N can be lost within six months of excretion when manure is poorly managed
14 (Tittonell et al. 2009).

15 Options to manage emissions in the livestock sector are not easy to design because they require
16 systems thinking and awareness of key driving factors in different livestock systems. Reducing N
17 emissions starts with feeding livestock balanced diets so that excreta are not rich in labile N, which is
18 easily lost as ammonia and enters the N cascade (Bouwman et al. 2013). In intensive systems, mineral
19 N can be captured effectively using bedding material, which has been increasingly excluded from
20 livestock facilities to reduce operational costs.

21 Manure is increasingly handled as slurry in tanks or anaerobic lagoons, which may reduce direct
22 nitrous oxide emissions during storage but can increase methane and ammonia loss and also increase
23 the risk of emissions during land spreading (Velthof and Mosquera 2011). However, optimising land
24 spreading of manures (in terms of timing or placement) to maximise N and P replacement value can
25 minimise ammonia losses while also displacing mineral fertiliser (Bourdin et al. 2014).

26 In intensive systems, emissions of ammonia and nitrous oxide can be managed by spatially shifting
27 livestock pens or the facilities where they overnight. Other options in more-intensive grazing systems
28 may include nitrification inhibitors, stand-off pads, delayed manure spreading collected in milking
29 sheds, although the fate of the full applied N and its partitioning between direct and indirect emissions
30 as a result of the specific option chosen must be evaluated (e.g., Lam et al., 2017)

31

32 *Uncertainties in demand-side technical mitigation potential*

33 There are several unresolved issues regarding modelling and quantification of marginal emissions
34 identified in the literature. Diet shift studies often focus on beef production emission intensities,
35 although the cattle industry in many locations includes both meat and dairy production; these
36 activities may be integrated in different types of farming systems (Flysjö et al. 2012) with
37 significantly lower emission intensities (Gerber et al. 2013a; Flysjö et al. 2012). Links between
38 ruminant meat production, the dairy sector (primarily cows and goats), and wool production in sheep
39 are often overlooked in diet shift studies. FAOStat 2017 data indicate there are 278 million dairy cows
40 worldwide, which make significant contributions to meat production (304 million head slaughtered
41 per year) by providing calves (lactating cows must calve to produce milk) and dairy cows
42 (replacements by younger females).

43 Attributional LCA values are often applied to diet shifts studies, overlooking the feedback loop
44 (rebound effect) of demand on production system emission intensities. There are a few examples of
45 consequential analysis of diet shifts (Tukker et al. 2011) (de Oliveira Silva et al. 2016) (Zech and
46 Schneider 2019), reporting modest potential for mitigation (i.e., from 0-8%) but each of them

1 emphasise only one particular aspect of diet shifts. Further, the application of those models to
2 different regions of the world may require further development.

3 Current attributional LCA studies present inconsistencies related to the definition of system
4 boundaries, allocation of co-products (including dairy), method of attribution of land use change, and
5 pasture productivity effects on soil carbon stocks (Lynch 2019) (Yan et al. 2011; Dudley et al. 2014).
6 Major differences in the results are due to how land use change affects emissions and soil carbon
7 stocks, particularly when addressing developing countries where deforestation and intensification can
8 both take place at the same time. Deforestation-related emissions have been attributed to first land use
9 (Bustamante et al. 2012), the activities under a given amortization time (Persson et al. 2014), change
10 in total land covered by the activity (Gerber et al. 2013a), or the missed potential carbon sink, i.e., the
11 opportunity for natural vegetation recovery (Schmidinger and Stehfest 2012) (Schmidt et al. 2015).

12 Also, variation in soil carbon stocks is not considered in most studies, while a few account for
13 variations up to 0.3 m soil depth, and very rarely consider 1.0 m soil depth for estimating soil carbon
14 variation. Overlooking soil carbon at deeper soil layers largely contributes to underestimating the
15 environmental benefits of transition to more productive systems. Time considerations in soil carbon
16 stocks dynamics also vary among studies, with some applying a standard 20-year equilibrium time
17 instantaneously and others using dynamic (discrete or continuous) models.

18 The type of food replacement is another major source of uncertainty in calculating the impact of
19 dietary changes (Smetana et al. 2015). Nutritional replacement with animal-based protein candidates
20 such as chicken, eggs, pork, fish, and insects is likely to vary widely in different geographical
21 contexts. While chicken and soybean are currently dominating international trade of protein sources
22 (FAOStat), legumes, pulses, seaweed, and yeast-derived foods are being tested as ingredients by the
23 food industry.

24 In regard to food quality, reducing meat consumption may lower the iron and zinc nutritional status of
25 certain vulnerable groups. For example, in Europe 22% of preschool children, 25% of pregnant
26 women, and 19% of nonpregnant women already have anemia (WHO, 2008). Reductions in red meat
27 consumption also may have food safety implications. Substituting meat with poultry or seafood might
28 increase foodborne illnesses, whereas replacement with pulses and vegetables would reduce them
29 (Lake et al., 2012).

30 GHG emissions associated with food preparation and food waste are usually unaccounted for in diet
31 shift studies with rare exceptions (Corrado et al. 2019). Dietary supplements (vitamin, minerals and
32 amino acids) are highly recommended for low-meat diets, but they are not considered in GHG
33 mitigation studies of diet shifts, mostly because of lack of LCA data for supplements (Corrado et al.
34 2019).

35 The varying proportions of CO₂, CH₄, and N₂O contributions to ruminant-related emissions, with a
36 high proportion of the short-lived methane, make interpretation sensitive to the global warming
37 metrics adopted (Reisinger and Clark 2018) (Lynch 2019). As more intensive systems or other diet
38 alternatives would alter the relative contributions to food of these gases, the choice of metric often
39 changes the ranking of mitigation options (Lynch and Pierrehumbert 2019)(Garnett, 2011). Most
40 projections related to diet shifts do not account for the potential of methane inhibitors, non-symbiotic
41 nitrogen fixation, advances in livestock and forage genetics, and other emerging technologies in the
42 livestock sector, some of which are close to market launch (Jayanegara et al. 2018).

43 In a systems view, dairy and wool production can be affected if reductions in ruminant meat demand
44 take place. While beef production systems are often characterised by low energy and protein
45 efficiency, milk production is as efficient energetically as egg production and second after eggs in
46 protein conversion efficiency among animal-based proteins (Eshel et al. 2016).

1 In summary, systems level analyses revealed wide variation in mitigation estimates of diet shifts, in
2 part due to differing accounting for the main interactions. There is *robust evidence* that diet shifts can
3 mitigate GHG emissions but *low agreement* on how much could be achieved and what would be the
4 effectiveness of interventions to promote diet shifts. In high-income industrialised countries, there is
5 scope for reducing consumption of livestock produce with tangible environmental benefits; in
6 developing countries, high meat-based diets are less prevalent and scope for reductions may be more
7 limited, but there are options for encouraging nutrition transitions towards healthy diets.

8

9

1 Section SM5.6

2 *Global meat consumption*

3 The issue of global meat consumption as a driver of GHG emission, can be weighed against the
 4 requirements of healthy diet. Healthy and sustainable diets are high in coarse grains, pulses, fruits and
 5 vegetables, and nuts and seeds; low in energy-intensive animal-sourced and discretionary foods (such
 6 as sugary beverages and fats); and have a carbohydrate threshold. Based on the potential impact of
 7 suboptimal diets on non-communicable diseases (NCD) mortality and morbidity, the World Health
 8 Organization (WHO) and the EAT-LANCET report (Willett et al. 2019) highlighted the need for
 9 improving diets across nations and made recommendations on how to balance nutrition to prevent
 10 malnutrition. The source of protein is not limited to meat; it is found in fish, vegetable and insects.
 11 The range of options in balancing protein sources runs primarily into cultural resistance, food habits,
 12 economic conditions and the social and economic factors influencing how the food system affects
 13 climate and land.

14 Most recent analyses, like the EAT-LANCET (Willett et al. 2019) work, show that reductions in
 15 consumption, especially of red meat, apply to over-consumers, while scope remains for growth in
 16 consumption in Low- and Middle-Income Countries (LMICs).

17

18 **Figure SM5.3 The “diet gap” between current dietary patterns and intakes of food in the planetary health**
 19 **diet (Willett et al. 2019).**

20 From the climate and land perspectives, there is a difference between red meat production and other
 21 meat production (Willett et al. 2019). The impacts of meat production will depend on resource use
 22 intensity to produce meat calories, the land and climate footprints of the processing and supply chains,
 23 and the scale of the production systems (i.e., livestock on crop by-products vs. pasture vs. intensive
 24 grain-fed) (Willett et al. 2019). Hence, the question is not about eating less meat for everyone, but to
 25 adopt sustainable supply and consumption practices across a broad range of food systems.

26 The biggest challenge to achieve changes in meat consumption is on how to start a transition that has
 27 increasing diversity of food sources with lower land and water requirements and GHG emissions. This
 28 could be a gradual transition that recognises the need for just transitions for people whose livelihoods
 29 depend on (red) meat production. In this regard, all parts of the food system, including production,
 30 trade, and consumption, play important roles.

1

2 **Section SM5.7**

3 ***Governance***

4 Governance of climate change and governance of food systems have been developed independently of
5 each other. This section highlights the main characteristics of food and climate governance and
6 assesses what options may exist for establishing arrangements that link the two. See Chapter 7 for
7 important characteristics of governance and institutions; here we describe those relevant for
8 enhancing the interactions between climate change and food systems.

9 In the governance of climate change, Huitema et al. (2016) highlighted differences between mitigation
10 and adaptation. Mitigation often requires global agreements and national policies while adaptation
11 requires local and regional considerations. However, in the case of food systems this difference does
12 not apply, because mitigation measures also require local actions (e.g., at the farm level), while
13 adaptation actions may also require measures at global and national levels (such as emergency food
14 aid for climate disasters and food safety nets).

15 Governance of food systems holds particular challenges because it is only recently that a systems
16 approach has been embraced by policy-makers. (Rivera-Ferre et al. 2013) proposed principles for
17 food systems management considering them as complex socioecological systems (SES) including:
18 learning, flexibility, adaptation, participation, diversity enhancement, and precaution. These principles
19 are part of the framework of adaptive governance (see Chapter 7). Termeer et al. (2018) developed a
20 diagnostic framework with five principles to assess governance options appropriate to food systems:
21 1) system-based problem framing; 2) connectivity across boundaries to span siloed governance
22 structures and include non-state actors; 3) adaptability to flexibly respond to inherent uncertainties
23 and volatility; 4) inclusiveness to facilitate support and legitimacy; and 5) transformative capacity to
24 overcome path dependencies and create conditions to foster structural change.

25 Both the food and climate systems require integrated governance and institutions (*high confidence*).
26 These need to span government levels and actors across a wide range of sectors including agriculture,
27 environment, economic development, health, education, and welfare (Misselhorn et al. 2012). For
28 climate and food system management, the creation of government entities or ministerial units
29 responsible for coordinating among these ministries (horizontal coordination) and for cutting across
30 different administrative levels (vertical coordination) have been proposed (Orr et al. 2017).

31 However, integration is not easy. Termeer et al. (2018) analysed three South African governance
32 arrangements that explicitly aim for a holistic system-based approach. They found that they were not
33 delivering the expected outcomes due to reversion to technical one-dimensional problem framing.
34 Issues included dominance of single departments, limited attention to monitoring and flexible
35 responses, and exclusion of those most affected by food insecurity. Newell et al. (2018) analysed the
36 governance process of climate smart agriculture (CSA) from global to local scales for Kenya and
37 found a triple disconnect between global, national, and local scales. Different levels of authority and
38 actors imposed their own framing of CSA, and how to implement it.. As a result of the competition
39 among different actors, siloed policy practices were reproduced.

40 Food systems governance must also include governance of the resources needed to produce food,
41 which vary from land tenure (see chapter 7) and seed sovereignty (see Chapter 6), to other resources
42 such as soil fertility. Montanarella and Vargas (2012) proposed a supranational structure to guarantee
43 soil conservation on all continents, such as the Global Soil Partnership. This can also apply for the
44 governance of food and climate systems.

45 Polycentric and multiscale governance structures have been proposed for coping with climate change
46 to address both mitigation and adaptation (Ostrom 2010), and were suggested by Rivera-Ferre et al.

1 (2013) for food systems. A polycentric approach provides more opportunities for experimentation and
2 learning across levels (Cole 2015), entails many policy experiments from which policymakers at
3 various levels of governance can learn (Ostrom 2010), and contributes to building trust among
4 stakeholders (e.g., nation states, public and private sectors, civil society). Polycentric approaches
5 have been suggested for the Sustainable Development Goals (SDGs) (Monkelbaan 2019).

6 Another governance option suggested for the SDGs (Monkelbaan 2019) are already implemented in
7 global atmospheric and marine agreements (e.g., the Montreal protocol (De Búrca et al. 2014; Armeni
8 2015) is global experimentalist governance). Global experimentalist governance is an institutionalised
9 process of participatory and multilevel collective problem-solving, in which the problems (and the
10 means of addressing them) are framed in an open-ended way, and subjected to periodic revision by
11 peer review in the light of locally generated knowledge (De Búrca et al. 2014), This favours learning,
12 participation and cooperation (Armeni 2015). This form of governance can establish processes that
13 enable unimagined alternatives.

15 ***Institutions***

16 As Candel (2014) highlighted, based on a systematic review of food security governance focused on
17 hunger, global governance of food security is lacking because there is no institution with a mandate to
18 address concerns across sectors and levels. No international organisation deals with food security in a
19 holistic and inclusive manner. This results in overlapping (often conflicting) norms, rules and
20 negotiations that generate a “regime complex” (Margulis 2013), particularly in regard to agriculture
21 and food, international trade and human rights (e.g. UN Committee of World Food Security (CFS),
22 WTO, G8, G20). In climate change governance there are also multiple overlapping institutions with
23 often-conflicting rules and actors (Keohane and Victor 2011).

24 New multi-stakeholder governance arrangements are emerging, such as the Global Agenda for
25 Sustainable Livestock (Breeman et al. 2015) and the CFS (Duncan 2015). Also relevant in food
26 systems and climate change governance is that food security governance is spread across domains,
27 sectors and spatial scales (global, regional, national, local, community, household, or individual) with
28 a lack of coherency and coordination across multiple scales (*high confidence*). Thus, a major
29 challenge is to coordinate all these domains, sectors and scales.

30 It is important to consider the variety of actors involved in food security governance at all levels
31 (international bodies, civil society organisations (CSOs), nation states, public sector groups, and
32 private sector entities), with different agendas and values. But new in this regard is the participation of
33 CSOs that can provide the policy-making process with bottom-up knowledge to identify food
34 insecurity issues and locally relevant responses. CSOs can also contribute to multi-sector and multi-
35 scalar approaches by bridging government agencies and levels (Candel 2014). Thus, to facilitate
36 coordination and coherence, new adaptive governance enables interactions across multiple levels and
37 scales (Pereira and Ruysenaar 2012) and the use of “boundary organisations” (Candel 2014). To
38 address different narratives regarding food security (Rivera-Ferre 2012; Lang and Barling 2012), a
39 first step is to agree on basic principles and values (Margulis 2013).

40 In this regard, an opportunity to address food systems governance challenges arises within the UN
41 Committee on World Food Security (CFS), where diverse actors, voices and narratives are integrated
42 in the global food security governance. As a point of departure, the CFS could provide the platform to
43 develop global experimentalist governance in food systems (Duncan 2015; Duncan and Barling 2012)
44 providing a combination of bottom-up and top-down initiatives (Lambek 2019). However, the
45 existence of overlapping structures with different focuses on food security and power may hinder the
46 potential of this institution. (Margulis and Duncan 2016).

1 Mainstreaming of collaborative and more inclusive modes of governance, such as those displayed at
2 the CFS, are needed to effectively address the impacts of a changing planet on food systems
3 (Barling and Duncan 2015) and improve the balance of sustainable production and food consumption.
4 Despite improvements in global food security, food systems and climate governance, the main focus
5 is still on food security as undernutrition. New challenges will arise from the increasing evidence of
6 the burden of obesity, for which other institutions, focused on nutrition, will be needed. The new
7 Global Strategy Framework for Food Security and Nutrition (Committee on World Food Security
8 2017) of the CFS provides a new overarching framework for food security and nutrition strategies,
9 policies and actions that includes environmental concerns within a food system approach and a broad
10 vision of food and nutrition security. This framework fits within the “governance through goals”
11 provided by the SDGs (Biermann et al. 2017).

12 Both in climate change and food systems, the sub-national governance at the level of cities and
13 communities is also becoming relevant in terms of responses (*high evidence, high agreement*). From a
14 climate change perspective (see Chapter 7 for more examples) transnational municipal networks,
15 particularly transnational municipal climate networks, have played a key role in climate change
16 mitigation and have potential to facilitate adaptation (Fünfgeld 2015; Busch et al. 2018; Rosenzweig
17 et al. 2018). Efficient food systems require subnational governments to include food policy councils
18 (Feenstra 2002; Schiff 2008) and cities networks to address food systems challenges (e.g., Sustainable
19 Food Cities in the UK or Agroecological Cities in Spain). Transition Towns are engaged in common
20 principles towards sustainable development, including food systems transformation for food security
21 (Sage 2014), health and well-being (Richardson et al. 2012), and climate change (Taylor Aiken 2015).

22

23 ***Scope for expanded policies***

24 The interaction of production-based support through agricultural policy, coupled with agricultural
25 research investment and the development of frameworks to liberalise trade has led to a range of
26 consequences for global and local food systems. Together, these policies have shaped the food system
27 and incentivised global intensification of agriculture, and significant gains in global production.
28 However, jointly they have also incentivised a concentration on a small number of energy-dense
29 commodity crops grown at large scales (*high confidence*) (just eight crops supply 75% of the world’s
30 consumed calories (West et al. 2014)). The production of these commodity crops underpin global
31 dietary transitions, leading to dietary homogenisation (based primarily on starchy grains/tubers,
32 vegetable oil, sugar and livestock produce) (Khoury et al. 2014).

33 Global intensification of agriculture, as well as increasing the supply of affordable calories, has
34 impacted soil, water, air quality and biodiversity in major and negative ways (Dalin et al. 2017;
35 Tamea et al. 2016; Newbold et al. 2015; García-Ruiz et al. 2015; Amundson et al. 2015; Paulot and
36 Jacob 2014). Importantly in the context of this report, a narrow focus on productivity has led to a food
37 system that emits a large proportion of GHGs (Section 5.4), is fragile in the face of climate shocks
38 (Section 5.3) and from which food is used inefficiently (through waste and over-consumption, Section
39 5.5.2.5). Mitigation of climate change, as well as adaptation, can then arise from a transformation of
40 the food system to one that provides nutrition and health (Willett et al. 2019; Springmann et al.
41 2018b,a; Godfray et al. 2018; Ramankutty et al. 2018; Chaudhary et al. 2018). There is therefore
42 *medium confidence*, that continued focus on the past drivers of the food system will be detrimental for
43 climate change and food security.

44 Addressing this challenge requires action across the food system to enhance synergies and co-benefits
45 and minimise trade-offs among multiple objectives of food security, adaptation and mitigation
46 (Sapkota et al. 2017; Palm et al. 2010; Jat et al. 2016; Sapkota et al. 2015) (Section 5.6), as well as
47 broader environmental goods exemplified by the SDG framework such as water, air-quality, soil
48 health and biodiversity (Obersteiner et al. 2016; Pradhan et al. 2017). In short, this requires greater

1 policy alignment and coherence between traditionally separate policy domains to recognise the
2 systemic nature of the problem. For example, aligning the policy goals of sustainable land
3 management for the purposes of managing both food security and biodiversity (Meyfroidt 2017;
4 Wittman et al. 2017), or public health and agricultural policies (Thow et al. 2018) that can drive
5 mitigation, as well as the enabling conditions of land rights, tenure and ownership. Significant co-
6 benefits can arise from integrated food systems policies, as well as integrated approaches to
7 generating evidence to underpin coherent policy, exemplified, for example, by the EU’s integrated
8 research and innovation strategy “Food2030” that aligns agriculture, environment, nutrition and
9 research policy (European Commission 2018).

5 **Executive summary**

6 **The land challenges, in the context of this report, are climate change mitigation, adaptation,**
7 **desertification, land degradation, and food security.** The chapter also discusses implications for
8 Nature’s Contributions to People (NCP), including biodiversity and water, and sustainable
9 development, by assessing intersections with the Sustainable Development Goals (SDGs). The
10 chapter assesses response options that could be used to address these challenges. These response
11 options were derived from the previous chapters and fall into three broad categories (land
12 management, value chain, and risk management).

13 **The land challenges faced today vary across regions; climate change will increase challenges in**
14 **the future, while socioeconomic development could either increase or decrease challenges (*high***
15 ***confidence*).** Increases in biophysical impacts from climate change can worsen desertification, land
16 degradation, and food insecurity (*high confidence*). Additional pressures from socioeconomic
17 development could further exacerbate these challenges; however, the effects are scenario dependent.
18 Scenarios with increases in income and reduced pressures on land can lead to reductions in food
19 insecurity; however, all assessed scenarios result in increases in water demand and water scarcity
20 (*medium confidence*). {6.1}

21 **The applicability and efficacy of response options are region and context specific; while many**
22 **value chain and risk management options are potentially broadly applicable, many land**
23 **management options are applicable on less than 50% of the ice-free land surface (*high***
24 ***confidence*).** Response options are limited by land type, bioclimatic region, or local food system
25 context (*high confidence*). Some response options produce adverse side-effects only in certain regions
26 or contexts; for example, response options that use freshwater may have no adverse side effects in
27 regions where water is plentiful, but large adverse side effects in regions where water is scarce (*high*
28 *confidence*). Response options with biophysical climate effects (e.g., afforestation, reforestation) may
29 have different effects on local climate depending on where they are implemented (*medium*
30 *confidence*). Regions with more challenges have fewer response options available for implementation
31 (*medium confidence*). {6.1, 6.2, 6.3, 6.4}

32 **Nine options deliver medium to large benefits for all five land challenges (*high confidence*).** The
33 options with medium to large benefits for all challenges are increased food productivity, improved
34 cropland management, improved grazing land management, improved livestock management,
35 agroforestry, improved forest management, increased soil organic carbon content, fire management
36 and reduced post-harvest losses. A further two options, dietary change and reduced food waste, have
37 no global estimates for adaptation but have medium to large benefits for all other challenges (*high*
38 *confidence*). {6.3, 6.4}

39 **Five options have large mitigation potential (> 3 GtCO₂e yr⁻¹) without adverse impacts on the**
40 **other challenges (*high confidence*).** These are increased food productivity, reduced deforestation and
41 degradation, increased soil organic carbon content, fire management and reduced post-harvest losses.
42 Two further options with large mitigation potential, dietary change and reduced food waste, have no
43 global estimates for adaptation but show no negative impacts across the other challenges. Five
44 options: improved cropland management, improved grazing land managements, agroforestry,

1 integrated water management and forest management, have moderate mitigation potential, with no
2 adverse impacts on the other challenges (*high confidence*). {6.3.6}

3 **Sixteen response options have large adaptation potential (>25 million people benefit), without
4 adverse side-effects on other land challenges (*high confidence*).** These are increased food
5 productivity, improved cropland management, agroforestry, agricultural diversification, improved
6 forest management, increased soil organic carbon content, reduced landslides and natural hazards,
7 restoration and reduced conversion of coastal wetlands, reduced post-harvest losses, sustainable
8 sourcing, management of supply chains, improved food processing and retailing, improved energy use
9 in food systems, livelihood diversification, use of local seeds, and disaster risk management (*high*
10 *confidence*). Some options (such as enhanced urban food systems or management of urban sprawl)
11 may not provide large global benefits but may have significant positive local effects without adverse
12 effects (*high confidence*). {6.3, 6.4}

13 **Seventeen of 40 options deliver co-benefits or no adverse side-effects for the full range of NCPs
14 and SDGs; only three options (afforestation, bioenergy and BECCS and some types of risk
15 sharing instruments, such as insurance) have potentially adverse side-effects for five or more
16 NCPs or SDGs (*medium confidence*).** The 17 options with co-benefits and no adverse side-effects
17 include most agriculture- and soil-based land management options, many ecosystem-based land
18 management options, improved forest management, reduced post-harvest losses, sustainable sourcing,
19 improved energy use in food systems, and livelihood diversification (*medium confidence*). Some of
20 the synergies between response options and SDGs include positive poverty reduction impacts from
21 activities like improved water management or improved management of supply chains. Examples of
22 synergies between response options and NCPs include positive impacts on habitat maintenance from
23 activities like invasive species management and agricultural diversification. However, many of these
24 synergies are not automatic, and are dependent on well-implemented activities requiring institutional
25 and enabling conditions for success. {6.4}

26 **Most response options can be applied without competing for available land; however, seven
27 options result in competition for land (*medium confidence*).** A large number of response options do
28 not require dedicated land, including several land management options, all value chain options, and all
29 risk management options. Four options could greatly increase competition for land if applied at scale:
30 afforestation, reforestation, and land used to provide feedstock for BECCS and biochar, with three
31 further options: reduced grassland conversion to croplands, restoration and reduced conversion of
32 peatlands and restoration and reduced conversion of coastal wetlands having smaller or variable
33 impacts on competition for land. Other options such as reduced deforestation and degradation, restrict
34 land conversion for other options and uses. Expansion of the current area of managed land into natural
35 ecosystems could have negative consequences for other land challenges, lead to the loss of
36 biodiversity, and adversely affect a range of NCPs (*high confidence*). {6.3.6, 6.4}

37 **Some options, such as bioenergy and BECCS, are scale dependent. The climate change
38 mitigation potential for bioenergy and BECCS is large (up to 11 GtCO₂ yr⁻¹); however, the
39 effects of bioenergy production on land degradation, food insecurity, water scarcity, GHG
40 emissions, and other environmental goals are scale and context specific (*high confidence*).** These
41 effects depend on the scale of deployment, initial land use, land type, bioenergy feedstock, initial
42 carbon stocks, climatic region and management regime (*high confidence*). Large areas of monoculture
43 bioenergy crops that displace other land uses can result in land competition, with adverse effects for
44 food production, food consumption, and thus food security, as well as adverse effects for land
45 degradation, biodiversity, and water scarcity (*medium confidence*). However, integration of bioenergy
46 into sustainably managed agricultural landscapes can ameliorate these challenges (*medium*
47 *confidence*). {6.2, 6.3, 6.4, Cross-Chapter Box 7 in this Chapter}

1 **Response options are interlinked; some options (e.g., land sparing and sustainable land**
2 **management options) can enhance the co-benefits or increase the potential for other options**
3 **(medium confidence).** Some response options can be more effective when applied together (*medium*
4 *confidence*); for example, dietary change and waste reduction expand the potential to apply other
5 options by freeing as much as 5.8 Mkm² (0.8-2.4 Mkm² for dietary change; ~2 Mkm² for reduced
6 post-harvest losses, and 1.4 Mkm² for reduced food waste) of land (*low confidence*). Integrated water
7 management and increased soil organic carbon can increase food productivity in some circumstances.
8 {6.4}

9 **Other response options (e.g., options that require land) may conflict; as a result, the potentials**
10 **for response options are not all additive, and a total potential from the land is currently**
11 **unknown (high confidence).** Combining some sets of options (e.g., those that compete for land) may
12 mean that maximum potentials cannot be realised, for example reforestation, afforestation, and
13 bioenergy and BECCS all compete for the same finite land resource so the combined potential is
14 much lower than the sum of potentials of each individual option calculated in the absence of
15 alternative uses of the land (*high confidence*). Given the interlinkages among response options and
16 that mitigation potentials for individual options assume that they are applied to all suitable land, the
17 total mitigation potential is much lower than the sum of the mitigation potential of the individual
18 response options (*high confidence*). {6.4}

19 **The feasibility of response options, including those with multiple co-benefits, is limited due to**
20 **economic, technological, institutional, socio-cultural, environmental and geophysical barriers**
21 **(high confidence).** A number of response options (e.g., most agriculture-based land management
22 options, forest management, reforestation and restoration) have already been implemented widely to
23 date (*high confidence*). There is robust evidence that many other response options can deliver co-
24 benefits across the range of land challenges, yet these are not being implemented. This limited
25 application is evidence that multiple barriers to implementation of response options exist (*high*
26 *confidence*). {6.3, 6.4}

27 **Coordinated action is required across a range of actors, including business, consumers, land**
28 **managers, indigenous and local communities and policymakers to create enabling conditions for**
29 **adoption of response options (high confidence).** The response options assessed face a variety of
30 barriers to implementation (economic, technological, institutional, socio-cultural, environmental and
31 geophysical) that require action across multiple actors to overcome (*high confidence*). There are a
32 variety of response options available at different scales that could form portfolios of measures applied
33 by different stakeholders from farm to international scales. For example, agricultural diversification
34 and use of local seeds by smallholders can be particularly useful poverty reduction and biodiversity
35 conservation measures, but are only successful when higher scales, such as national and international
36 markets and supply-chains, also value these goods in trade regimes, and consumers see the benefits of
37 purchasing these goods. However, the land and food sectors face particular challenges of institutional
38 fragmentation, and often suffer from a lack of engagement between stakeholders at different scales
39 (*medium confidence*). {6.3, 6.4}

40 **Delayed action will result in an increased need for response to land challenges and a decreased**
41 **potential for land-based response options due to climate change and other pressures (high**
42 **confidence).** For example, failure to mitigate climate change will increase requirements for adaptation
43 and may reduce the efficacy of future land-based mitigation options (*high confidence*). The potential
44 for some land management options decreases as climate change increases; for example, climate alters
45 the sink capacity for soil and vegetation carbon sequestration, reducing the potential for increased soil
46 organic carbon (*high confidence*). Other options (e.g., reduced deforestation and degradation) prevent
47 further detrimental effects to the land surface; delaying these options could lead to increased
48 deforestation, conversion, or degradation, serving as increased sources of GHGs and having

1 concomitant negative impacts on NCPs (*medium confidence*). Carbon dioxide removal (CDR)
2 options, like reforestation, afforestation, bioenergy and BECCS, are used to compensate for
3 unavoidable emissions in other sectors; delayed action will result in larger and more rapid deployment
4 later (*high confidence*). Some response options will not be possible if action is delayed too long; for
5 example, peatland restoration might not be possible after certain thresholds of degradation have been
6 exceeded, meaning that peatlands could not be restored in certain locations (*medium confidence*) {6.2,
7 6.3, 6.4}.

8 **Early action, however, has challenges including technological readiness, upscaling, and**
9 **institutional barriers (*high confidence*).** Some of the response options have technological barriers
10 that may limit their wide-scale application in the near-term (*high confidence*). Some response options,
11 e.g., BECCS, have only been implemented at small-scale demonstration facilities; challenges exist
12 with upscaling these options to the levels discussed in this Chapter (*medium confidence*). Economic
13 and institutional barriers, including governance, financial incentives and financial resources, limit the
14 near-term adoption of many response options, and ‘policy lags’, by which implementation is delayed
15 by the slowness of the policy implementation cycle, are significant across many options (*medium*
16 *confidence*). Even some actions that initially seemed like ‘easy wins’ have been challenging to
17 implement, with stalled policies for REDD+ providing clear examples of how response options need
18 sufficient funding, institutional support, local buy-in, and clear metrics for success, among other
19 necessary enabling conditions. {6.2, 6.4}

20 **Some response options reduce the consequences of land challenges, but do not address**
21 **underlying drivers (*high confidence*).** For example, management of urban sprawl can help reduce
22 the environmental impact of urban systems; however, such management does not address the
23 socioeconomic and demographic changes driving the expansion of urban areas. By failing to address
24 the underlying drivers, there is a potential for the challenge to re-emerge in the future (*high*
25 *confidence*). {6.4}

26 **Many response options have been practiced in many regions for many years; however, there is**
27 **limited knowledge of the efficacy and broader implications of other response options (*high***
28 ***confidence*).** For the response options with a large evidence base and ample experience, further
29 implementation and upscaling would carry little risk of adverse side-effects (*high confidence*).
30 However, for other options, the risks are larger as the knowledge gaps are greater; for example,
31 uncertainty in the economic and social aspects of many land response options hampers the ability to
32 predict their effects (*medium confidence*). Furthermore, Integrated Assessment Models, like those
33 used to develop the pathways in the IPCC Special Report on Global Warming of 1.5°C (SR15), omit
34 many of these response options and do not assess implications for all land challenges (*high*
35 *confidence*). {6.4}

36

37

1 **6.1 Introduction**

2 **6.1.1 Context of this chapter**

3 This chapter focuses on the interlinkages between response options¹ to deliver climate mitigation and
4 adaptation, to address desertification and land degradation, and to enhance food security, and also
5 assesses reported impacts on Nature's Contributions to People (NCP) and contributions to the UN
6 Sustainable Development Goals (SDG). By identifying which options provide the most co-benefits
7 with the fewest adverse side-effects, this chapter aims to provide *integrated response options* that
8 could co-deliver across the range of challenges. This chapter *does not consider*, in isolation, response
9 options that affect only one of climate mitigation, adaptation, desertification, land degradation, or
10 food security, since these are the subjects of Chapters 2–5; this chapter *considers only* interlinkages
11 between response options and two or more of these challenges in the land sector.

12 Since the aim is to assess and provide guidance on integrated response options, each response option
13 is first described and categorised drawing on previous chapters 2-5 (Section 6.2), and their impact on
14 climate mitigation / adaptation, desertification, land degradation, and food security are quantified
15 (Section 6.3). The feasibility of each response option, respect to costs, barriers, saturation and
16 reversibility is then assessed (Section 6.4.1), before considering their sensitivity to future climate
17 change (Section 6.4.2).

18 The *co-benefits* and *adverse side-effects*² of each integrated response option across the five land
19 challenges, and their impacts on the NCP and the SDG, are then assessed in Section 6.4.3. In section
20 6.4.4, the spatial applicability of these integrated response options is assessed in relation to the
21 location of the challenges with the aim of identifying which options have the greatest potential to co-
22 deliver across the challenges, and the contexts and circumstances in which they do so. Interlinkages
23 among response options and challenges in future scenarios are also assessed in 6.4.4. Finally, section
24 6.4.5 discusses the potential consequences of delayed action.

25 In providing this evidence-based assessment, drawing on the relevant literature, this chapter does not
26 assess the merits of policies to deliver these integrated response options - Chapter 7 assesses the
27 various policy options currently available to deliver these interventions - rather this chapter provides
28 an assessment of the integrated response options and their ability to co-deliver across the multiple
29 challenges addressed in this Special Report.

30 **6.1.2 Framing social challenges and acknowledging enabling factors**

31 In this section we outline the approach used in assessing the evidence for interactions between
32 response options to deliver climate mitigation and adaptation, to prevent desertification and land
33 degradation, and to enhance food security. Overall, while defining and presenting the response
34 options to meet these goals is the primary goal of this chapter, we note that these options must not be
35 considered only as technological interventions, or one-off actions. Rather, they need to be understood
36 as responses to socio-ecological challenges whose success will largely depend on external enabling
37 factors. There have been many previous efforts at compiling positive response options that meet
38 numerous Sustainable Development Goals, but which have not resulted in major shifts in

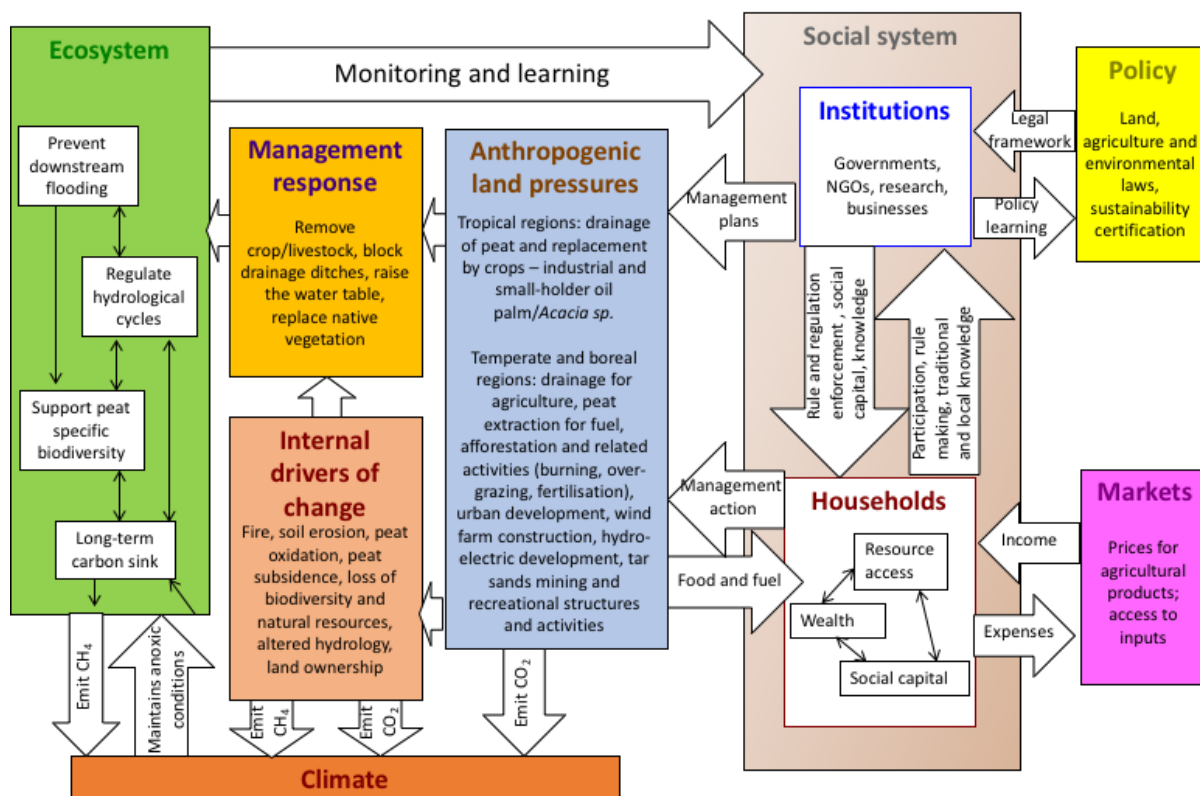

¹ FOOTNOTE: Many of the response options considered are *sustainable land management* options, but several response options are not based on land management, for example those based on value chain management and governance and risk management options

² FOOTNOTE: We use the IPCC AR5 WGIII definitions of co-benefits and adverse side-effect – see glossary. Co-benefits and adverse side-effects can be biophysical and/or socio-economic in nature, and all are assessed as far as the literature allows.

1 implementation; for example, online databases of multiple response options for sustainable land
2 management (SLM), adaptation, and other objectives have been compiled by many donor agencies,
3 including World Overview of Conservation Approaches and Technologies (WOCAT), Climate Adapt,
4 and the Adaptation Knowledge Portal, (Schwilch et al.,2012)³. Yet clearly barriers to adoption
5 remain, or these actions would have been more widely used by now. Much of the scientific literature
6 on barriers to implementing response options focuses on the individual and household level, and
7 discusses limits to adoption, often primarily identified as economic factors (Nigussie et al. 2017;
8 Dallimer et al. 2018). While a useful approach, such studies often are unable to account for the larger
9 enabling factors that might assist in more wide scale implementation (chapter 7 discusses these
10 governance factors and barriers to be overcome in more detail).

11 Instead, this chapter proposes that each response option identified and assessed needs to be
12 understood as an intervention within complex socio-ecological systems (SES) (introduced in Chapter
13 1). In this understanding, physical changes affect human decision-making over land and risk
14 management options, as do economics, policies, and cultural factors, which in turn may drive
15 additional ecological change (Rawlins et al.,2010). This co-evolution of responses within an SES
16 provides a more nuanced understanding of the dynamics between drivers of change and impacts of
17 interventions. Thus, in discussions of the 40 specific response options in this chapter, it must be kept
18 in mind that all need to be contextualised within the specific SES in which they are deployed (see
19 Figure 6.1). Framing response options within SESs also recognises the interactions *between* different
20 response options. However, a major problem within SESs is that the choice and use of different
21 response options requires knowledge of the problems they are aimed at solving, which may be
22 unclear, contested, or not shared equally among stakeholders (Carmenta et al., 2017). Drivers of
23 environmental change often have primarily social or economic rather than technological roots, which
24 requires acknowledgement that response options that do not aim at reducing the drivers of change
25 may thus be less successful (Schwilch et al., 2014).

2 **Figure 6.1 Model to represent a social-ecological system of one of the integrated response options in this**
3 **chapter, using restoration and reduced impact of peatlands as an example. The boxes show systems**
4 **(ecosystem, social system), external and internal drivers of change and the management response – here**
5 **enacting the response option. Unless included in the internal drivers of change box, all other drivers of**
6 **change are external (e.g. climate, policy, markets, anthropogenic land pressures). The arrows represent**
7 **how the systems can influence each other, with key drivers of impact written in the arrow in the direction**
8 **of effect.**

9 Response options must also account for the uneven distribution of impacts among populations of
10 both environmental change and intervention responses to this change. Understanding the integrated
11 response options available in a given context requires an understanding of the specificities of social
12 vulnerability, adaptive capacity, and institutional support to assist communities, households and
13 regions to reach their capabilities and achievement of the SDG and other social and land
14 management goals. Vulnerability reflects how assets are distributed within and among communities,
15 shaped by factors that are not easily overcome with technical solutions, including inequality and
16 marginalisation, poverty, and access to resources (Adger et al. 2004; Hallegate et al 2016).
17 Understanding why some people are vulnerable and what structural factors perpetuate this
18 vulnerability requires attention to both micro and meso scales (Tschakert et al. 2013). These
19 vulnerabilities create barriers to adoption of even low-cost high-return response options, such as soil
20 carbon management, that may seem obviously beneficial to implement (Mutoko et al. 2014;
21 Cavanagh et al. 2017). Thus, assessment of the differentiated vulnerabilities that may prevent
22 response option adoption needs to be considered as part of any package of interventions.

23 Adaptive capacity relates to the ability of institutions or people to modify or change characteristics or
24 behaviour so as to cope better with existing or anticipated external stresses (Moss et al. 2001;
25 Brenkert and Malone 2005; Brooks et al. 2005). Adaptive capacity reflects institutional and policy
26 support networks, and has often been associated at the national level with strong developments in the
27 fields of economics, education, health, and governance and political rights (Smit et al. 2001). Areas

1 with low adaptive capacity, as reflected in low Human Development Index scores, might constrain
2 the ability of communities to implement response options (section 6.4.4.1 and Figure 6.7).

3 Further, while environmental changes like land degradation have obvious social and cultural impacts,
4 as discussed in the preceding chapters, so do response options, and thus careful thought is needed
5 about what impacts are expected and what trade-offs are acceptable. One potential way to assess the
6 impact of response interventions relates to the idea of capabilities, a concept first proposed by
7 economist Amartya Sen (Sen 1992). Understanding capability as the “freedom to achieve well-being”
8 frames a problem as being a matter of facilitating what people aspire to do and be, rather than telling
9 them to achieve a standardised or predetermined outcome (Nussbaum and Sen 1993). Thus a
10 capability approach is generally a more flexible and multi-purpose framework, appropriate to an SES
11 understanding because of its open-ended approach (Bockstael and Berkes 2017). Thus, one question
12 for any decision-maker approaching schematics of response options is to determine which response
13 options lead to increased or decreased capabilities for the stakeholders who are the objects of the
14 interventions, given the context of the SES in which the response option will be implemented.

15 Section 6.4.3 examines some of the capabilities that are reflected in the UN Sustainable Development
16 Goals (SDG), such as gender equity and education, and assesses how each of the 40 response options
17 may affect those goals, either positively or negatively, through a review of the available literature.

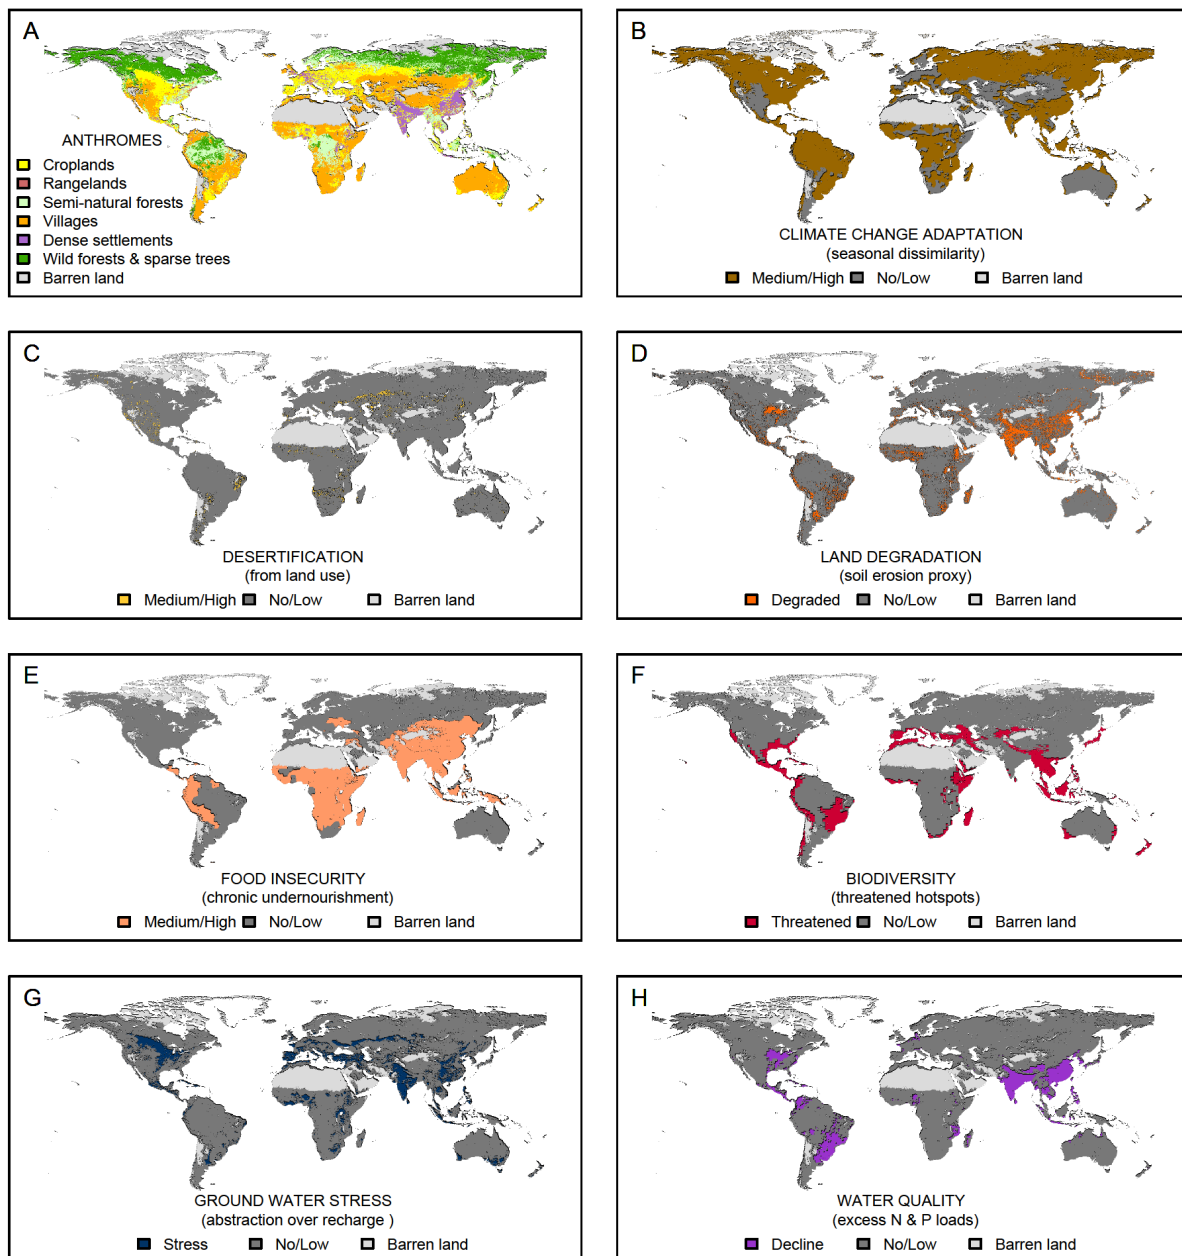

18 **6.1.2.1 Enabling conditions**

19 Response options are not implemented in a vacuum and rely on knowledge production and socio-
20 economic and cultural strategies and approaches embedded within them to be successful. For
21 example, it is well known that “Weak grassroots institutions characterised by low capacity, failure to
22 exploit collective capital and poor knowledge sharing and access to information, are common barriers
23 to sustainable land management and improved food security” (Oloo and Omondi 2017). Achieving
24 broad goals such as reduced poverty or sustainable land management requires conducive enabling
25 conditions, such as attention to gender issues and the involvement of stakeholders, like indigenous
26 peoples, as well as attention to governance, including adaptive governance, stakeholder engagement,
27 and institutional facilitation (see section 6.4.4.3). These enabling conditions – such as gender-
28 sensitive programming or community-based solutions - are not categorised as individual response
29 options in subsequent sections of this chapter because they are conditions that can potentially help
30 improve *all* response options when used in tandem to produce more sustainable outcomes. Chapter 7
31 picks up on these themes and discusses the ways various policies to implement response options have
32 tried to minimise unwanted social and economic impacts on participants in more depth, through
33 deeper analysis of concepts such as citizen science and adaptive governance. Here we simply note the
34 importance of assessing the contexts within which response options will be delivered, as no two
35 situations are the same, and no single response option is likely to be a ‘silver bullet’ to solve all land-
36 climate problems, as each option comes with potential challenges and trade-offs (section 6.2), barriers
37 to implementation (section 6.4.1), interactions with other sectors of society (section 6.4.3), and
38 potential environmental limitations (section 6.4.4).

39 **6.1.3 Challenges and response options in current and historical interventions**

40 Land-based systems are exposed to multiple overlapping challenges including climate change
41 (adaptation and mitigation), desertification (Chapter 3), land degradation (Chapter 4) and food
42 insecurity (Chapter 5), as well as loss of biodiversity, ground water stress (from over-abstraction) and
43 water quality. The spatial distribution of these individual land-based challenges is shown in Figure
44 6.2, based on recent studies and using the following indicators:

- 1 • Desertification attributed to land use is estimated from vegetation remote sensing (Figure
2 3.7c), mean annual change in NDVImax < -0.001 (between 1982-2015) in dryland areas
3 (Aridity Index > 0.65), noting however that desertification has multiple causes (Chapter 3);
4 • Land degradation (see Chapter 4) is based on a soil erosion (Borrelli et al. 2017) proxy
5 (annual erosion rate of 3 t ha⁻¹ or above);
6 • The climate change challenge for adaptation is based on a dissimilarity index of monthly
7 means of temperature and precipitation between current and end of century scenarios
8 (dissimilarity index equal to 0.7 or above, Netzel and Stepinski 2018), noting however that
9 rapid warming could occur in all land regions (Chapter 2);
10 • The food security challenge is estimated as the prevalence of chronic undernourishment
11 (higher or equal to 5%) by country in 2015 (FAO 2017a), noting however that food security
12 has several dimensions (see Chapter 5);
13 • The biodiversity challenge uses threatened terrestrial biodiversity hotspots (areas where
14 exceptional concentrations of endemic species are undergoing exceptional loss of habitat,
15 (Mittermeier et al. 2011), noting however that biodiversity concerns more than just
16 threatened endemic species;
17 • The groundwater stress challenge is estimated as groundwater abstraction over recharge
18 ratios above one (Gassert et al. 2014) in agricultural areas (croplands and villages);
19 • The water quality challenge is estimated as critical loads (higher or equal to 1000 kg N km⁻²
20 or 50 kg P km⁻²) of nitrogen (N) and phosphorus (P) (Xie and Ringler 2017)
- 21 Overlapping land-based challenges affect all land use categories: croplands, rangelands, semi-natural
22 forests, villages, dense settlements, wild forests and sparse trees and barren lands. These land use
23 categories can be defined as anthropogenic biomes, or anthromes, and their global distribution was
24 mapped by Ellis and Ramankutty (2008) (Figure 6.2).

7
 8 The majority of the global population is concentrated in dense settlements and villages accounting for
 9 less than 7% of the global ice-free land area, while croplands and rangelands use 39% of land. The
 10 remainder of the ice-free land area (more than half) is used by semi-natural forests, by wild forests
 11 and sparse trees and by barren lands (Table 6.1).

12 Land use types (or anthromes) are exposed to multiple overlapping challenges. Climate change could
 13 induce rapid warming in all land areas (see Chapter 2). In close to 70% of the ice-free land area, the
 14 climate change adaptation challenge could be reinforced by a strong dissimilarity between end of
 15 century and current temperature and precipitation seasonal cycles (Netzel and Stepinski 2018).
 16 Chronic undernourishment (a component of food insecurity) is concentrated in 20% of global ice-free
 17 land area. Severe soil erosion (a proxy of land degradation) and desertification from land use affect 13
 18 and 3% of ice-free land area, respectively. Both groundwater stress and severe water quality decline
 19 (12 and 10% of ice-free land area, respectively) contribute to the water challenge. Threatened
 20 biodiversity hot-spots (15% of ice-free land area) are significant for the biodiversity challenge (Table
 21 6.1).

22 Since land-based challenges overlap, part of the ice-free land area is exposed to combinations of two
 23 or more challenges. For instance, land degradation (severe soil erosion) or desertification from land
 24 use and food insecurity (chronic undernourishment) are combined with a strong climate change
 25 adaptation challenge (dissimilarity in seasonal cycles) in 4.5% of the ice-free land area (Figure 6.3).

1
2 **Figure 6.3 Example of overlap between land challenges. A. Overlap between the desertification (from**
3 **land use) challenge and the climate change adaptation (strong dissimilarity in seasonal cycles) challenge.**
4 **B. Overlap between the land degradation (soil erosion proxy) challenge and the climate change**
5 **adaptation challenge. C. Overlap between the desertification or land degradation challenges and the food**
6 **insecurity (chronic undernourishment) challenge. D. Overlap between challenges shown in C and the**
7 **climate change adaptation challenge. For challenges definitions, see text; references as in Figure 6.2.**

8 The global distribution of land area by the number of overlapping land challenges (Figure 6.4) shows:
9 the least exposure to land challenges in barren lands; less frequent exposure to two or more challenges
10 in wild forests than in semi-natural forests; more frequent exposure to two or more challenges in
11 agricultural anthromes (croplands and rangelands) and dense settlements than in forests; most
12 frequent exposure to 3 or more challenges in villages compared to other land use types. Therefore,
13 land use types intensively used by humans are, on average, exposed to a larger number of challenges
14 than land use types (or anthromes) least exposed to human use.

Figure 6.4 Percentage distribution of land use type (or anthrome) area by number of overlapping land challenges for the villages, dense settlements, croplands, rangelands, semi-natural forests, wild forests & sparse trees and barren land use types. Values in brackets show the mean number of land challenges per land use type. Land challenges include desertification (from land use), land degradation (soil erosion proxy), climate change adaptation (seasonal dissimilarity proxy), food security (chronic undernourishment), biodiversity (threatened hot spots), groundwater stress (over abstraction) and water quality (critical N and P loads).

Case studies located in different world regions are presented for each anthrome, in order to provide historical context on the interlinkages between multiple challenges and responses (Box 6.1: A to E). Taken together, these case studies illustrate the large contrast across anthromes in land-based interventions and the way these interventions respond to combinations of challenges.

Box 6.1 Case studies by anthrome type showing historical interlinkages between land-based challenges and the development of local responses

A. Croplands. Land degradation, groundwater stress and food insecurity: soil and water conservation measures in the Tigray region of Ethiopia

In northern Ethiopia, the Tigray region is a drought-prone area that has been subjected to severe land degradation (Frankl et al. 2013) and to recurrent drought and famine during 1888–1892, 1973–1974 and 1984–1985 (Gebremeskel et al. 2018). The prevalence of stunting and being underweight among children under five years is high (Busse et al. 2017) and the region was again exposed to a severe drought during the strong El Niño event of 2015–2016. Croplands are the dominant land-use type, with approximately 90% of the households relying on small-scale plough-based cultivation. Gullies affect nearly all slopes and frequently exceed 2 m in depth and 5 m in top width. Landsat imagery shows that cropland area peaked in 1984–1986 and increased erosion rates in the 1980s and 1990s caused the drainage density and volume to peak in 1994 (Frankl et al. 2013). Since ca. 2000, the large-scale implementation of Soil and Water Conservation (SWC) measures, integrated catchment management, conservation agriculture and indigenous tree regeneration has started to yield positive effects on the vegetation cover and led to the stabilisation of about 25% of the gullies by 2010 (Frankl

1 et al. 2013). Since 1991, farmers have provided labour for SWC in January as a free service for 20
2 consecutive working days, followed by food for work for the remaining days of the dry season. Most
3 of the degraded landscapes have been restored, with positive impacts over the last two decades on soil
4 fertility, water availability and crop productivity. However, misuse of fertilisers, low survival of tree
5 seedlings and lack of income from exclosures may affect the sustainability of these land restoration
6 measures (Gebremeskel et al. 2018).

7 **B. Rangelands. Biodiversity hotspot, land degradation and climate change: pasture** 8 **intensification in the Cerrados of Brazil**

10 Cerrados are a tropical savannah ecoregion in Brazil corresponding to a biodiversity hot spot with less
11 than 2% of its region protected in national parks and conservation areas (Cava et al. 2018). Extensive
12 cattle ranching (limited mechanisation, low use of fertiliser and seed inputs) has led to pasture
13 expansion, including clearing forests to secure properties rights, occurring mainly over 1950–1975
14 (Martha et al. 2012). Despite observed productivity gains made over the last three decades (Martha et
15 al. 2012), more than half of the pasture area is degraded to some extent and challenges remain to
16 reverse grassland degradation while accommodating growing demand and simultaneously avoiding
17 the conversion of natural habitats (de Oliveira Silva et al. 2018). The largest share of production is on
18 unfertilised pastures, often sown with perennial forage grasses of African origin, mainly *Brachiaria*
19 spp. (Cardoso et al. 2016). This initial intensification era was partly at the expense of significant
20 uncontrolled deforestation and average animal stocking rates remained well below the potential
21 carrying capacity (Strassburg et al. 2014). Changes in land use are difficult to reverse since pasture
22 abandonment does not lead to the spontaneous restoration of old-growth savannah (Cava et al. 2018);
23 moreover pasture to crop conversion is frequent, supporting close to half of cropland expansion in
24 Mato Grosso state over 2000–2013 (Cohn et al. 2016). Pasture intensification through liming,
25 fertilisation and controlled grazing could increase soil organic carbon and reduce net GHG emission
26 intensity per unit meat product, but only at increased investment cost per unit of area (de Oliveira
27 Silva et al. 2017). Scenarios projecting a decoupling between deforestation and increased pasture
28 intensification, provide the basis for a Nationally Determined Contribution (NDC) of Brazil that is
29 potentially consistent with accommodating an upward trend in livestock production to meet increasing
30 demand (de Oliveira Silva et al. 2018). Deforestation in Brazil has declined significantly between
31 2004 and 2014 in the national inventory but recent data and analyses suggest that the decrease in
32 deforestation and the resulting GHG emissions reductions have slowed down or even stopped (UNEP
33 2017).

35 **C. Semi-natural forests. Biodiversity hotspot, land degradation, climate change and food** 36 **insecurity: restoration and resilience of tropical forests in Indonesia**

37 During the last two decades, forest cover in Indonesia declined by 150,000 km² in the period 1990-
38 2000 (Stibig et al. 2014) and approximately 158,000 km² in the period 2000–2012 (Hansen et al.
39 2013a), most of which was converted to agricultural lands (e.g., oil palm, pulpwood plantations).
40 According to recent estimates, deforestation in Indonesia mainly concerns primary forests, including
41 intact and degraded forests, thus leading to biodiversity loss and reduced carbon sequestration
42 potentials (e.g., Margono et al. 2014). For example, Graham et al. (2017) estimated that the following
43 strategies to reduce deforestation and degradation may cost-effectively increase carbon sequestration
44 and reduce carbon emissions in 30 years: reforestation (3.54 Gt CO₂), limiting the expansion of oil
45 palm and timber plantations into forest (3.07 Gt CO₂ and 3.05 Gt CO₂, respectively), reducing illegal
46 logging (2.34 Gt CO₂), and halting illegal forest loss in Protected Areas (1.52 Gt CO₂) at a total cost
47 of 15.7 USD tC⁻¹. The importance of forest mitigation in Indonesia is indicated by the NDC, where
48 between half and two-thirds of the 2030 emission target relative to business-as-usual scenario is from
49 reducing deforestation, forest degradation, peatland drainage and fires (Grassi et al. 2017). Avoiding
50 deforestation and reforestation could have multiple co-benefits by improving biodiversity
51 conservation and employment opportunities, while reducing illegal logging in protected areas.
52 However, these options could also have adverse side-effects if they deprive local communities of
53 access to natural resources (Graham et al. 2017). The adoption of the Roundtable on Sustainable Palm
54 Oil certification in oil palm plantations reduced deforestation rates by approximately 33% in the

1 period 2001–2015 (co-benefits with mitigation), and fire rates much more than for non-certified
2 plantations (Carlson et al. 2018). However, given that large-scale oil palm plantations are one of
3 largest drivers of deforestation in Indonesia, objective information on the baseline trajectory for land
4 clearance for oil palm is needed to further assess commitments, regulations and transparency in
5 plantation development (Gaveau et al. 2016). For adaptation options, the community forestry scheme
6 “Hutan Desa” (Village Forest) in Sumatra and Kalimantan helped to avoid deforestation (co-benefits
7 with mitigation) by between 0.6 and 0.9 ha km⁻² in Sumatra and 0.6 and 0.8 ha km⁻² in Kalimantan in
8 the period 2012–2016; Santika et al. 2017), improve local livelihood options, and restore degraded
9 ecosystems (positive side-effects for NCP provision) (e.g., Pohnan et al. 2015). Finally, the
10 establishment of Ecosystem Restoration Concessions in Indonesia (covering more than 5.5 thousand
11 km² of forests now, and 16 thousand km² allocated for the future) facilitates the planting of
12 commercial timber species (co-benefits with mitigation), while assisting natural regeneration,
13 preserving important habitats and species, and improving local well-being and incomes (positive side-
14 effects for Nature’s Contributions to People provision), at relatively lower costs compared with timber
15 concessions (Silalahi et al. 2017).

16 17 **D. Villages. Land degradation, groundwater overuse, climate change and food insecurity: 18 climate smart villages in India**

19 Indian agriculture, which includes both monsoon-dependent rainfed (58%) and irrigated agriculture, is
20 exposed to climate variability and change. Over the past years, the frequency of droughts, cyclones,
21 and hailstorms has increased, with severe droughts in 8 of 15 years between 2002 and 2017 (Srinivasa
22 Rao et al. 2016; Mujumdar et al. 2017). Such droughts result in large yield declines for major crops
23 like wheat in the Indo-Gangetic plain (Zhang et al. 2017). The development of a submersible pump
24 technology in the 1990s, combined with public policies that provide farmers free electricity for
25 groundwater irrigation, resulted in a dramatic increase in irrigated agriculture (Shah et al. 2012). This
26 shift has led to increased dependence on irrigation from groundwater and induced a groundwater
27 crisis, with large impacts on socio-ecosystems. An increasing number of farmers report bore-well
28 failures either due to excessive pumping of an existing well or a lack of water in new wells. The
29 decrease in the groundwater table level has suppressed the recharge of river beds, turning permanent
30 rivers into ephemeral streams (Srinivasan et al. 2015). Wells have recently been drilled in upland
31 areas, where groundwater irrigation is also increasing (Robert et al. 2017). Additional challenges are
32 declining soil organic matter and fertility under monocultures and rice/wheat systems. Unoccupied
33 land is scarce, meaning that the potential for expanding the area farmed is very limited (Aggarwal et
34 al. 2018). In rural areas, diets are deficient in protein, dietary fibre and iron, and mainly comprised of
35 cereals and pulses grown and/or procured through welfare programs (Vatsala et al. 2017). Cultivators
36 are often indebted and suicide rates are much higher than the national average, especially for those
37 strongly indebted (Merriott 2016). Widespread use of diesel pumps for irrigation, especially for
38 paddies, high use of inorganic fertilisers and crop residue burning lead to high GHG emissions
39 (Aggarwal et al. 2018). The Climate-Smart Village (CSV) approach aims at increasing farm yield,
40 income, input use efficiency (water, nutrients, and energy) and reducing GHG emissions (Aggarwal et
41 al. 2018). Climate-smart agriculture interventions are considered in a broad sense by including
42 practices, technologies, climate information services, insurance, institutions, policies, and finance.
43 Options differ based on the CSV site, its agro-ecological characteristics, level of development, and the
44 capacity and interest of farmers and the local government (Aggarwal et al. 2018). Selected
45 interventions included crop diversification, conservation agriculture (minimum tillage, residue
46 retention, laser levelling), improved varieties, weather-based insurance, agro-advisory services,
47 precision agriculture and agroforestry. Farmers’ cooperatives were established to hire farm
48 machinery, secure government credit for inputs, and share experiences and knowledge. Tillage
49 practices and residue incorporation increased rice–wheat yields by 5–37%, increased income by 28–
50 40%, reduced GHG emissions by 16–25%, and increased water-use efficiency by 30% (Jat et al.,
51 2014). The resulting portfolio of options proposed by the CSV approach has been integrated with the
52 agricultural development strategy of some states like Haryana.

53 54 **E. Dense settlements. Climate change and food: green infrastructures**

1 Extreme heat events have led to particularly high rates of mortality and morbidity in cities as urban
2 populations are pushed beyond their adaptive capacities, leading to an increase in mortality rates of
3 30–130% in major cities in developed countries (Norton et al. 2015). Increased mortality and
4 morbidity from extreme heat events are exacerbated in urban populations by the urban heat island
5 effect (Gabriel and Endlicher 2011; Schatz and Kucharik 2015), which can be limited by developing
6 green infrastructure in cities. Urban green infrastructure includes public and private green spaces,
7 including remnant native vegetation, parks, private gardens, golf courses, street trees, urban farming
8 and more engineered options such as green roofs, green walls, biofilters and raingardens (Norton et al.
9 2015). Increasing the amount of vegetation, or green infrastructure, in a city is one way to help reduce
10 urban air temperature maxima and variation. Increasing vegetation by 10% in Melbourne, Australia
11 was estimated to reduce daytime urban surface temperatures by approximately 1°C during extreme
12 heat events (Coutts and Harris 2013). Urban farming (a type of urban green infrastructure) is largely
13 driven by the desire to reconnect food production and consumption (Whittinghill and Rowe 2012; see
14 Chapter 5). Even though urban farming can only meet a very small share of the overall urban food
15 demand, it provides fresh and local food, especially perishable fruits and crops that are usually
16 shipped from far and sold at high prices (Thomaier et al. 2015). Food-producing urban gardens and
17 farms are often started by grassroots initiatives (Ercilla-Montserrat et al. 2019) that occupy vacant
18 urban spaces. In recent years, a growing number of urban farming projects (termed Zero-Acreage
19 farming, or Z-farming, Thomaier et al. 2015) were established in and on existing buildings, using
20 rooftop spaces or abandoned buildings through contracts between food businesses and building
21 owners. Almost all Z-farms are located in cities with more than 150,000 inhabitants, with a majority
22 in North American cities such as New York City, Chicago and Toronto (Thomaier et al. 2015). They
23 depend on the availability of vacant buildings and roof tops thereby competing with other uses, such
24 as roof-based solar systems. Urban farming, however, has potentially high levels of soil pollution and
25 air pollutants, which may lead to crop contamination and health risks. These adverse effects could be
26 reduced on rooftops (Harada et al. 2019) or in controlled environments.

28 **6.1.4 Challenges represented in future scenarios**

29 In this section, the evolution of several challenges (climate change, mitigation, adaptation,
30 desertification, land degradation, food insecurity, biodiversity and water) in the future are assessed,
31 focusing on global analyses. The effect of response options on these land challenges in the future is
32 discussed in Section 6.4.4. Where possible, studies quantifying these challenges in the Shared Socio-
33 economic Pathways (SSPs) (Chapter 1; Cross-Chapter Box 1: Scenarios, Chapter 1; Cross-Chapter
34 Box 9: Illustrative Climate and Land Pathways, in this chapter; O'Neill et al. 2014), as these studies
35 can be used to assess which future scenarios could experience multiple challenges in the future.

36 *Climate change:* Absent any additional efforts to mitigate, global mean temperature rise is expected to
37 increase by anywhere from 2°C to 7.8°C in 2100 relative to the 1850-1900 reference period (Clarke et
38 al. 2014a; Chapter 2). The level of warming varies depending on the climate model (Collins et al.
39 2013), uncertainties in the Earth system (Clarke et al. 2014), and socioeconomic/technological
40 assumptions (Clarke et al. 2014a; Riahi et al. 2017) Warming over land is 1.2 to 1.4 times higher than
41 global mean temperature rise; warming in the arctic region is 2.4 to 2.6 times higher than warming in
42 the tropics (Collins et al. 2013). Increases in global mean temperature are accompanied by increases
43 in global precipitation; however, the effect varies across regions with some regions projected to see
44 increases in precipitation and others to see decreases (Collins et al. 2013; Chapter 2). Additionally,
45 climate change also has implications for extreme events (e.g., drought, heat waves, etc.), freshwater
46 availability, and other aspects of the terrestrial system (Chapter 2).

47 *Mitigation:* Challenges to mitigation depend on the underlying emissions and “mitigative capacity”,
48 including technology availability, policy institutions, and financial resources (O'Neill et al. 2014b).
49 Challenges to mitigation are high in the SSP3 and SSP5, medium in SSP2, and low in SSP1 and SSP4
50 (O'Neill et al. 2014b, 2017; Riahi et al. 2017a).

1 *Adaptation:* Challenges to adaptation depend on climate risk and adaptive capacity, including
 2 technology availability, effectiveness of institutions, and financial resources (O'Neill et al. 2014b).
 3 Challenges to adaptation are high in the SSP3 and SSP4, medium in SSP2, and low in SSP1 and SSP5
 4 (O'Neill et al. 2014b, 2017; Riahi et al. 2017a).

5 *Desertification:* The combination of climate and land use changes can lead to decreases in soil cover
 6 in drylands (Chapter 3). Population living in drylands is expected to increase by 43% in the SSP2-
 7 Baseline, due to both population increases and an expansion of dryland area (UNCCD 2017).

8 *Land degradation:* Future changes in land use and climate have implications for land degradation,
 9 including impacts on soil erosion, vegetation, fire, and coastal erosion (Chapter 4; Scholes et al.
 10 2018). For example, soil organic carbon is expected to decline by 99 GtCO_{2e} in 2050 in an SSP2-
 11 Baseline scenario, due to both land management and expansion in agricultural area (Brink et al.
 12 2018).

13 *Food insecurity:* Food insecurity in future scenarios varies significantly, depending on socio-
 14 economic development and study. For example, the population at risk of hunger ranges from 0 to 800
 15 million in 2050 (Hasegawa et al. 2015a; Ringler et al. 2016; Fujimori et al. 2018b; Hasegawa et al.
 16 2018; Fujimori et al. 2018a; Baldos and Hertel 2015) and 0–600 million in 2100 (Hasegawa et al.
 17 2015a). Food prices in 2100 in non-mitigation scenarios range from 0.9 to about 2 times their 2005
 18 values (Hasegawa et al. 2015a; Calvin et al. 2014a; Popp et al. 2017). Food insecurity depends on
 19 both income and food prices (Fujimori et al. 2018b). Higher income (e.g., SSP1, SSP5), higher yields
 20 (e.g., SSP1, SSP5), and less meat intensive diets (e.g., SSP1) tend to result in reduced food insecurity
 21 (Hasegawa et al. 2018; Fujimori et al. 2018b).

22 *Biodiversity:* Future species extinction rates vary from modest declines to 100-fold increases from
 23 20th century rates, depending on the species (e.g., plants, vertebrates, invertebrates, birds, fish,
 24 corals), the degree of land-use change, the level of climate change, and assumptions about migration
 25 (Pereira et al., 2010). Mean species abundance (MSA) is also estimated to decline in the future by 10–
 26 20% in 2050 (Vuuren et al., 2015; Pereira et al. 2010). Scenarios with greater cropland expansion lead
 27 to larger declines in MSA (UNCCD 2017) and species richness (Newbold et al., 2015).

28 *Water stress:* Changes in both water supply (due to climate change) and water demand (due to
 29 socioeconomic development) in the future have implications for water stress. Water withdrawals for
 30 irrigation increase from about 2500 km³ yr⁻¹ in 2005 to between 2900 and 9000 km³ yr⁻¹ at the end of
 31 the century (Chaturvedi et al. 2013; Kim et al. 2016; Bonsch et al., 2015; Wada and Bierkens 2014;
 32 Graham et al. 2018; Hejazi et al. 2014); total water withdrawals at the end of the century range from
 33 5000 to 13000 km³ yr⁻¹ (Wada and Bierkens 2014a; Hejazi et al. 2014a; Graham et al. 2018; Kim et
 34 al. 2016). The magnitude of change in both irrigation and total water withdrawals depend on
 35 population, income, and technology (Hejazi et al. 2014a; Graham et al. 2018a). The combined effect
 36 of changes in water supply and water demand will lead to an increase of between 1 and 6 billion
 37 people living in water stressed areas (Schlosser et al. 2014; Hanasaki et al. 2013a; Hejazi et al.
 38 2014c). Changes in water quality are not assessed here but could be important (Liu et al. 2017).

39 *Scenarios with Multiple Challenges:* Table 6.2 summarises the challenges across the five SSP
 40 Baseline scenarios.

41 **Table 6.2: Assessment of future challenges to climate change, mitigation, adaptation, desertification, land
 42 degradation, food insecurity, water stress, and biodiversity in the SSP Baseline scenarios**

SSP	Summary of Challenges
SSP1	The SSP1 (van Vuuren et al. 2017b) has low challenges to mitigation and adaptation. The resulting Baseline scenario includes: <ul style="list-style-type: none"> Continued, but moderate, <i>climate change</i>: global mean temperature increases by 3 to 3.5°C in

	<p>2100 (Riahi et al. 2017a; Huppmann et al. 2018),</p> <ul style="list-style-type: none"> • Low levels of <i>food insecurity</i>: malnourishment is eliminated by 2050 (Hasegawa et al. 2015b), • Declines in <i>biodiversity</i>: biodiversity loss increases from 34% in 2010 to 38% in 2100 (UNCCD 2017), and • High <i>water stress</i>: global water withdrawals decline slightly from the baseline in 2071-2100, but ~2.6 billion people live in water stressed areas (Hanasaki et al. 2013b). <p>Additionally, this scenario is likely to have lower challenges related to desertification, land degradation, and biodiversity loss than the SSP2 as it has lower population, lower land use change and lower climate change (Riahi et al. 2017a).</p>
SSP2	<p>The SSP2 (Fricko et al. 2017) is a scenario with medium challenges to mitigation and high challenges to adaptation. The resulting Baseline scenario includes:</p> <ul style="list-style-type: none"> • Continued <i>climate change</i>: global mean temperature increases by 3.8 to 4.3°C in 2100 (Fricko et al. 2017; Riahi et al. 2017a; Huppmann et al. 2018), • Increased challenges related to <i>desertification</i>: the population living in drylands is expected to increase by 43% in 2050 (UNCCD 2017), • Increased <i>land degradation</i>: soil organic carbon is expected to decline by 99 GtCO₂e in 2050 (Brink et al. 2018), • Low levels of <i>food insecurity</i>: malnourishment is eliminated by 2100 (Hasegawa et al. 2015b), • Declines in <i>biodiversity</i>: biodiversity loss increases from 34% in 2010 to 43% in 2100 (UNCCD 2017), and • High <i>water stress</i>: global water withdrawals nearly doubles from the baseline in 2071-2100, with ~4 billion people living in water stressed areas (Hanasaki et al. 2013).
SSP3	<p>The SSP3 (Fujimori et al.,2017) is a scenario with high challenges to mitigation and high challenges to adaptation. The resulting Baseline scenario includes:</p> <ul style="list-style-type: none"> • Continued <i>climate change</i>: global mean temperature increases by 4 to 4.8°C in 2100 (Riahi et al. 2017a; Huppmann et al. 2018), • High levels of <i>food insecurity</i>: about 600 million malnourished in 2100 (Hasegawa et al. 2015b), • Declines in <i>biodiversity</i>: biodiversity loss increases from 34% in 2010 to 46% in 2100 (UNCCD 2017), and • High <i>water stress</i>: global water withdrawals more than double from the baseline in 2071-2100, with ~5.5 billion people living in water stressed areas (Hanasaki et al. 2013). <p>Additionally, this scenario is likely to have higher challenges to desertification, land degradation, and biodiversity loss than the SSP2 as it has higher population, higher land use change and higher climate change (Riahi et al. 2017a).</p>
SSP4	<p>The SSP4 (Calvin et al. 2017a) has high challenges to adaptation but low challenges to mitigation. The resulting Baseline scenario includes:</p> <ul style="list-style-type: none"> • Continued <i>climate change</i>: global mean temperature increases by 3.4 to 3.8°C in 2100 (Calvin et al. 2017b; Riahi et al. 2017a; Huppmann et al. 2018), • High levels of <i>food insecurity</i>: about 400 million malnourished in 2100 (Hasegawa et al. 2015b), and • High <i>water stress</i>: about 3.5 billion people live in water stressed areas in 2100 (Hanasaki et al. 2013). <p>Additionally, this scenario is likely to have similar effects on biodiversity loss as the SSP2 as it has similar land use change and similar climate change (Riahi et al. 2017a).</p>
SSP5	<p>The SSP5 (Kriegler et al. 2017) has high challenges to mitigation but low challenges to adaptation. The resulting Baseline scenario includes:</p> <ul style="list-style-type: none"> • Continued <i>climate change</i>: global mean temperature increases by 4.6 to 5.4°C in 2100 (Kriegler et al. 2017; Riahi et al. 2017a; Huppmann et al. 2018), • Low levels of <i>food insecurity</i>: malnourishment is eliminated by 2050 (Hasegawa et al. 2015b), and • Increased water use and water scarcity: global water withdrawals increase by ~80% in 2071-

<p>2100 with nearly 50% of the population living in water stressed areas (Hanasaki et al. 2013b). Additionally, this scenario is likely to have higher effects on biodiversity loss as the SSP2 as it has similar land use change and higher climate change (Riahi et al. 2017a).</p>

6.2 Response options, co-benefits and adverse side-effects across the land challenges

This section describes the integrated response options available to address the land challenges of climate change mitigation, climate change adaptation, desertification, land degradation and food security. These can be categorised into options that rely on a) land management, b) value chain management and c) risk management (Figure 6.5). The land management integrated response options can be grouped according to those that are applied in agriculture, in forests, on soils, in other/all ecosystems and those that are applied specifically for carbon dioxide removal (CDR). The value chain management integrated response options can be categorised as those based demand management and supply management. The risk management options are grouped together (Figure 6.5).

Figure 6.5 Broad categorisation of response options categorised into three main classes and eight sub-classes.

Note that the integrated response options are not mutually exclusive (e.g. cropland management might also increase soil organic matter stocks), and a number of the integrated response options are comprised of a number of practices (e.g., improved cropland management is a collection of practices consisting of a) management of the crop: including high input carbon practices, e. g., improved crop varieties, crop rotation, use of cover crops, perennial cropping systems, agricultural biotechnology; b) nutrient management: including optimised fertiliser application rate, fertiliser type [organic and mineral], timing, precision application, inhibitors; c) reduced tillage intensity and residue retention; d) improved water management: including drainage of waterlogged mineral soils and irrigation of crops in arid / semi-arid conditions; and e) improved rice management: including water management such as mid-season drainage and improved fertilisation and residue management in paddy rice systems).

In this section we deal only with integrated response options, not the policies that are currently / could be implemented to enable their application; that is the subject of Chapter 7. Also note that enabling

1 conditions such as indigenous and local knowledge, gender issues, governance etc. are not categorised
 2 as integrated response options (see Section 6.1.2). Some suggested methods to address land
 3 challenges are better described as *overarching frameworks* than as integrated response options. For
 4 example, *climate smart agriculture* is a collection of integrated response options aimed at delivering
 5 mitigation and adaptation in agriculture, including improved cropland management, grazing land
 6 management and livestock management. Table 6.3 shows how a number of overarching frameworks
 7 are comprised of a range of integrated response options.

8 Similarly, policy goals, such as *land degradation neutrality* (discussed further in Chapter 7), are not
 9 considered as integrated response options. For this reason, *land degradation neutrality*, and
 10 overarching frameworks, such as those described in Table 6.3 do not appear as response options in the
 11 following sections, but the component integrated response options that contribute to these policy goals
 12 or over-arching frameworks are addressed in detail.

13 **Table 6.3 Examples of overarching frameworks that consist of a range of response options, showing how**
 14 **various response options contribute to the overarching frameworks**

Framework (definition used)	Nature based solutions (IUCN)	Agro-ecology (FAO)	Climate smart agriculture (FAO)	Ecosystem based adaptation (CBD)	Conservation agriculture (FAO)	Community based adaptation (IIED)	Integrated landscape management including integrated coastal zone management (FAO)	Precision agriculture (FAO)	Sustainable forest management (UN)	Sustainable intensification (Cross Chapter Box 5; Chapter 5)	Organic agriculture (FAO)

2 The SR15 considered a range of response options (from a mitigation / adaptation perspective only).
3 Table 6.4 shows how the SR15 options map on to the response options considered in this report
4 (SRCCL). Note that this report excludes most of the energy-related options from SR15, as well as
5 green infrastructure and sustainable aquaculture.

6

Table 6.4 Mapping of response options considered in this report (SRCCL) and SR15

SRCCL Response Option or Options	SR15 Response Option or Options
Afforestation	Afforestation
Reforestation and forest restoration	Reforestation and reduced land degradation and forest restoration

Agricultural diversification	Mixed crop-livestock systems
Agroforestry	Agroforestry and silviculture
Biochar addition to soil	Biochar
Biodiversity conservation	Biodiversity conservation
Bioenergy and BECCS	Biomass use for energy production with carbon capture and sequestration (BECCS) (through combustion, gasification, or fermentation)
Dietary change	Dietary changes, reducing meat consumption
Disaster risk management	Climate services
	Community-based adaptation
Enhanced urban food systems	Urban and peri-urban agriculture and forestry
Enhanced weathering of minerals	Mineralisation of atmospheric CO ₂ through enhanced weathering of rocks
Fire management	Fire management and (ecological) pest control
Improved forest management	Forest management
Improved cropland management	Methane reductions in rice paddies
Improved cropland management	Nitrogen pollution reductions, e.g., by fertiliser reduction, increasing nitrogen fertiliser efficiency, sustainable fertilisers
	Precision agriculture
	Conservation agriculture
Improved food processing and retailing	
Improved grazing land management	Livestock and grazing management, for example, methane and ammonia reductions in ruminants through feeding management or feed additives, or manure management for local biogas production to replace traditional biomass use
Improved livestock management	
Increased energy efficiency in food systems	Manure management
Increased food productivity	Increasing agricultural productivity
Increased soil organic carbon content	Changing agricultural practices enhancing soil carbon
	Soil carbon enhancement, enhancing carbon sequestration in biota and soils, e.g. with plants with high carbon sequestration potential (also AFOLU measure)
Integrated water management	Irrigation efficiency
Livelihood diversification	
Management of invasive species / encroachment	
Management of supply chains	
Management of urban sprawl	Urban ecosystem services
	climate resilient land use
Material substitution	Material substitution of fossil CO ₂ with bio-CO ₂ in industrial application (e.g. the beverage industry)
	Carbon Capture and Usage – CCU; bioplastics (bio-based materials replacing fossil fuel uses as feedstock in the production of chemicals and polymers), carbon fibre
Reduced soil erosion	
Reduced soil compaction	
Reduced deforestation	Reduced deforestation, forest protection, avoided forest conversion
Reduced food waste (consumer or retailer)	Reduction of food waste (incl. reuse of food processing waste for fodder)
Reduced grassland conversion to cropland	
Reduced landslides and natural hazards	
Reduced pollution including acidification	Reduced air pollution
Reduced post-harvest losses	

Reduced soil salinisation	
Restoration and reduced conversion of coastal wetlands	Managing coastal stress
Restoration and reduced conversion of peatlands	Restoration of wetlands (e.g., coastal and peat-land restoration, blue carbon) and wetlands management
Risk sharing instruments	Risk sharing
Sustainable sourcing	
Use of local seeds	

1 Before providing the quantitative assessment of the impacts of each response option in addressing
 2 mitigation, adaptation, desertification, land degradation and food security in section 6.3, the integrated
 3 response options are described in section 6.2.1 and any context specificities in the effects are noted.

4 **6.2.1 Integrated response options based on land management**

5 **6.2.1.1 Integrated response options based on land management in agriculture**

6 Integrated response options based on land management in agriculture are described in Table 6.5,
 7 which also notes any context specificities in the effects of the response options and provides the
 8 evidence base.

9 **6.2.1.2 Integrated response options based on land management in forests**

10 Integrated response options based on land management in forests are described in Table 6.6, which
 11 also notes any context specificities in the effects of the response options and provides the evidence
 12 base.

13 **6.2.1.3 Integrated response options based on land management of soils**

14 Integrated response options based on land management of soils are described in Table 6.7, which also
 15 notes any context specificities in the effects of the response options and provides the evidence base.

16 **6.2.1.4 Integrated response options based on land management of all/other ecosystems**

17 Integrated response options based on land management in all/other ecosystems are described in Table
 18 6.8, which also notes any context specificities in the effects of the response options and provides the
 19 evidence base.

20 **6.2.1.5 Integrated response options based on land management specifically for carbon dioxide 21 removal (CDR)**

22 Integrated response options based on land management specifically for CDR are described in Table
 23 6.9, which also notes any context specificities in the effects of the response options and provides the
 24 evidence base.

1

Table 6.5 Integrated response options based on land management in agriculture

Integrated response option	Description	Context and caveats	Supporting evidence
Increased food productivity	Increased food productivity arises when the output of food commodities increases per unit of input, e.g. per unit of land or water. It can be realised through many other interventions such as improved cropland, grazing land and livestock management.	Many interventions to increase food production, particularly those predicated on very large inputs of agro-chemicals, have a wide range of negative externalities leading to the proposal of sustainable intensification as a mechanism to deliver future increases in productivity that avoid these adverse outcomes. Intensification through additional input of N fertiliser, for example, would result in negative impacts on climate, soil, water and air pollution. Similarly, if implemented in a way that over-exploits the land significant negative impacts would occur, but if achieved through sustainable intensification, and used to spare land, it could reduce the pressure on land.	Cross-Chapter Box 6 on Agricultural Intensification, Chapter 5; Chapter 3; Burney et al. 2010; Foley et al. 2011; Garnett et al. 2013; Godfray et al. 2010; Lal 2016; Lamb et al. 2016; Lobell et al 2008.; Shcherbak et al. 2014; Smith et al. 2013; Tilman et al. 2014; Scholes et al. 2018; Balmford et al. 2018
Improved cropland management	Improved cropland management is a collection of practices consisting of a) <i>management of the crop</i> : including high input carbon practices, for example, improved crop varieties, crop rotation, use of cover crops, perennial cropping systems, integrated production systems, crop diversification, agricultural biotechnology, b) <i>nutrient management</i> : including optimised fertiliser application rate, fertiliser type (organic manures, compost and mineral), timing, precision application, nitrification inhibitors, c) <i>reduced tillage intensity and residue retention</i> , d) <i>improved water management</i> : including drainage of waterlogged mineral soils and irrigation of crops in arid / semi-arid conditions, e) <i>improved rice management</i> : including water management such as mid-season drainage and improved fertilisation and residue management in paddy rice systems, and f) <i>biochar application</i> .	Improved cropland management can reduce greenhouse gas emissions and create soil carbon sinks, though if poorly implemented, it could increase N ₂ O and CH ₄ emissions from N fertilisers, crop residues and organic amendments. It can improve resilience of food crop production systems to climate change and can be used to tackle desertification and land degradation by improving sustainable land management. It can also contribute to food security by closing crop yield gaps to increase food productivity.	Chapter 4; Chapter 3; Chapter 2; Chapter 5; Bryan et al. 2009; Chen et al. 2010; Labrière et al. 2015; Lal 2011; Poeplau and Don 2015; Porter et al. 2014a; Smith et al. 2014b; Smith 2008; Tilman et al. 2011
Improved grazing land	Improved grazing land management is a collection of practices consisting of a) <i>management of vegetation</i> : including improved grass varieties / sward composition, deep rooting grasses,	Improved grazing land management can increase soil carbon sinks, reduce greenhouse gas emissions, improve the resilience of grazing lands to future	Chapter 2; Chapter 3; Chapter 4; Chapter 5; Section 6.3; Archer et al. 2011; Briske et al. 2015;

management	increased productivity, and nutrient management, b) <i>animal management</i> : including appropriate stocking densities fit to carrying capacity, fodder banks, and fodder diversification, and c) <i>fire management</i> : improved use of fire for sustainable grassland management, including fire prevention and improved prescribed burning (see also fire management as a separate response option; Table 6.8).	climate change, help reduce desertification and land degradation by optimising stocking density and reducing overgrazing, and can enhance food security through improved productivity.	Conant et al. 2017; Herrero et al. 2016; Porter et al. 2014a; Schwilch et al. 2014; Smith et al. 2014b; Tighe et al. 2012
Improved livestock management	Improved livestock management is a collection of practices consisting of a) <i>improved feed and dietary additives</i> (e.g., bioactive compounds, fats), used to increase productivity and reduce emissions from enteric fermentation; b) <i>breeding</i> (e.g., breeds with higher productivity or reduced emissions from enteric fermentation), c) <i>herd management</i> , including decreasing neo-natal mortality, improving sanitary conditions, animal health and herd renewal, and diversifying animal species, d) <i>emerging technologies</i> (of which some are not legally authorised in several countries) such as propionate enhancers, nitrate and sulphate supplements, archaea inhibitors and archaeal vaccines, methanotrophs, acetogens, defaunation of the rumen, bacteriophages and probiotics, ionophores / antibiotics; and e) <i>improved manure management</i> , including manipulation of bedding and storage conditions, anaerobic digesters; biofilters, dietary change and additives, soil-applied and animal-fed nitrification inhibitors, urease inhibitors, fertiliser type, rate and timing, manipulation of manure application practices, and grazing management.	Improved livestock management can reduce greenhouse gas emissions, particularly from enteric methane and manure management. It can improve the resilience of livestock production systems to climate change by breeding better adapted livestock. It can help with desertification and land degradation, e.g. through use of more efficient and adapted breeds to allow reduced stocking densities. Improved livestock sector productivity can also increase food production.	Chapter 2; Chapter 3; Chapter 4; Chapter 5; Archer et al. 2011; Herrero et al. 2016; Miao et al. 2015; Porter et al. 2014a; Rojas-Downing et al. 2017; Smith et al. 2008, 2014b; Squires et al. 2005; Tighe et al. 2012
Agroforestry	Agroforestry involves the deliberate planting of trees in croplands and silvo-pastoral systems.	Agroforestry sequesters carbon in vegetation and soils. The use of leguminous trees can enhance biological N fixation and resilience to climate change. Soil improvement and the provision of perennial vegetation can help to address desertification and land degradation. Agroforestry can increase agricultural productivity, with benefits for food security. Additionally, agroforestry can enable payments to farmers for ecosystem services and reduce vulnerability to climate shocks.	Antwi-Agyei et al. 2014; Mbow et al. 2014a; Mutuo et al. 2005; Rosenstock et al. 2014; Sain et al. 2017; Sida et al. 2018; Vignola et al. 2015; Yirdaw et al. 2017 Benjamin et. al. 2018; Guo et al. 2018; Herder et al. 2017; Mosquera-Losada et al. 2018; Nair et al. 2014; Ram et al. 2017; Santiago-Freijanes et. al. 2018;

Agricultural diversification	Agricultural diversification includes a set of agricultural practices and products obtained in the field that aim to improve the resilience of farmers to climate variability and climate change and to economic risks posed by fluctuating market forces. In general, the agricultural system is shifted from one based on low-value agricultural commodities to one that is more diverse, composed of a basket of higher value-added products.	Agricultural diversification is targeted at adaptation but could also deliver a small carbon sink, depending on how it is implemented. It could reduce pressure on land, benefiting desertification, land degradation, food security and household income. However, the potential to achieve household food security is influenced by the market orientation of a household, livestock ownership, non-agricultural employment opportunities, and available land resources.	Birthal et al. 2015; Campbell et al. 2014; Cohn et al. 2017; Lambin and Meyfroidt 2011; Lipper et al. 2014; Massawe et al. 2016; Pellegrini and Tasciotti 2014; Waha et al. 2018
Reduced grassland conversion to cropland	Grasslands can be converted to croplands by ploughing of grassland and seeding with crops. Since croplands have a lower soil carbon content than grasslands and are also more prone to erosion than grasslands, reducing conversion of grassland to croplands will prevent soil carbon losses by oxidation and soil loss through erosion. These processes can be reduced if the rate of grassland conversion to cropland is reduced.	Stabilising soils by retaining grass cover also improves resilience, benefiting adaptation, desertification and land degradation. Since conversion of grassland to cropland usually occurs to remedy food security challenges, food security could be adversely affected, since more land is required to produce human food from livestock products on grassland than from crops on cropland.	Chapter 3; Chapter 4; Chapter 5; Clark and Tilman 2017; Lal 2001a; de Ruiter et al. 2017; Poore & Nemecek, 2018
Integrated water management	Integrated water management is the process of creating holistic strategies to promote integrated, efficient, equitable and sustainable use of water for agroecosystems. It includes a collection of practices including water-use efficiency and irrigation in arid/semi-arid areas, improvement of soil health through increases in soil organic matter content, and improved cropland management, agroforestry and conservation agriculture. Increasing water availability, and reliability of water for agricultural production, can be achieved by using different techniques of water harvesting, storage, and its judicious utilisation through farm ponds, dams, and community tanks in rainfed agriculture areas can benefit adaptation.	These practices can reduce aquifer and surface water depletion, and prevent over extraction, and the management of climate risks. Many technical innovations, e.g., precision water management, can have benefits for both adaptation and mitigation, although trade-offs are possible. Maintaining the same level of yield through use of site-specific water management-based approach could have benefits for both food security and mitigation.	Chapter 3; Chapter 4; Chapter 5; Brindha and Pavelic 2016; Jat et al. 2016; Jiang 2015; Keesstra et al. 2018; Liu et al. 2017; Nejad 2013; Rao et al. 2017; Shaw et al. 2014; Sapkota et al. 2017; Scott et al. 2011; Waldron et al. 2017

Table 6.6 Integrated response options based on land management in forests

Integrated response option	Description	Context and caveats	Supporting evidence
Improved forest management	Improved forest management refers to management interventions in forests for the purpose of climate change mitigation. It includes a wide variety of practices affecting the growth of trees and the biomass removed, including improved regeneration (natural or artificial) and a better schedule, intensity and execution of operations (thinning, selective logging, final cut; reduced impact logging, etc.). Sustainable forest management is the stewardship and use of forests and forest lands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity, vitality and their potential to fulfil, now and in the future, relevant ecological, economic and social functions, at local, national, and global levels, and that does not cause damage to other ecosystems.	Sustainable forest management can enhance the carbon stock in biomass, dead organic matter, and soil – while providing wood-based products to reduce emissions in other sectors through material and energy substitution. A trade-off exists between different management strategies: higher harvest decreases the carbon in the forest biomass in the short term but increases the carbon in wood products and the potential for substitution effects. Sustainable forest management, also through close-to-nature silvicultural techniques, can potentially offer many co-benefits in terms of climate change mitigation, adaptation, biodiversity conservation, microclimatic regulation, soil erosion protection, coastal area protection and water and flood regulation. Forest management strategies aimed at increasing the biomass stock levels may have adverse side-effects, such as decreasing the stand-level structural complexity, biodiversity and resilience to natural disasters. Forest management also affects albedo and evapotranspiration.	Chapter 2; Chapter 4; D’Amato et al. 2011; Dooley and Kartha 2018a; Ellison et al. 2017; Erb et al. 2017; Grassi et al. 2018; Griscom et al. 2017a; Jantz et al. 2014; Kurz et al. 2016; Locatelli 2011; Luysaert et al. 2018; Nabuurs et al. 2017; Naudts et al. 2016; Putz et al. 2012; Seidl et al. 2014; Smith et al. 2014a; Smyth et al. 2014; Stanturf et al. 2015; Forest Europe 2016 Pingoud et al. 2018
Reduced deforestation and degradation	Reduced deforestation and forest degradation includes conservation of existing carbon pools in forest vegetation and soil by controlling the drivers of deforestation (i.e., commercial and subsistence agriculture, mining, urban expansion) and forest degradation (i.e., overharvesting including fuelwood collection, poor harvesting practices, overgrazing, pest outbreaks, and extreme wildfires), also through establishing protected areas, improving law enforcement, forest governance and land tenure, supporting community forest management and introducing forest certification.	Reducing deforestation and degradation is a major strategy to reduce global GHG emissions. The combination of reduced GHG emissions and biophysical effects results in a large climate mitigation effect, with benefits also at local level. Reduced deforestation preserves biodiversity and ecosystem services more efficiently and at lower costs than afforestation/reforestation. Efforts to reduce deforestation and forest degradation may have potential adverse side-effects, for example, reducing availability of land for farming, restricting the rights and access of local people to forest resources (e.g. firewood), or increasing the dependence of local people to insecure external funding.	Chapter 2; Alkama and Cescatti 2016; Baccini et al. 2017; Barlow et al. 2016; Bayrak et al. 2016; Caplow et al. 2011; Curtis et al. 2018; Dooley and Kartha 2018; Griscom et al. 2017a; Hansen et al. 2013b; Hosonuma et al. 2012; Houghton et al. 2015; Lewis et al. 2015; Pelletier et al. 2016; Rey Benayas et al. 2009
Reforestation	Reforestation is the conversion to forest of land that has	Reforestation is similar to afforestation with respect to the co-	Chapter 2; Dooley and

<p>and forest restoration</p>	<p>previously contained forests but that has been converted to some other use. Forest restoration refers to practices aimed at regaining ecological integrity in a deforested or degraded forest landscape. As such, it could fall under reforestation if it were re-establishing trees where they have been lost, or under forest management if it were restoring forests where not all trees have been lost. For practical reasons, here forest restoration is treated together with reforestation.</p>	<p>benefits and adverse side-effects among climate change mitigation, adaptation, desertification, land degradation and food security (see row on Afforestation below). Forest restoration can increase terrestrial carbon stocks in deforested or degraded forest landscapes and can offer many co-benefits in terms of increased resilience of forests to climate change, enhanced connectivity between forest areas and conservation of biodiversity hotspots. Forest restoration may threaten livelihoods and local access to land if subsistence agriculture is targeted.</p>	<p>Kartha 2018; Ellison et al. 2017; Locatelli 2011; Locatelli et al. 2015a; Smith et al. 2014b; Stanturf et al. 2015</p>
<p>Afforestation</p>	<p>Afforestation is the conversion to forest of land that historically have not contained forests (see also reforestation).</p>	<p>Afforestation increases terrestrial carbon stocks but can also change the physical properties of land surfaces, such as surface albedo and evapotranspiration with implications for local and global climate. In the tropics, enhanced evapotranspiration cools surface temperatures, reinforcing the climate benefits of CO₂ sequestration in trees. At high latitudes and in areas affected by seasonal snow cover, the decrease in surface albedo after afforestation becomes dominant and causes an annual average warming that counteracts carbon benefits. Net biophysical effects on regional climate from afforestation is seasonal and can reduce the frequency of climate extremes, such as heat waves, improving adaptation to climate change and reducing the vulnerability of people and ecosystems. Afforestation helps to address land degradation and desertification, as forests tend to maintain water quality by reducing runoff, trapping sediments and nutrients, and improving groundwater recharge. However, food security could be hampered since an increase in global forest area can increase food prices through land competition. Other adverse side-effects occur when afforestation is based on non-native species, especially with the risks related to the spread of exotic fast-growing tree species. For example, exotic species can upset the balance of evapotranspiration regimes, with negative impacts on water availability, particularly in dry regions.</p>	<p>Chapter 2; Chapter 3; Chapter 4; Chapter 5; Alkama and Cescatti 2016; Arora and Montenegro 2011; Bonan 2008; Boysen et al. 2017; Brundu and Richardson 2016; Cherubini et al. 2017; Ciais et al. 2013; Ellison et al. 2017; Findell et al. 2017; Idris Medugu et al. 2010; Kongsager et al. 2016; Kreidenweis et al. 2016a; Lejeune et al. 2018.; Li et al. 2015; Locatelli et al. 2015a; Perugini et al. 2017; Salvati et al. 2014; Smith et al. 2013, 2014b; Trabucco et al. 2008;</p>

Table 6.7 Integrated response options based on land management of soils

Integrated response option	Description	Context and caveats	Supporting evidence
Increased soil organic carbon content	Practices that increase soil organic matter content include a) <i>land use change</i> to an ecosystem with higher equilibrium soil carbon levels (e.g. from cropland to forest), b) <i>management of the vegetation</i> : including high input carbon practices, for example, improved varieties, rotations and cover crops, perennial cropping systems, biotechnology to increase inputs and recalcitrance of below ground carbon, c) <i>nutrient management and organic material input</i> to increase carbon returns to the soil: including optimised fertiliser and organic material application rate, type, timing and precision application, d) <i>reduced tillage intensity and residue retention</i> , and e) <i>improved water management</i> : including irrigation in arid / semi-arid conditions.	Increasing soil carbon stocks removes CO ₂ from the atmosphere and increases the water holding capacity of the soil thereby conferring resilience to climate change and enhancing adaptation capacity. It is a key strategy for addressing both desertification and land degradation. There is some evidence that crop yields and yield stability increase by increased organic matter content, though some studies show equivocal impacts. Some practices to increase soil organic matter stocks vary in their efficacy. For example, the impact of no till farming and conservation agriculture on soil carbon stocks is often positive, but can be neutral or even negative, depending on the amount of crop residues returned to the soil. If soil organic carbon stocks were increased by increasing fertiliser inputs to increase productivity, emissions of nitrous oxide from fertiliser use could offset any climate benefits arising from carbon sinks. Similarly, if any yield penalty is incurred from practices aimed at increasing soil organic carbon stocks (e.g. through extensification), emissions could be increased through indirect land use change, and there could also be adverse side-effects on food security.	Bestelmeyer and Briske 2012; Cheesman et al. 2016; Frank et al. 2017; Gao et al. 2018; Keesstra et al 2016.; Lal 2016, 2006; Lambin and Meyfroidt 2011; de Moraes Sá et al. 2017; Palm et al. 2014; Pan et al. 2009; Paustian et al. 2016; Powlson et al. 2014, 2016, Smith et al. 2013, 2016a, 2014b; Soussana et al. 2019a; Steinbach et al 2006.; VandenBygaart 2016; Hijbeek et al., 2017; Schjønning et al., 2018;
Reduced soil erosion	Soil erosion is the removal of soil from the land surface by water, wind or tillage, which occurs worldwide but it is particularly severe in Asia, Latin America and the Caribbean, and the Near East and North Africa. Soil erosion management includes conservation practices (e.g., the use of minimum tillage or zero tillage, crop rotations and cover crops, rational grazing systems), engineering-like practices (e.g., construction of terraces and contour cropping for controlling water erosion), or forest barriers and strip	The fate of eroded soil carbon is uncertain, with some studies indicating a net source of CO ₂ to the atmosphere and others suggesting a net sink. Reduced soil erosion has benefits for adaptation as it reduces vulnerability of soils to loss under climate extremes, increasing resilience to climate change. Some management practices implemented to control erosion, such as increasing ground cover, can reduce the vulnerability of soils to degradation / landslides, and prevention of soil erosion is a key measure used to tackle desertification. Because it protects the capacity of land to produce food, it also contributes positively to food security.	Chapter 3; Chen 2017; Derpsch et al. 2010; FAO and ITPS 2015; FAO 2015; Garbrecht et al. 2015; Jacinthe and Lal 2001; de Moraes Sá et al. 2017; Poeplau and Don 2015; Smith et al. 2001; Stallard 1998; Lal and Moldenhauer 1987; Van Oost et al. 2007; Lugato et al. 2016; Smith et al. 2005; Lal 2001a

	cultivation for controlling wind erosion. In eroded soils, the advance of erosion gullies and sand dunes can be limited by increasing plant cover, among other practices.		
Reduced soil salinisation	Soil salinisation is a major process of land degradation that decreases soil fertility and affects agricultural production, aquaculture and forestry. It is a significant component of desertification processes in drylands. Practices to reduce soil salinisation include improvement of water management (e.g., water-use efficiency and irrigation/drainage technology in arid/semi-arid areas, surface and groundwater management), improvement of soil health (through increase in soil organic matter content) and improved cropland, grazing land and livestock management, agroforestry and conservation agriculture.	Techniques to prevent and reverse soil salinisation may have small benefits for mitigation by enhancing carbon sinks. These techniques may benefit adaptation and food security by maintaining existing crop systems and closing yield gaps for rainfed crops. These techniques are central to reducing desertification and land degradation, since soil salinisation is a primary driver of both.	Section 3.5; Chapter 4; Chapter 5; Baumhardt et al. 2015; Dagar et al. 2016a; Datta et al. 2000; DERM 2011; Evans and Sadler 2008; He et al. 2015; D'Odorico et al. 2013; Prathapar 1988; Qadir et al. 2013; Rengasamy 2006; Singh 2009; UNCTAD 2011; Wong et al. 2010
Reduced soil compaction	Reduced soil compaction mainly includes agricultural techniques (e.g. crop rotations, control of livestock density) and control of agricultural traffic.	Techniques to reduce soil compaction have variable impacts on GHG emissions but may benefit adaptation by improving soil climatic resilience. Since soil compaction is a driver of both desertification and land degradation, a reduction of soil compaction could benefit both. It could also help close yield gaps in rainfed crops.	Chamen et al. 2015; Epron et al. 2016; ITPS-FAO 2015; Hamza and Anderson 2005; Soane and van Ouwkerk 1994; Tullberg et al. 2018
Biochar addition to soil	The use of biochar, a solid product of the pyrolysis process, as a soil amendment increases the water-holding capacity of soil. It may therefore provide better access to water and nutrients for crops and other vegetation types (so can form part of cropland, grazing land and improved forest management).	The use of biochar increases carbon stocks in the soil. It can enhance yields in the tropics (but less so in temperate regions), thereby benefiting both adaptation and food security. Since it can improve soil water holding capacity and nutrient use efficiency, and can ameliorate heavy metal pollution and other impacts, it can benefit desertification and land degradation. The positive impacts could be tempered by additional pressure on land if large quantities of biomass are required as feedstock for biochar production.	Chapter 2; Chapter 3; Chapter 4; Chapter 5; Jeffery et al. 2017; Smith 2016; Sohi 2012; Woolf et al. 2010

Table 6.8 Integrated response options based on land management of all/other ecosystems

Integrated response option	Description	Context and caveats	Supporting evidence
Fire management	Fire management is a land management option aimed at safeguarding life, property and resources through the prevention, detection, control, restriction and suppression of fire in forest and other vegetation. It includes the improved use of fire for sustainable forestry management, including wildfire prevention and prescribed burning. Prescribed burning is used to reduce the risk of large, uncontrollable fires in forest areas, and controlled burning is among the most effective and economic methods of reducing fire danger and stimulating natural reforestation under the forest canopy and after clear felling.	The frequency and severity of large wildfires have increased around the globe in recent decades, which has impacted forest carbon budgets. Fire can cause various greenhouse gas emissions such as CO ₂ , CH ₄ , and N ₂ O, and others such as CO, volatile organic carbon, and smoke aerosols. Fire management can reduce GHG emissions and can reduce haze pollution, which has significant health and economic impacts. Fire management helps to prevent soil erosion and land degradation and is used in rangelands to conserve biodiversity and to enhance forage quality.	Chapter 2; Cross-Chapter Box 3 on fire and climate; Esteves et al. 2012; FAO 2006; Lin et al. 2017; O'Mara 2012; Rulli et al. 2006; Scasta et al. 2016; Seidl et al. 2014; Smith et al. 2014b; Tacconi 2016; Valendik et al. 2011; Westerling et al. 2006; Whitehead et al. 2008; Yong and Peh 2016
Reduced landslides and natural hazards	Landslides are mainly triggered by human activity (e.g. legal and illegal mining, fire, deforestation) in combination with climate. Management of landslides and natural hazards (e.g. floods, storm surges, droughts) is based on vegetation management (e.g. afforestation) and engineering works (e.g. dams, terraces, stabilisation and filling of erosion gullies).	Management of landslides and natural hazards is important for adaptation and is a very important intervention for managing land degradation, since landslides and natural hazards are among the most severe degradation processes. In countries where mountain slopes are planted with food crops, reduced landslides will help deliver benefits for food security. Most deaths caused due to different disasters have occurred in developing countries, in which poverty, poor education and health facilities, and other aspects of development increase exposure, vulnerability and risk.	IPCC AR5 WG2 Chapter 14; Arnáez J et al. 2015; Campbell 2015; ITPS-FAO 2015; Gariano and Guzzetti 2016; Mal et al. 2018
Reduced pollution including acidification	Management of air pollution is connected to climate change by emission sources of air polluting materials and their impacts on climate, human health, and ecosystems, including agriculture. Acid deposition is one of the many consequences of air pollution, harming trees and other vegetation, as well as being a significant driver of land degradation. Practices that reduce acid deposition include prevention of emissions of nitrogen oxides (NO _x) and sulphur dioxide (SO ₂), which also reduce GHG emissions and	There are a few potential adverse side effects of reduction in air pollution to carbon sequestration in terrestrial ecosystems, because some forms of air pollutants can enhance crop productivity by increasing diffuse sunlight, compared to direct sunlight. Reactive N deposition could also enhance CO ₂ uptake in boreal forests and increase soil carbon pools to some extent. Air pollutants have different impacts on climate depending primarily on the composition, with some aerosols (and clouds seeded by them) increasing the reflection of solar radiation to space leading to net cooling, while others (e.g. black carbon and tropospheric ozone) having a net warming effect. Therefore, control of these different pollutants will have both positive and negative impacts on climate mitigation.	Chapter 2; Anderson et al. 2017; Chum et al. 2013; Carter et al. 2015; Coakley; Maaroufi et al. 2015; Markandya et al. 2018; Melamed and Schmale 2016; Mostofa et al. 2016.; Nemet et al. 2010; Ramanathan et al. 2001; Seinfeld and

	<p>other Short-Lived Climate Pollutants (SLCPs). Reductions of SLCPs reduce warming in the near term and the overall rate of warming, which can be crucial for plants that are sensitive to even small increases in temperature. Management of harmful air pollutants such as fine particulate matter (PM_{2.5}) and ozone (O₃) also mitigate the impacts of incomplete fossil fuel combustion and GHG emissions. In addition, management of pollutants such as tropospheric O₃ has beneficial impacts on food production, since O₃ decreases crop production. Control of urban and industrial air pollution would also mitigate the harmful effects of pollution and provide adaptation co-benefits <i>via</i> improved human health. Management of pollution contributes to aquatic ecosystem conservation since controlling air pollution, rising atmospheric CO₂ concentrations, acid deposition, and industrial waste will reduce acidification of marine and freshwater ecosystems.</p>		<p>Pandis; Smith et al. 2015b; UNEP 2017; Wild et al. 2012 UNEP and WMO 2011; Xu & Ramanathan, 2017; Xu et al., 2013</p>
<p>Management of invasive species / encroachment</p>	<p>Agriculture and forests can be diverse but often, much of the diversity is non-native. Invasive species in different biomes have been introduced intentionally or unintentionally through export of ornamental plants or animals, and through the promotion of modern agriculture and forestry. Non-native species tend to be more numerous in larger than in smaller human-modified landscapes (e.g. over 50% of species in an urbanised area or extensive agricultural fields can be non-native). Invasive alien species in the United States cause major environmental damage amounting to almost USD120 billion yr⁻¹. There are approximately 50,000 foreign species and the number is increasing. About 42% of the species on the Threatened or Endangered species lists are at risk primarily because of alien-invasive species. Invasive species can be managed</p>	<p>Exotic species are used in forestry where local indigenous forests cannot produce the type, quantity and quality of forest products required. Planted forests of exotic tree species make significant contributions to the economy and provide multiple products and Nature's Contributions to People. In general, exotic species are selected to have higher growth rates than native species and produce more wood per unit of area and time. In 2015, the total area of planted forest with non-native tree species was estimated to around 0.5 Mkm². Introduced species were dominant in South America, Oceania and Eastern and Southern Africa, where industrial forestry is dominant. The use of exotic tree species has played an important role in the production of roundwood, fibre, firewood and other forest products. The challenge is to manage existing and future plantation forests of alien trees to maximise current benefits, while minimising present and future risks and negative impacts, and without compromising future benefits. In many countries or regions, non-native trees planted for production or other purposes often lead to sharp conflicts of interest when they become invasive, and to negative impacts on Nature's Contributions to People and nature conservation.</p>	<p>Brundu and Richardson 2016; Cossalter and Pye-Smith 2003; Dresner et al. 2015; Payn et al. 2015; Pimentel et al. 2005; Vilà et al. 2011</p>

	through manual clearance of invasive species, while in some areas, natural enemies of the invasive species are introduced to control them.		
Restoration and reduced conversion of coastal wetlands	Coastal wetland restoration involves restoring degraded / damaged coastal wetlands including mangroves, salt marshes and seagrass ecosystems.	Coastal wetland restoration and avoided coastal wetland impacts have the capacity to increase carbon sinks and can provide benefits by regulating water flow and preventing downstream flooding. Coastal wetlands provide a natural defence against coastal flooding and storm surges by dissipating wave energy, reducing erosion and by helping to stabilise shore sediments. Since large areas of global coastal wetlands are degraded, restoration could provide benefits land degradation. Since some areas of coastal wetlands are used for food production, restoration could displace food production and damage local food supply (Section 6.3.4), though some forms (e.g. mangrove restoration) can improve local fisheries.	Griscom et al. 2017a; Lotze et al. 2006; Munang et al. 2014; Naylor et al. 2000
Restoration and reduced conversion of peatlands	Peatland restoration involves restoring degraded / damaged peatlands which both increases carbon sinks, but also avoids ongoing CO ₂ emissions from degraded peatlands, so it both prevents future emissions and creates a sink, as well as protecting biodiversity.	Avoided peat impacts and peatland restoration can provide significant mitigation, though restoration can lead to an increase in methane emissions, particularly in nutrient rich fens. There may also be benefits for climate adaptation by regulating water flow and preventing downstream flooding. Considering that large areas of global peatlands are degraded, peatland restoration is a key tool in addressing land degradation. Since large areas of tropical peatlands and some northern peatlands have been drained and cleared for food production, their restoration could displace food production and damage local food supply, potentially leading to adverse impacts on food security locally, though the global impact would be limited due to the relatively small areas affected.	Griscom et al. 2017a; Jauhiainen et al. 2008; Limpens et al. 2008; Munang et al. 2014
Biodiversity conservation	Biodiversity conservation refers to practices aiming at maintaining components of biological diversity. It includes conservation of ecosystems and natural habitats, maintenance and recovery of viable populations of species in their natural surroundings (<i>in-situ</i> conservation) and, in the case of domesticated or cultivated species, in the surroundings where they have developed their distinctive properties outside their natural habitats (<i>ex-situ</i> conservation). Examples of biodiversity conservation measures are establishment of protected areas to achieve specific conservation objectives, preservation of biodiversity hotspots, land management to recover natural habitats, interventions to expand	Biodiversity conservation measures interact with the climate system through many complex processes, which can have either positive or negative impacts. For example, establishment of protected areas can increase carbon storage in vegetation and soil, and tree planting to promote species richness and natural habitats can enhance carbon uptake capacity of ecosystems. Management of wild animals can influence climate <i>via</i> emissions of GHGs (from anaerobic fermentation of plant materials in the rumen), impacts on vegetation (<i>via</i> foraging), changes in fire frequency (as grazers lower grass and vegetation densities as potential fuels), and nutrient cycling and transport (by adding nutrients to soils). Conserving and restoring megafauna in northern regions also prevents thawing of permafrost and reduces woody encroachment, thus avoiding methane emissions and increases in albedo. Defaunation affects carbon storage in tropical forests and savannahs. In the tropics, the loss of mega-faunal frugivores is estimated be responsible for up to 10% reduction in carbon storage of global tropical forests. Frugivore	Bello et al. 2015; Campbell et al. 2008; Crooms et al. 2018; Kapos et al. 2008; Osuri et al. 2016; Schmitz et al. 2018a; Secretariat of the Convention on Biological Diversity 2008

	<p>or control selective plant or animal species in productive lands or rangelands (e.g., rewilding).</p>	<p>rewilding programmes in the tropics are seen as carbon sequestration options that can be equally effective as tree planting schemes. Biodiversity conservation measures generally favour adaptation, but can interact with food security, land degradation or desertification. Protected areas for biodiversity reduce the land available for food production, and abundancies in some species like large animals can influence land degradation processes by grazing, trampling and compacting soil surfaces, thereby altering surface temperatures and chemical reactions affecting sediment and carbon retention.</p>

Table 6.9 Integrated response options based on land management specifically for CDR

Integrated response option	Description	Context and caveats	Supporting evidence
Enhanced weathering of minerals	The enhanced weathering of minerals that naturally absorb CO ₂ from the atmosphere has been proposed as a CDR technology with a large mitigation potential. The rocks are ground to increase the surface area and the ground minerals are then applied to the land where they absorb atmospheric CO ₂ .	Enhanced mineral weathering can remove atmospheric CO ₂ . Since ground minerals can increase pH, there could be some benefits for efforts to prevent or reverse land degradation where acidification is the driver of degradation. Since increasing soil pH in acidified soils can increase productivity, the same effect could provide some benefit for food security. Minerals used for enhanced weathering need to be mined, and mining has large impacts locally, though the total area mined is likely to be small on the global scale.	Lenton 2010; Schuiling and Krijgsman 2006; Smith et al. 2016a; Taylor et al. 2016a; Beerling et al. 2018
Bioenergy and BECCS	Bioenergy production can mitigate climate change by delivering an energy service, therefore avoiding combustion of fossil energy. It is the most common renewable energy source used today in the world and has a large potential for future deployment (see Cross-Chapter Box 7 on bioenergy in this chapter). BECCS entails the use of bioenergy technologies (e.g. bioelectricity or biofuels) in combination with CO ₂ capture and storage (see also Glossary). BECCS simultaneously provides energy and can reduce atmospheric CO ₂ concentrations (see Chapter 2 and Cross-Chapter Box 7 on bioenergy in this chapter) for a discussion of potentials and atmospheric	Bioenergy and BECCS can compete for land and water with other uses. Increased use of bioenergy and BECCS can result in large expansion of cropland area, significant deforestation, and increased irrigation water use and water scarcity. Large-scale use of bioenergy can result in increased food prices and can lead to an increase in the population at risk of hunger. As a result of these effects, large-scale bioenergy and BECCS can have negative impacts for food security. Interlinkages of bioenergy and BECCS with climate change adaptation, land degradation, desertification, and biodiversity are highly dependent on local factors such as the type of energy crop, management practice, and previous land use. For example, intensive agricultural practices aiming to achieve high crop yields, as is the case for some bioenergy systems, may have significant effects on soil health, including depletion of soil organic matter, resulting in negative impacts on land degradation and desertification. However, with low inputs of fossil fuels and chemicals, limited irrigation, heat/drought tolerant species, using marginal land, biofuel programs can be beneficial to future adaptation of ecosystems. Planting bioenergy crops, like perennial grasses, on degraded land can increase soil carbon and ecosystem quality (including biodiversity), thereby helping to preserve soil quality, reverse land degradation, prevent desertification processes, and reduce food insecurity. These effects depend on the scale of deployment, the feedstock, the prior land use, and which other response options are included (see Section 6.4.4.2). Large-scale production of	Cross-Chapter Box 7 on Bioenergy in this chapter; IPCC SR15; Chapter 2; Chapter 4; Section 6.4; Chapter 7; Baker et al. 2019a; Calvin et al. 2014c; Chaturvedi et al. 2013; Chum et al. 2011; Clarke et al. 2014a; Correa et al. 2017; Creutzig et al. 2015; Dasgupta et al. 2014; Don et al. 2012; Edelenbosch et al. 2017; Edenhofer et al. 2011; FAO 2011; Favero and Mendelsohn 2014; Fujimori et al. 2018a; Fuss et al. 2016, 2018a; Hejazi et al. 2015a; Kemper 2015; Kline et al. 2017; Lal 2014; Lotze-Campen et al. 2013; Mello et al. 2014b; Muratori et al. 2016; Noble et al. 2014; Obersteiner et al. 2016a; Popp et al. 2011c, 2014a, 2017; Riahi et al. 2017a; Robertson et al. 2017b; Sánchez et al. 2017; Searchinger et al. 2018; Sims et al. 2014; Slade et al. 2014; Smith

	<p>effects); thus, BECCS is considered a CDR technology. While several BECCS demonstration projects exist, it has yet to be deployed at scale. Bioenergy and BECCS are widely-used in many future scenarios as a climate change mitigation option in the energy and transport sector, especially those scenarios aimed at a stabilisation of global climate at 2°C or less above pre-industrial levels.</p>	<p>bioenergy can require significant amounts of land, increasing potential pressures for land conversion and land degradation. Low levels of bioenergy deployment require less land, leading to smaller effects on forest cover and food prices; however, these land requirements could still be substantial. In terms of feedstocks, some feedstocks, grown in some regions, may not need irrigation, and thus would not compete for water with food crops. Additionally, the use of residues or microalgae could limit competition for land and biodiversity loss; however, residues could result in land degradation or decreased soil organic carbon. Whether woody bioenergy results in increased competition for land or not is disputed in the literature, with some studies suggesting reduced competition and others suggesting enhanced. One study noted that this effect changes over time, with complementarity between woody bioenergy and forest carbon sequestration in the near-term, but increased competition for land with afforestation/reforestation in the long-term. Additionally, woody bioenergy could also result in land degradation.</p>	<p>et al. 2016a; Torvanger 2018; van Vuuren et al. 2011, 2015b, 2016; Wise et al. 2015; Tian et al. 2018;</p>

Integrated response option	Description	Context and caveats	Supporting evidence
Dietary change	Sustainable healthy diets represent a range of dietary changes to improve human diets, to make them healthy in terms of the nutrition delivered, and also (economically, environmentally and socially) sustainable. A “contract and converge” model of transition to sustainable healthy diets would involve a reduction in overconsumption (particularly of livestock products) in over-consuming populations, with increased consumption of some food groups in populations where minimum nutritional needs are not met. Such a conversion could result in a decline in undernourishment, as well as reduction in the risk of morbidity and mortality due to over-consumption.	A dietary shift away from meat can reduce greenhouse gas emissions, reduce cropland and pasture requirements, enhance biodiversity protection, and reduce mitigation costs. Additionally, dietary change can both increase potential for other land-based response options and reduce the need for them by freeing land. By decreasing pressure on land, demand reduction through dietary change could also allow for decreased production intensity, which could reduce soil erosion and provide benefits to a range of other environmental indicators such as deforestation and decreased use of fertiliser (N and P), pesticides, water and energy, leading to potential benefits for adaptation, desertification, and land degradation.	Chapter 5; Section 6.4.4.2; Aleksandrowicz et al. 2016a; Bajželj et al. 2014; Bonsch et al. 2016; Erb et al. 2016; Godfray et al. 2010; Haberl et al. 2011; Havlík et al. 2014; Muller et al. 2017a; Smith et al. 2013; Springmann et al. 2018a; Stehfest et al. 2009; Tilman and Clark 2014; Wu et al. 2019
Reduced post-harvest losses	Approximately one-third of the food produced for human consumption is wasted in post-production operations. Most of these losses are due to poor storage management. Post-harvest food losses underlie the food system’s failure to equitably enable accessible and affordable food in all countries. Reduced post-harvest food losses can improve food security in developing countries (while food loss in developed countries mostly occurs at the retail/consumer stage). The key drivers for post-harvest waste in developing countries are structural and infrastructure deficiencies. Thus, reducing food waste at the post-harvest stage requires responses that process,	Differences exist between farm food waste reduction technologies between small-scale agricultural systems and large-scale agricultural systems. A suite of options includes farm level storage facilities, trade or exchange processing technologies including food drying, onsite farm processing for value addition, and improved seed systems. For large scale agri-food systems, options include cold chains for preservation, processing for value addition and linkages to value chains that absorb the harvests almost instantly into the supply chain. In addition to the specific options to reduce food loss and waste, there are more systemic possibilities related to food systems. Improving and expanding the ‘dry chain’ can significantly reduce food losses at the household level. Dry chains are analogous to the	Chapter 5; Anisah et al. 2017; Bajželj et al. 2014; Billen et al. 2018; Bradford et al. 2018; Chaboud and Daviron 2017; Göbel et al. 2015; Gustavsson et al. 2011; Hengsdijk and de Boer 2017; Hodges et al. 2011; Ingram et al. 2016;

	preserve and, where appropriate, redistribute food to where it can be consumed immediately.	cold chain and refers to the ‘initial dehydration of durable commodities to levels preventing fungal growth’ followed by storage in moisture-proof containers. Regional and local food systems are now being promoted to enable production, distribution, access and affordability of food. Reducing post-harvest losses has the potential to reduce emissions and could simultaneously reduce food costs and increase availability. The perishability and safety of fresh foods are highly susceptible to temperature increase.	Kissinger et al. 2018; Kumar and Kalita 2017; Ritzema et al. 2017; Sheahan and Barrett 2017; Wilhelm et al. 2016
Reduced food waste (consumer or retailer)	Since approximately 9-30% of all food is wasted, reducing food waste can reduce pressure on land (see also reducing post-harvest losses).	Reducing food waste could lead to a reduction in cropland area and GHG emissions, resulting in benefits for mitigation. By decreasing pressure on land, food waste reduction could allow for decreased production intensity, which could reduce soil erosion and provide benefits to a range of other environmental indicators such as deforestation and decreases in use of fertiliser (N and P), pesticides, water and energy, leading to potential benefits for adaptation, desertification, and land degradation.	Alexander et al. 2016; Bajželj et al. 2014; Gustavsson et al. 2011; Kummu et al. 2012a; Muller et al. 2017a; Smith et al. 2013; Vermeulen et al. 2012b
Material substitution	Material substitution involves the use of wood or agricultural biomass (e.g. straw bales) instead of fossil fuel-based materials (e.g. concrete, iron, steel, aluminium) for building, textiles or other applications.	Material substitution reduces carbon emissions both because the biomass sequesters carbon in materials while re-growth of forests can lead to continued sequestration, and because it reduces the demand for fossil fuels, delivering a benefit for mitigation. However, a potential trade-off exists between conserving carbon stocks and using forests for wood products. If the use of material for substitution was large enough to result in increased forest area, then the adverse side-effects for adaptation and food security would be similar to that of reforestation and afforestation. In addition, some studies indicate that wooden buildings, if properly constructed, could reduce fire risk compared to steel, creating a co-benefit for adaptation. The effects of material substitution on land degradation depend on management practice; some forms of logging can lead to increased land degradation. Long-term forest management with carbon storage in long-lived products also results in atmospheric carbon dioxide (CO ₂) removal. Table 6.11 Integrated response options based on value chain management through supply management

Integrated response option	Description	Context and caveats	Supporting evidence
Sustainable sourcing	Sustainable sourcing includes approaches to ensure that the production of goods is done in a sustainable way, such as through low-impact agriculture, zero-deforestation supply chains, or sustainably harvested forest products. Currently around 8% of global forest area has been certified in some manner, and 25% of global industrial roundwood comes from certified forests. Sustainable sourcing also aims to enabling producers to increase their percentage of the final value of commodities. Adding value to products requires improved innovation, coordination and efficiency in the food supply chain, as well as labelling to ensure consumer demands. As such, sustainable sourcing is an approach that combines both supply and demand-side management. Promoting sustainable and value-added products can reduce the need for compensatory extensification of agricultural areas and is a specific commitment of some sourcing programs (such as forest certification programs). Table 7.3 (Chapter 7) provides examples of the many sustainable sourcing programs now available globally.	Sustainable sourcing is expanding but accounts for only a small fraction of overall food and material production; many staple food crops do not have strong sustainability standards. Sustainable sourcing provides potential benefits for both climate mitigation and climate adaptation by reducing drivers of unsustainable land management, and by diversifying and increasing flexibility in the food system to climate stressors and shocks. Sustainable sourcing can lower expenditures of food processors and retailers by reducing losses. Adding value to products can extend a producer's marketing season and provide unique opportunities to capture niche markets thereby increasing their adaptive capacity to climate change. Sustainable sourcing can also provide significant benefits for food security, while simultaneously creating economic alternatives for the poor. Sustainable sourcing programmes often also have positive impacts on the overall efficiency of the food supply chain and can create closer and more direct links between producers and consumers. In some cases, processing of value-added products could lead to higher emissions or demand of resources in the food system, potentially leading to small adverse impacts on land degradation and desertification challenges.	Chapter 2; Chapter 3; Chapter 5; Section 6.4; Accorsi et al. 2017; Bajželj et al. 2014; Bustamante et al. 2014a; Clark and Tilman 2017; Garnett 2011; Godfray et al. 2010a; Hertel 2015; Ingram et al. 2016a; James and James 2010a; Muller et al. 2017a; Tilman and Clark 2014a; Springer et al. 2015; Tayleur et al. 2017
Management of supply chains	Management of supply chains include a set of polycentric governance processes focused on improving efficiency and sustainability across the supply chain for each product, to reduce climate risk and profitably reduce emissions. Trade-driven food supply chains are becoming increasingly complex and contributing to emissions. Improved management of supply chains can include both: 1) better food transport and increasing the economic value or reduce risks	Successful implementation of supply chain management practices is dependent on organisational capacity, the agility and flexibility of business strategies, the strengthening of public-private policies and effectiveness of supply-chain governance. Existing practices include a) greening supply chains (e.g. utilising products and services with a reduced impact on the environment and human health), b) adoption of specific sustainability instruments among agri-food companies (e.g. eco-	Chapter 5; Barthel and Isendahl 2013; Haggblade et al. 2017; Lewis and Witham 2012; Michellini et al. 2018; Minot 2014; Mundler and Rumpus 2012; Tadasse et al.

	of commodities through production processes (e.g., packaging, processing, cooling, drying, extracting) and 2) improved policies for stability of food supply, as globalised food systems and commodity markets are vulnerable to food price volatility. The 2007-2008 food price shocks negatively affected food security for millions, most severely in Sub-Saharan Africa. Increasing the stability of food supply chains is a key goal to increase food security, given that climate change threatens to lead to more production shocks in the future.	innovation practices), c) adopting emission accounting tools (e.g. carbon and water foot-printing), and d) implementing “demand forecasting” strategies (e.g. changes in consumer preference for 'green' products). In terms of food supply, measures to improve stability in traded markets can include: 1) financial and trade policies, such as reductions on food taxes and import tariffs; 2) shortening food supply chains (SFSCs); 3) increasing food production; 4) designing alternative distribution networks; 5) increasing food market transparency and reducing speculation in futures markets; 6) increasing storage options; and 7) increasing subsidies and food-based safety nets.	2016; Wheeler and von Braun 2013; Wilhelm et al. 2016; Wodon and Zaman 2010; The World Bank 2011
Enhanced urban food systems	Urban areas are becoming the principal territories for intervention in improving food access through innovative strategies that aim to reduce hunger and improve livelihoods. Interventions include Urban and Peri-urban Agriculture and Forestry and local food policy and planning initiatives such as Food Policy Councils and city-region-wide regional food strategies. Such systems have demonstrated inter-linkages of the city and its citizens with surrounding rural areas to create sustainable, and more nutritious food supplies for the city, while improving the health status of urban dwellers, reducing pollution levels, adapting to and mitigating climate change, and stimulating economic development. Options include support for urban and peri-urban agriculture, green infrastructure (e.g., green roofs), local markets, enhanced social (food) safety nets and development of alternative food sources and technologies, such as vertical farming.	Urban territorial areas have a potential to reduce GHG emissions through improved food systems to reduce vehicle miles of food transportation, localised carbon capture and food waste reduction. The benefits of Urban food forests that are intentionally planted woody perennial food producing species, are also cited for their carbon sequestration potentials. However, new urban food systems may have diverse unexpected adverse side-effects with climate systems, such as lower efficiencies in food supply and higher costs than modern large-scale agriculture. Diversifying markets, considering value added products in the food supply system may help to improve food security by increasing its economic performance and revenues to local farmers.	Akhtar et al. 2016; Benis and Ferrão 2017; Brinkley et al. 2013, 2016; Chappell et al. 2016; Goldstein et al. 2016; Kowalski and Conway 2018; Lee-Smith 2010; Barthel and Isendahl 2013; Lwasa et al. 2014, 2015; Revi et al. 2014; Specht et al. 2014; Tao et al. 2015; UPAF (date)
Improved food processing and retailing	Improved food processing and retailing involves several practices related to a) greening supply chains (e.g., utilising products and services with a reduced impact on the environment and human health), b) adoption of specific sustainability instruments among agri-food companies (e.g., eco-innovation practices), c) adopting emission accounting tools (e.g., carbon and water foot-printing), d) implementing “demand forecasting” strategies (e.g., changes in consumer	Improved food processing and retailing can provide benefits for climate mitigation since GHG-friendly foods can reduce agri-food GHG emissions from transportation, waste and energy use. In cases where climate extremes and natural disasters disrupt supply chain networks, improved food processing and retailing can benefit climate adaptation by buffering the impacts of changing temperature and rainfall patterns on upstream agricultural production. It can provide benefits for food security	Chapter 2; Chapter 5; Avetisyan et al. 2014; Garnett et al. 2013; Godfray et al. 2010; Mohammadi et al. 2014; Porter et al. 2016; Ridoutt et al. 2016; Song et al. 2017

	preference for 'green' products) and, e) supporting polycentric supply-chain governance processes.	by supporting healthier diets and reducing food loss and waste. Successful implementation is dependent on organisational capacity, the agility and flexibility of business strategies, the strengthening of public-private policies and effectiveness of supply-chain governance.	
Improved energy use in food systems	Energy efficiency of agriculture can be improved to reduce the dependency on non-renewable energy sources. This can be realised either by decreased energy inputs, or through increased outputs per unit of input. In some countries, managerial inefficiency (rather than a technology gap) is the main source for energy efficiency loss. Heterogenous patterns of energy efficiency exist at the national scale and promoting energy efficient technologies along with managerial capacity development can reduce the gap and provide large benefits for climate adaptation. Improvements in carbon monitoring and calculation techniques such as the foot-printing of agricultural products can enhance energy efficiency transition management and uptake in agricultural enterprises.	Transformation to low carbon technologies such as renewable energy and energy efficiency can offer opportunities for significant climate change mitigation by providing a substitute to transport fuel (for example) that could benefit marginal agricultural resources, while simultaneously contributing to long term economic growth. In poorer nations, increased energy efficiency in agricultural value-added production, in particular, can provide large mitigation benefits. Under certain scenarios, the efficiency of agricultural systems can stagnate and could exert pressure on grasslands and rangelands, thereby impacting land degradation and desertification. Rebound effects can also occur, with adverse impacts on emissions.	Al-Mansour F and Jejeic V 2017; Baptista et al. 2013; Gunatilake et al. 2014; Begum et al. 2015; Jebli and Youssef 2017; van Vuuren et al. 2017b

Table 6.12 Integrated response options based on risk management

Integrated response option	Description	Context and caveats	Supporting evidence
Management of urban sprawl	Unplanned urbanisation leading to sprawl and extensification of cities along the rural-urban fringe has been identified as a driver of forest and agricultural land loss and a threat to food production around cities. It has been estimated that urban expansion will result in a 1.8–2.4% loss of global croplands by 2030. This rapid urban expansion is especially strong in new emerging towns and cities in Asia and Africa. Policies to prevent such urbanisation have included integrated land use planning, agricultural zoning ordinances and agricultural districts, urban redevelopment, arable land reclamation, and transfer/purchase of development rights or easements.	The prevention of uncontrolled urban sprawl may provide adaptation co-benefits, but adverse side effects for adaptation might arise due to restricted ability of people to move in response to climate change.	Barbero-Sierra et al. 2013a; Bren d'Amour et al. 2016; Cai et al. 2013; Chen 2007; Francis et al. 2012a; Gibson et al. 2015; Lee et al. 2015; Qian et al. 2015; Shen et al. 2017; Tan et al. 2009
Livelihood diversification	When households' livelihoods depend on a small number of sources of income without much diversification, and when those income sources are in fields that are highly climate dependent, like agriculture and fishing, this dependence can put food security and livelihoods at risk. Livelihood diversification (drawing from a portfolio of dissimilar sources of livelihood as a tool to spread risk) has been identified as one option to increase incomes and reduce poverty, increase food security, and promote climate resilience and risk reduction.	Livelihood diversification offers benefits for desertification and land degradation, particularly through non-traditional crops or trees in agroforestry systems which improve soil. Livelihood diversification may increase on-farm biodiversity due to these investments in more ecosystem-mimicking production systems, like agroforestry and polycultures. Diversification into non-agricultural fields, such as wage labour or trading, is increasingly favoured by farmers as a low-cost strategy, particularly to respond to increasing climate risks.	Adger 1999; Ahmed and Stepp 2016a; Antwi-Agyei et al. 2014; Barrett et al. 2001; Berman et al. 2012; Bryceson 1999; DiGiano and Racelis 2012; Ellis 1998, 2008; Ngigi et al. 2017; Rakodi 1999; Thornton and Herrero 2014; Little et al. 2001
Use of local seeds	Using local seeds (also called seed sovereignty) refers to use of non-improved, non-commercial seeds varieties. These can be used and stored by local farmers as low-cost inputs and can often help contribute to the conservation of local varieties and land races, increasing local biodiversity. Many local seeds also require no pesticide or fertiliser use, leading to less land degradation in their use.	Use of local seeds is important in the many parts of the developing world that do not rely on commercial seed inputs. Promotion of local seed saving initiatives can include seed networks, banks and exchanges, and non-commercial open source plant breeding. These locally developed seeds can both help protect local agrobiodiversity and can often be more climate resilient than generic commercial varieties, although	Bowman 2015; Campbell and Veteto 2015; Coomes et al. 2015; Kloppenberg 2010; Luby et al. 2015; van Niekerk and Wynberg 2017; Patnaik et al. 2017; Reisman 2017;

		the impacts on food security and overall land degradation are inconclusive.	Vasconcelos et al. 2013; Wattnem 2016
Disaster risk management	Disaster risk management encompasses many approaches to try to reduce the consequences of climate and weather-related disasters and events on socio-economic systems. The Hyogo Plan of Action is a UN framework for nations to build resilience to disasters through effective integration of disaster risk considerations into sustainable development policies. For example, in Vietnam a national strategy on disasters based on Hyogo has introduced the concept of a “four-on-the-spot” approach for disaster risk management of: proactive prevention; timely response; quick and effective recovery; and sustainable development. Other widespread approaches to disaster risk management include using early warning systems that can encompass 1) education systems; 2) hazard and risk maps; 3) hydrological and meteorological monitoring (such as flood forecasting or extreme weather warnings); and 4) communications systems to pass on information to enable action. These approaches have long been considered to reduce the risk of household asset damage during one-off climate events and are increasingly being combined with climate adaptation policies.	Community-based disaster risk management has been pointed to as one of the most successful ways to ensure information reaches people, who need to be participants in risk reduction. Effective disaster risk management approaches must be ‘end-to-end,’ both reaching communities at risk and supporting and empowering vulnerable communities to take appropriate action. The most effective early warning systems are not simply technical systems of information dissemination, but utilise and develop community capacities, create local ownership of the system, and are based on a shared understanding of needs and purpose. Tapping into existing traditional or local knowledge has also been recommended for disaster risk management approaches to reducing vulnerability.	Ajibade and McBean 2014; Alessa et al. 2016; Bouwer et al. 2014; Carreño et al. 2007; Cools et al. 2016; Djalante et al. 2012; Garschagen 2016; Maskrey 2011; Mercer 2010; Sternberg and Batbuyan 2013; Thomalla et al. 2006; Vogel and O’Brien 2006; Schipper and Pelling 2006
Risk sharing instruments	Risk sharing instruments can encompass a variety of approaches. Intra-household risk pooling is a common strategy in rural communities, such as through extended family financial transfers; one study found 65% of poor households in Jamaica report receiving transfers, and such transfers can account for up to 75% of household income or more after crisis events. Community rotating credit associations (ROSCAs) have long been used for general risk pooling and can be a source of financing to cope with climate variability as well. Credit services have been shown to be important for adaptation actions and risk reduction. Insurance of various kinds is also a form of risk pooling. Commercial crop insurance is one of the most widely used risk-hedging	Locally developed risk pooling measures show general positive impacts on household livelihoods. However, more commercial approaches have mixed effects. Commercial crop insurance is highly subsidised in much of the developed world. Index insurance programmes have often failed to attract sufficient buyers or have remained financially unfeasible for commercial insurance sellers. The overall impact of index insurance on food production supply and access has also not been assessed. Traditional crop insurance has generally been seen as positive for food security as it leads to expansion of agricultural production areas and increased food supply. However, insurance may also ‘mask’ truly risky agriculture and prevent farmers from seeking less risky	Akter et al. 2016; Annan and Schlenker 2015; Claassen et al. 2011; Fenton et al. 2017; Giné et al. 2008; Goodwin and Smith 2003; Hammill et al. 2008; Havemenn and Muccione 2011; Jaworski 2016; Meze-Hausken et al. 2009; Morduch and Sharma 2002; Bhattamishra and Barrett 2010; Peterson 2012;

	<p>financial vehicles, and can involve both traditional indemnity-based insurance that reimburses clients for estimated financial losses from shortfalls, or index insurance that pays out the value of an index (such as weather events) rather than actual losses; the former is more common for large farms in the developed world and the latter for smaller non-commercial farms in developing countries.</p>	<p>production strategies. Insurance can also provide perverse incentives for farmers to bring additional lands into crop production, leading to greater risk of degradation.</p>	<p>Sanderson et al. 2013; Skees and Collier 2012; Smith and Glauber 2012</p>

Cross-Chapter Box 7: Bioenergy and Bioenergy with Carbon Dioxide Capture and Storage (BECCS) in mitigation scenarios

Katherine Calvin (The United States of America), Almut Arneth (Germany), Luis Barioni (Brazil), Francesco Cherubini (Norway/Italy), Annette Cowie (Australia), Joanna House (United Kingdom), Francis X. Johnson (Sweden), Alexander Popp (Germany), Joana Portugal Pereira (United Kingdom), Mark Rounsevell (United Kingdom), Raphael Slade (United Kingdom), Pete Smith (United Kingdom)

Bioenergy and BECCS potential

Using biomass to produce heat, electricity and transport fuels (bioenergy) instead of coal, oil, and natural gas can reduce GHG emissions. Combining biomass conversion technologies with systems that capture CO₂ and inject it into geological formations (bioenergy with carbon dioxide capture and storage (BECCS)) can deliver net negative emissions. The net climate effects of bioenergy and BECCS depend on the magnitude of bioenergy supply chain emissions and land/climate interactions, described further below.

Biomass in 2013 contributed ~60 EJ (10%) to global primary energy⁴ (WBA 2016). In 2011, the IPCC *Special Report on Renewable Energy Sources* concluded that biomass supply for energy could reach 100-300 EJ yr⁻¹ by 2050 with the caveat that the technical potential⁵ cannot be determined precisely while societal preferences are unclear; that deployment depends on “factors that are inherently uncertain”; and that biomass use could evolve in a “sustainable” or “unsustainable” way depending on the governance context (IPCC, 2011). The IPCC WGIII AR5 report noted, in addition, that high deployment levels would require extensive use of technologies able to convert lignocellulosic biomass such as forest wood, agricultural residues, and lignocellulosic crops. The SR15 noted that high levels of bioenergy deployment may result in adverse side-effects for food security, ecosystems, biodiversity, water use, and nutrients (de Coninck et al. 2018).

Although estimates of potential are uncertain, there is *high confidence* that the most important factors determining future biomass supply are land availability and land productivity. These factors are in turn determined by competing uses of land and a myriad of environmental and economic considerations (Dornburg et al. 2010; Batidzirai et al. 2012; Erb et al. 2012; Slade 2014, Searle and Malins 2014). Overlaying estimates of technical potential with such considerations invariably results in a smaller estimate. Recent studies that have attempted to do this estimate that 50-244 EJ biomass could be produced on 0.1-13 Mkm² (Fuss et al. 2018a; Schueler et al. 2016; Searle and Malins 2014; IPCC SR15; Wu et al. 2019; Heck et al. 2018; de Coninck et al. 2018). While preferences concerning economic, social and environmental objectives vary geographically and over time, studies commonly estimate “sustainable” potentials by introducing restrictions intended to protect environmental values and avoid negative effects on poor and vulnerable segments in societies.

Estimates of global geological CO₂ storage capacity are large – ranging from 1680 GtCO₂ to 24000 GtCO₂ (McCollum et al. 2014) – however the potential of BECCS may be significantly constrained by socio-political and technical and geographical considerations, including limits to knowledge and experience (Chapter 6, 7).

⁴ FOOTNOTE: Of this, more than half was traditional biomass, predominately used for cooking and heating in developing regions, bioelectricity accounted for ~1.7EJ, and transport biofuels for 3.19EJ. (Cross-Chapter Box 12 on Traditional Biomass, Chapter 7)

⁵ FOOTNOTE: The future availability of biomass is usually discussed in terms of a hierarchy of potentials: theoretical>technical>economic. Caution is required, however, as these terms are not always defined consistently and estimates depend on the specific definitions and calculation methodologies.

Bioenergy and BECCS use in mitigation scenarios

Most mitigation scenarios include substantial deployment of bioenergy technologies (Clarke et al. 2014; Fuss et al. 2014; IPCC SR15). Across all scenarios, the amount of bioenergy and BECCS ranges from 0 EJ yr⁻¹ to 561 EJ yr⁻¹ in 2100 (Cross-Chapter Box 7 Figure 1, left panel). Notably, all 1.5°C pathways include bioenergy, requiring as much as 7 Mkm² to be dedicated to the production of energy crops in 2050 (Rogelj et al. 2018a). If BECCS is excluded as a mitigation option, studies indicate that more biomass may be required in order to substitute for a greater proportion of fossil fuels (Muratori et al. 2016; Rose et al. 2014a).

Different Integrated Assessment Models (IAMs) use alternative approaches to land allocation when determining where and how much biomass is used, with some relying on economic approaches and some relying on rule-based approaches (Popp et al. 2014b). Despite these differences a consistent finding across models is that increasing biomass supply to the extent necessary to support deep decarbonisation is likely to involve substantial land use change (Popp et al. 2017) (Cross-Chapter Box 9). In model runs, bioenergy deployment and the consequent demand for biomass and land, is influenced by assumptions around the price of bioenergy, the yield of bioenergy crops, the cost of production (including the costs of fertiliser and irrigation if used), the demand for land for other uses, and the inclusion of policies (e.g., subsidies, taxes, constraints) that may alter land use or bioenergy demand. In general, higher carbon prices result in greater bioenergy deployment (Cross-Chapter Box 7 Figure 1, right panel) and a larger percentage of BECCS. Other factors can also strongly influence bioenergy use, including the cost and availability of fossil fuels (Calvin et al. 2016a), socioeconomics (Popp et al. 2017), and policy (Calvin et al. 2014a; Reilly et al. 2012a).

Cross-Chapter Box 7 Figure 1: Global bioenergy consumption in IAM scenarios. Data is from an update of the IAMC Scenario Explorer developed for the SR15 (Huppmann et al. 2018; Rogelj et al. 2018a). The left panel shows bioenergy deployment over time for the entire scenario database (grey areas) and the four illustrative pathways from SR15 (Rogelj et al. 2018a). The right panel shows global land area for energy crops in 2100 versus total global bioenergy consumption in 2100; colours indicate the carbon price in 2100 (in 2010 USD per tCO₂). Note that this figure includes 409 scenarios, many of which exceed 1.5°C.

Co-benefits, adverse side effect, and risks associated with bioenergy

The production and use of biomass for bioenergy can have co-benefits, adverse side effects, and risks for land degradation, food insecurity, GHG emissions, and other environmental goals. These impacts are context specific and depend on the scale of deployment, initial land use, land type, bioenergy feedstock, initial carbon stocks, climatic region and management regime (Qin et al. 2016; Del Grosso et al. 2014; Alexander et al. 2015; Popp et al. 2017; Davis et al. 2013a; Mello et al. 2014b; Hudiburg

1 et al. 2015; Carvalho et al. 2016; Silva-Olaya et al. 2017; Whitaker et al. 2018; Robledo-Abad et al.
2 2017; Jans et al. 2018).

3 Synergistic outcomes with bioenergy are possible, for example, strategic integration of perennial
4 bioenergy crops with conventional crops can provide multiple production and environmental benefits
5 including management of dryland salinity, enhanced biocontrol and biodiversity, and reduced
6 eutrophication (Davis et al. 2013b; Larsen et al. 2017; Cacho et al. 2018; Odgaard et al. 2019).
7 Additionally, planting perennial bioenergy crops on low carbon soil could enhance soil carbon
8 sequestration (Bárcena et al. 2014; Schröder et al. 2018; Walter et al. 2015; Robertson et al. 2017a;
9 Rowe et al. 2016; Chadwick et al. 2014; Immerzeel et al. 2014; Del Grosso et al. 2014; Mello et al.
10 2014c; Whitaker et al. 2018). However, large-scale expansion of bioenergy may also result in
11 increased competition for land (DeCicco 2013; Humpenöder et al. 2018a; Bonsch et al. 2016; Harris
12 et al. 2015; Richards et al. 2017; Ahlgren et al. 2017; Bárcena et al. 2014), increased greenhouse gas
13 emissions from land use change and land management, loss in biodiversity, and nutrient leakage
14 (Harris et al. 2018; Harper et al. 2018; Popp et al. 2011c; Wiloso et al. 2016; Behrman et al. 2015;
15 Valdez et al. 2017; Hof et al. 2018). If biomass crops are planted on land with a high carbon stock, the
16 carbon loss due to land conversion may take decades to over a century to be compensated by either
17 fossil fuel substitution or CCS (Harper et al. 2018). Competition for land may be experienced locally
18 or regionally and is one of the determinants of food prices, food security (Popp et al. 2014a; Bailey
19 2013; Pahl-Wostl et al. 2018; Rulli et al. 2016; Yamagata et al. 2018; Franz et al. 2017; Kline et al.
20 2017; Schröder et al. 2018) and water availability (Rulli et al. 2016; Bonsch et al. 2015b; Pahl-Wostl
21 et al. 2018; Bailey 2013; Chang et al. 2016; Bárcena et al. 2014).

22 Experience in countries at quite different levels of economic development (Brazil, Malawi and
23 Sweden) has shown that persistent efforts over several decades to combine improved technical
24 standards and management approaches with strong governance and coherent policies, can facilitate
25 long-term investment in more sustainable production and sourcing of liquid biofuels (Johnson and
26 Silveira 2014). For woody biomass, combining effective governance with active forest management
27 over long time periods can enhance substitution-sequestration co-benefits, such as in Sweden where
28 bioenergy has tripled during the last 40 years (currently providing about 25% of total energy supply)
29 while forest carbon stocks have continued to grow (Lundmark et al. 2014). A variety of approaches
30 are available at landscape level and in national and regional policies to better reconcile food security,
31 bioenergy and ecosystem services, although more empirical evidence is needed (Mudombi et al. 2018;
32 Manning et al. 2015; Kline et al. 2017; Maltsoglou et al. 2014; Lamers et al.).

33 Thus, while there is *high confidence* that the technical potential for bioenergy and BECCS is large,
34 there is also *very high confidence* that this potential is reduced when environmental, social and
35 economic constraints are considered. The effects of bioenergy production on land degradation, water
36 scarcity, biodiversity loss, and food insecurity are scale and context specific (*high confidence*).
37 Large areas of monoculture bioenergy crops that displace other land uses can exacerbate these
38 challenges, while integration into sustainably managed agricultural landscapes can ameliorate them
39 (*medium confidence*).

40 **Inventory reporting for BECCS and bioenergy**

41 One of the complications in assessing the total GHG flux associated with bioenergy under
42 UNFCCC reporting protocols is that fluxes from different aspects of bioenergy life cycle are reported
43 in different sectors and are not linked. In the energy sector, bioenergy is treated as carbon neutral at
44 the point of biomass combustion because all change in land carbon stocks due to biomass harvest or
45 land use change related to bioenergy are reported under AFOLU sector. Use of fertilisers is captured
46 in the Agriculture sector, while fluxes related to transport/conversion and removals due to CCS are
47 reported in the energy sector. IAMs follow a similar reporting convention. Thus, the whole life cycle

GHG effects of bioenergy systems are not readily observed in national GHG inventories or modelled emissions estimates (see also IPCC 2006; SR15 Chapter 2 Technical Annex; Chapter 2).

Bioenergy in this report

Bioenergy and BECCS are discussed throughout this special report. Chapter 1 provides an introduction to bioenergy and BECCS and its links to land and climate. Chapter 2 discusses mitigation potential, land requirements and biophysical climate implications. Chapter 4 includes a discussion of the threats and opportunities with respect to land degradation. Chapter 5 discusses linkages between bioenergy and BECCS and food security. Chapter 6 synthesises the co-benefits and adverse side-effects for mitigation, adaptation, desertification, land degradation, and food security, as well as barriers to implementation (e.g., cost, technological readiness, etc.). Chapter 7 includes a discussion of risk, policy, governance, and decision-making with respect to bioenergy and BECCS.

6.3 Potentials for addressing the land challenges

In this section, we assess how each of the integrated response options described in Section 6.2 address the land challenges of climate change mitigation (6.3.1), climate change adaptation (6.3.2), desertification (6.3.3), land degradation (6.3.4), and food security (6.3.5). The quantified potentials across all of mitigation, adaptation, desertification, land degradation and food security are summarised and categorised for comparison in section 6.3.6.

6.3.1 Potential of the integrated response options for delivering mitigation

In this section, the impacts of integrated response options on climate change mitigation are assessed.

6.3.1.1 Integrated response options based on land management

In this section, the impacts on climate change mitigation of integrated response options based on land management are assessed. Some of the caveats of these potential mitigation studies are discussed in Chapter 2 and section 6.2.1.

6.3.1.1.1 Integrated response options based on land management in agriculture

Increasing the productivity of land used for food production can deliver significant mitigation by avoiding emissions that would occur if increased food demand were met through expansion of the agricultural land area (Burney et al., 2010). If pursued through increased agrochemical inputs, numerous adverse impacts on greenhouse gas emissions (and other environmental sustainability) can occur (Table 6.5), but if pursued through sustainable intensification, increased food productivity could provide high levels of mitigation. For example, yield improvement has been estimated to have contributed to emissions savings of >13 GtCO₂ yr⁻¹ since 1961 (Burney et al., 2010; Table 6.13). This can also reduce the greenhouse gas intensity of products (Bennetzen et al., 2016) which means a smaller environmental footprint of production, since demand can be met using less land and/or with fewer animals.

Improved cropland management could provide moderate levels of mitigation (1.4-2.3 GtCO₂e yr⁻¹; Smith et al. 2008, 2014c; Pradhan et al., 2013; Table 6.13). The lower estimate of potential is from Pradhan et al. (2013) for decreasing emissions intensity, and the upper end of technical potential is estimated by adding technical potentials for cropland management (about 1.4 GtCO₂e yr⁻¹), rice management (about 0.2 GtCO₂e yr⁻¹) and restoration of degraded land (about 0.7 GtCO₂e yr⁻¹) from Smith et al. (2008) and Smith et al. (2014c). Note that much of this potential arises from soil carbon sequestration so there is an overlap with that response option (see 6.3.1.1.3).

Grazing lands can store large stocks of carbon in soil and root biomass compartments (Conant and Paustian 2002; O'Mara 2012; Zhou et al. 2017). The global mitigation potential is moderate (1.4–1.8 GtCO₂ yr⁻¹), with the lower value in the range for technical potential taken from Smith et al. (2008)

1 which includes only grassland management measures, and the upper value in the range from Herrero
 2 et al. (2016), which includes also indirect effects and some components of livestock management, and
 3 soil carbon sequestration, so there is overlap with these response options (see below and 6.3.1.1.3).
 4 Conant et al. (2005) caution that increases in soil carbon stocks could be offset by increases in N₂O
 5 fluxes.

6 The mitigation potential of improved livestock management is also moderate (0.2–1.8 GtCO₂e yr⁻¹;
 7 Smith et al. (2008) including only direct livestock measures; Herrero et al. (2016) include also indirect
 8 effects, and some components of grazing land management and soil carbon sequestration) to high
 9 (6.13 Gt CO₂e yr⁻¹; Pradhan et al., 2013; Table 6.13). There is an overlap with other response options
 10 (see above and 6.3.1.1.3).

11 Zomer et al. (2017) reported that the trees agroforestry landscapes have increased carbon stock by
 12 7.33 GtCO₂ between 2000–2010, which is equivalent to 0.7 GtCO₂ yr⁻¹. Estimates of global potential
 13 range from 0.1 GtCO₂ yr⁻¹ to 5.7 GtCO₂ yr⁻¹ (from an optimum implantation scenario of Hawken,
 14 2014), based on an assessment of all values in Griscom et al. (2017a), Hawken (2014), Zomer et al
 15 2016., and Dickie et al. (2014) (Table 6.13).

16 Agricultural diversification mainly aims at increasing climate resilience, but it may have a small (but
 17 globally unquantified) mitigation potential as a function of type of crop, fertiliser management, tillage
 18 system, and soil type (Campbell et al. 2014; Cohn et al. 2017).

19 Reducing conversion of grassland to cropland could provide significant climate mitigation by
 20 retaining soil carbon stocks that might otherwise be lost. When grasslands are converted to croplands,
 21 they lose about 36% of their soil organic carbon stocks after 20 years (Poeplau et al. 2011). Assuming
 22 an average starting soil organic carbon stock of grasslands of 115 t C ha⁻¹ (Poeplau et al. 2011), this is
 23 equivalent to a loss of 41.5 t C ha⁻¹ on conversion to cropland. Mean annual global cropland
 24 conversion rates (1961–2003) have been around 47000 km² yr⁻¹ (Krause et al. 2017), or 940000 km²
 25 over a 20 year period. The equivalent loss of soil organic carbon over 20 years would therefore be 14
 26 Gt CO₂e = 0.7 Gt CO₂ yr⁻¹. Griscom et al. (2017a) estimate a cost-effective mitigation potential of
 27 0.03 Gt CO₂ yr⁻¹ (Table 6.13).

28 Integrated water management provides moderate benefits for climate mitigation due to interactions
 29 with other land management strategies. For example, promoting soil carbon conservation (e.g.
 30 reduced tillage) can improve the water retention capacity of soils. Jat et al. (2015) found that
 31 improved tillage practices and residue incorporation increased water-use efficiency by 30%, rice–
 32 wheat yields by 5–37%, income by 28–40% and reduced GHG emission by 16–25%. While irrigated
 33 agriculture accounts for only 20% of the total cultivated land, the energy consumption from
 34 groundwater irrigation is significant. However, current estimates of mitigation potential are limited to
 35 reductions in greenhouse gas emissions mainly in cropland and rice cultivation (Chapter 2; Table
 36 6.13; Smith et al. 2008, 2014c). Li et al. (2006) estimated a 0.52–0.72 GtCO₂ yr⁻¹ reduction using the
 37 alternate wetting and drying technique. Current estimates of N₂O release from terrestrial soils and
 38 wetlands accounts for 10–15% of anthropogenically fixed nitrogen on the Earth System (Wang et al.
 39 2017).

40 Table 6.13 summarises the mitigation potentials for agricultural response options, with confidence
 41 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
 42 exhaustive) references upon which the evidence is based.

43 **Table 6.13 Mitigation effects of response options based on land management in agriculture**

Integrated response option	Potential	Confidence	Citation
Increased food productivity	>13 GtCO ₂ e yr ⁻¹	Low confidence	Chapter 5; Burney et al. 2010

Improved cropland management ^a	1.4-2.3 GtCO ₂ e yr ⁻¹	Medium confidence	Chapter 2; Chapter 5; Smith et al. 2008, 2014c; Pradhan et al., 2013;
Improved grazing land management ^a	1.4-1.8 GtCO ₂ e yr ⁻¹	Medium confidence	Chapter 2; Chapter 5; Conant et al. 2017; Herrero et al. 2016; Smith et al. 2008, 2014c
Improved livestock management ^a	0.2-2.4 GtCO ₂ e yr ⁻¹	Medium confidence	Chapter 2; Chapter 5; Smith et al. 2008, 2014c; Herrero et al. 2016
Agroforestry	0.1-5.7 Gt CO ₂ e yr ⁻¹	Medium confidence	Chapter 2; Griscom et al. 2017a; Zomer et al. 2016; Dickie et al. 2014; Hawken 2014;
Agricultural diversification	> 0	Low confidence	Campbell et al. 2014; Cohn et al. 2017
Reduced grassland conversion to cropland	0.03-0.7 Gt CO ₂ e yr ⁻¹	Low confidence	Note high value not shown in Chapter 2; Calculated from values in Krause et al. 2017 and Poeplau et al. 2011; Griscom et al. 2017
Integrated water management	0.1-0.72 Gt CO ₂ yr ⁻¹	Low confidence	IPCC 2014; Smith et al. 2008, 2014b; Howell et al. 2015; Li et al. 2006; Rahman and Bulbul 2015

1 ^a Note that Chapter 2 reports mitigation potential for subcategories within this response option and not the combined total
2 reported here.

3 **6.3.1.1.2 Integrated response options based on land management in forests**

4 Improved forest management could potentially contribute to moderate mitigation benefits globally, up
5 to about 2 Gt CO₂e yr⁻¹ (Chapter 2, Table 6.14). For managed forests, the most effective forest carbon
6 mitigation strategy is the one that, through increasing biomass productivity, optimises the carbon
7 stocks (in forests and in long-lived products) as well as the wood substitution effects for a given time
8 frame (Smyth et al. 2014; Grassi et al. 2018; Nabuurs et al. 2007; Lewis et al. 2019) (Kurz et al. 2016;
9 Erb et al. 2018). Estimates of the mitigation potential vary also depending on the counterfactual, such
10 as business-as-usual management (e.g. Grassi et al. 2018) or other scenarios. Climate change will
11 affect the mitigation potential of forest management due to an increase in extreme events like fires,
12 insects and pathogens (Seidl et al. 2017). More detailed estimates are available at regional or biome
13 level. For instance, according to Nabuurs et al. (2017), the implementation of Climate-Smart Forestry
14 (a combination of improved forest management, expansion of forest areas, energy substitution,
15 establishment of forest reserves, etc.) in the European Union has the potential to contribute to an
16 additional 0.4 Gt CO₂ yr⁻¹ mitigation by 2050. Sustainable forest management is often associated with
17 a number of co-benefits for adaptation, ecosystem services, biodiversity conservation, microclimatic
18 regulation, soil erosion protection, coastal area protection and water and flood regulation (Locatelli
19 2011). Forest management mitigation measures are more likely to be long-lasting if integrated into
20 adaptation measures for communities and ecosystems, for example, through landscape management
21 (Locatelli et al. 2011). Adoption of reduced-impact logging and wood processing technologies along
22 with financial incentives can reduce forest fires, forest degradation, maintain timber production, and
23 retain carbon stocks (Sasaki et al. 2016). Forest certification may support sustainable forest
24 management, helping to prevent forest degradation and over-logging (Rametsteiner and Simula 2003).
25 Community forest management has proven a viable model for sustainable forestry, including for
26 carbon sequestration (Chhatre and Agrawal 2009, Chapter 7, section 7.6.4).

27 Reducing deforestation and forest degradation rates represents one of the most effective and robust
28 options for climate change mitigation, with large mitigation benefits globally (Chapter 2, Chapter 4,
29 Table 6.14). Because of the combined climate impacts of GHGs and biophysical effects, reducing
30 deforestation in the tropics has a major climate mitigation effect, with benefits at local levels too

1 (Chapter 2, Alkama and Cescatti 2016). Reduced deforestation and forest degradation typically lead to
2 large co-benefits for other ecosystem services (Table 6.14).

3 A large range of estimates exist in the scientific literature for the mitigation potential of reforestation
4 and forest restoration, and they sometimes overlap with estimates for afforestation. At global level the
5 overall potential for these options is large, reaching about 10 GtCO₂ yr⁻¹ (Chapter 2, Table 6.14). The
6 greatest potential for these options is in tropical and subtropical climate (Houghton and Nassikas
7 2018). Furthermore, climate change mitigation benefits of afforestation, reforestation and forest
8 restoration are reduced at high latitudes owing to the surface albedo feedback (see Chapter 2).

9 Table 6.14 summarises the mitigation potentials for forest response options, with confidence estimates
10 based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive)
11 references upon which the evidence is based.

12 **Table 6.14 Mitigation effects of response options based on land management in forests**

Integrated response option	Potential	Confidence	Citation
Improved forest management	0.4-2.1 Gt CO ₂ e yr ⁻¹	Medium confidence	Chapter 2; Griscom 2017; Sasaki et al. 2016
Reduced deforestation and degradation	0.4-5.8 Gt CO ₂ e yr ⁻¹	High confidence	Chapter 2; Houghton & Nassikas 2018; Griscom 2017; Baccini 2017; Hawken 2017; Houghton et al 2015; Smith et al. 2014a
Reforestation and forest restoration	1.5-10.1 Gt CO ₂ e yr ⁻¹	Medium confidence	Chapter 2; Dooley and Kartha 2018a; Hawken 2017; Houghton & Nassikas 2018; Griscom 2017. Estimates partially overlapping with Afforestation.
Afforestation	0.5-8.9 Gt CO ₂ e yr ⁻¹	Medium confidence	Chapter 2; Fuss et al. 2018; Hawken 2017; Kreidenweis et al. 2016; Lenton 2010. Estimates partially overlapping with Reforestation.

13

14 **6.3.1.1.3 Integrated response options based on land management of soils**

15 The global mitigation potential for increasing soil organic matter stocks in mineral soils is estimated
16 to be in the range of 1.3–5.1 GtCO₂e yr⁻¹, though the full literature range is wider (Smith et al. 2008;
17 Smith 2016; Fuss et al 2018.; Sanderman et al. 2017; Sommer & Bossio 2014; Lal 2004; Lal et al.
18 2010; Table 6.15).

19 The management and control of erosion may prevent losses of organic carbon in water- or wind-
20 transported sediments, but since the final fate of eroded material is still debated, ranging from a
21 source of 1.36–3.67 GtCO₂ yr⁻¹ (Jacinthe and Lal 2001; Lal et al., 2004) to a sink of 0.44–3.67 GtCO₂
22 yr⁻¹ (Stallard 1998; Smith et al. 2001, 2005; Van Oost et al. 2007; Table 6.15), the overall impact of
23 erosion control on mitigation is context-specific and at the uncertain at the global level (Hoffmann et
24 al., 2013).

1 Salt-affected soils are highly constrained environments that require permanent prevention of
2 salinisation. Their mitigation potential is likely to be small (Wong et al. 2010; UNCTAD 2011; Dagar
3 et al. 2016b).

4 Soil compaction prevention could reduce N₂O emissions by minimising anoxic conditions favourable
5 for denitrification (Mbow et al. 2010), but its carbon sequestration potential depends on crop
6 management and the global mitigation potential, though globally unquantified, is likely to be small
7 (Chamen et al. 2015; Epron et al. 2016; Tullberg et al. 2018; Table 6.15).

8 For biochar, a global analysis of technical potential, in which biomass supply constraints were applied
9 to protect against food insecurity, loss of habitat and land degradation, estimated technical potential
10 abatement of 3.7–6.6 GtCO₂e yr⁻¹ (including 2.6–4.6 GtCO₂e yr⁻¹ carbon stabilisation). Considering
11 all published estimates by Woolf et al. (2010), Smith (2016), Fuss et al. (2018b), Griscom et al.
12 (2017), Hawken (2017), Paustian et al. (2016), Powell & Lenton (2012), Dickie et al. (2014), Lenton
13 (2010), Lenton (2014), Roberts et al. (2010), Pratt & Moran (2010) and IPCC (2018), the low value
14 for the range of potentials of 0.03 GtCO₂e yr⁻¹ is for the “plausible” scenario of Hawken, 2017; Table
15 6.15). Fuss et al. (2018) propose a range of 0.5–2 GtCO₂e yr⁻¹ as the sustainable potential for negative
16 emissions through biochar, similar to the range proposed by Smith (2016) and IPCC (2018).

17 Table 6.15 summarises the mitigation potentials for soil-based response options, with confidence
18 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
19 exhaustive) references upon which the evidence is based.

20 **Table 6.15 Mitigation effects of response options based on land management of soils**

Integrated response option	Potential	Confidence	Citation

Biochar addition to soil	0.03-6.6 GtCO ₂ e yr ⁻¹	Medium confidence	Chapter 2; IPCC 2018; Fuss et al. 2018b; Griscom et al. 2017a; Lenton 2010; Paustian et al. 2016; Smith 2016; Woolf et al. 2010; Dickie et al. 2014; Hawken 2017; Lenton 2014; Powell & Lenton 2012; Pratt & Moran 2010; Roberts et al 2010;

21

22 **6.3.1.1.4 Integrated response options based on land management in all/other ecosystems**

23 For fire management, total emissions from fires have been in the order of 8.1 GtCO₂e yr⁻¹ for the
24 period 1997-2016 (see Chapter 2, Cross-Chapter Box 3) and there are important synergies between air
25 pollution and climate change control policies. Reduction in fire CO₂ emissions due to fire suppression
26 and landscape fragmentation associated with increases in population density is calculated to enhance

1 land carbon uptake by 0.48 Gt CO₂e yr⁻¹ for the 1960–2009 period (Arora and Melton 2018; Table
2 6.16).

3 Management of landslides and natural hazards is a key climate adaptation option but due to limited
4 global areas vulnerable to landslides and natural hazards, its mitigation potential is likely to be modest
5 (Noble et al. 2015).

6 In terms of management of pollution, including acidification, UNEP and WMO (2011) and Shindell et
7 al. (2012) identified measures targeting reduction in SLCP emissions that reduce projected global
8 mean warming about 0.5°C by 2050. Bala et al. (2013) reported that a recent coupled modelling study
9 showed N deposition and elevated CO₂ could have a synergistic effect, which could explain 47% of
10 terrestrial carbon uptake in the 1990s. Estimates of global terrestrial carbon uptake due to current N
11 deposition ranges between 0.55 and 1.28 GtCO₂ yr⁻¹ (de Vries et al. 2006; de Vries et al. 2009; Bala et
12 al. 2013; Zaehle and Dalmonech 2011; Table 6.16).

13 There are no global data on the impacts of management of invasive species / encroachment on
14 mitigation.

15 Coastal wetland restoration could provide high levels of climate mitigation, with avoided coastal
16 wetland impacts and coastal wetland restoration estimated to deliver 0.3-3.1 GtCO₂e yr⁻¹ in total when
17 considering all global estimates from Griscom et al. (2017a), Hawken (2017), Pendleton et al. (2012),
18 Howard et al. (2017) and Donato et al. (2010) (Table 6.16).

19 Peatland restoration could provide moderate levels of climate mitigation, with avoided peat impacts
20 and peat restoration estimated to deliver 0.6-2 GtCO₂e yr⁻¹ from all global estimates published in
21 Griscom et al. (2017a), Hawken (2017), Hooijer et al. (2010), Couwenberg et al. (2010) and Joosten
22 and Couwenberg (2008), though there could be an increase in methane emissions after restoration
23 (Jauhiainen et al. 2008; Table 6.16).

24 Mitigation potential from biodiversity conservation varies depending on the type of intervention and
25 specific context. Protected areas are estimated to store over 300 Gt carbon, roughly corresponding to
26 15% of terrestrial carbon stocks (Kapos et al. 2008; Campbell et al. 2008). At global level, the
27 potential mitigation resulting from protection of these areas for the period 2005-2095 is on average
28 about 0.9 GtCO₂-eq. yr⁻¹ relative to a reference scenario (Calvin et al. 2014a). The potential effects on
29 the carbon cycle of management of wild animal species are case context dependent. For example,
30 moose browsing in boreal forests can decrease the carbon uptake of ecosystems by up to 75%
31 (Schmitz et al. 2018b), and reducing moose density through active population management in Canada
32 is estimated to be a carbon sink equivalent to about 0.37 Gt CO₂e yr⁻¹ (Schmitz et al. 2014).

33 Table 6.16 summarises the mitigation potentials for land management response options in all/other
34 ecosystems, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6,
35 and indicative (not exhaustive) references upon which the evidence is based.

36 **Table 6.16 Mitigation effects of response options based on land management in all/other ecosystems**

2 **6.3.1.1.5 Integrated response options based on land management specifically for CDR**

3 Enhanced mineral weathering provides substantial climate mitigation, with a global mitigation
4 potential in the region of about 0.5–4 GtCO₂e yr⁻¹ (Beerling et al 2018.; Lenton 2010; Smith et al.
5 2016c; Taylor et al. 2016; Table 6.17).

6 The mitigation potential for bioenergy and BECCS derived from bottom-up models is large (IPCC
7 SR15; Chapter 2; Cross-Chapter Box 7 on Bioenergy in this chapter), with technical potential
8 estimated at 100-300 EJ yr⁻¹ (IPCC 2011; Cross-Chapter Box 7 in this chapter) or up to ~11 GtCO₂ yr⁻¹
9 (Chapter 2). These estimates, however, exclude N₂O associated with fertiliser application and land-
10 use change emissions. Those effects are included in the modelled scenarios using bioenergy and
11 BECCS, with the sign and magnitude depending on where the bioenergy is grown (Wise et al. 2015),
12 at what scale, and whether N fertiliser is used.

13 Table 6.17 summarises the mitigation potentials for land management options specifically for CDR,
14 with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and
15 indicative (not exhaustive) references upon which the evidence is based.

18 **6.3.1.2 Integrated response options based on value chain management**

19 In this section, the impacts on climate change mitigation of integrated response options based on
20 value chain management are assessed.

21 **6.3.1.2.1 Integrated response options based on value chain management through demand 22 management**

23 Dietary change and waste reduction can provide large benefits for mitigation, with potentials of 0.7-8
24 GtCO₂ yr⁻¹ for both (Bajželj et al. 2014; Stehfest et al. 2009; Tilman and Clark 2014b;
25 Aleksandrowicz et al. 2016; Herrero et al. 2016; Springmann et al. 2016; Smith et al. 2013; Dickie et
26 al. 2014; Popp et al. 2010; Hawken 2017; Hedenus (2014)). Estimates for food waste reduction

1 (Hawken 2017; Hic et al. 2016; Dickie et al. 2014) (Bajželj et al. 2014) include both consumer /
2 retailed waste and post-harvest losses (Table 6.18).

3 Some studies indicate that material substitution has the potential for significant mitigation, with one
4 study estimating a 14–31% reduction in global CO₂ emissions (Oliver et al. 2014); other studies
5 suggest more modest potential (Gustavsson et al. 2006; Table 6.18).

6 Table 6.18 summarises the mitigation potentials for demand management options, with confidence
7 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
8 exhaustive) references upon which the evidence is based.

9 **Table 6.18 Mitigation effects of response options based on demand management**

Integrated response option	Potential	Confidence	Citation

Reduced post-harvest losses	4.5 GtCO ₂ yr ⁻¹	High confidence	Chapter 5; Bajželj et al. 2014
Reduced food waste (consumer or retailer)	0.8 to 4.5 GtCO ₂ yr ⁻¹	High confidence	Chapter 5; Bajželj et al. 2014; Dickie et al. 2014; Hawken 2017; Hic et al. 2016
Material substitution	0.25 to 1 GtCO ₂ yr ⁻¹	Medium confidence	Chapter 2; Dugan et al. 2018; Gustavsson et al. 2006; Leskinen et al. 2018; McLaren 2012; Sathre and O'Connor 2010; Miner 2010; Kauppi 2001; Smyth et al. 2016

10

11 **6.3.1.2.2 Integrated response options based on value chain management through supply** 12 **management**

13 While sustainable sourcing presumably delivers a mitigation benefit, there are no global estimates of
14 potential. Palm oil production alone is estimated to contribute 0.038 to 0.045 GtC yr⁻¹, and Indonesian
15 palm oil expansion contributed up to 9% of tropical land use change carbon emissions in the 2000s
16 (Carlson and Curran 2013), however, the mitigation benefit of sustainable sourcing of palm oil has not
17 been quantified. There are no estimates of the mitigation potential for urban food systems.

18 Efficient use of energy and resources in food transport and distribution contribute to a reduction in
19 GHG emissions, estimated to be 1% of global CO₂ emissions (James and James 2010; Vermeulen et
20 al. 2012). Given that global CO₂ emissions in 2017 were 37 GtCO₂, this equates to 0.37 GtCO₂ yr⁻¹
21 (covering food transport and distribution, improved efficiency of food processing and retailing, and
22 improved energy efficiency; Table 6.19).

23 Table 6.19 summarises the mitigation potentials for supply management options, with confidence
24 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
25 exhaustive) references upon which the evidence is based.

2 **6.3.1.3 Integrated response options based on risk management**

3 In this section, the impacts on climate change mitigation of integrated response options based on risk
4 management are assessed. In general, because these options are focused on adaptation and other
5 benefits, the mitigation benefits are modest, and mostly unquantified.

6 Extensive and less dense urban development tends to have higher energy usage, particularly from
7 transport (Liu et al. 2015), such that a 10% reduction of very low density urban fabrics is correlated
8 with 9% fewer emissions per capita in Europe (Baur et al. 2015). However, the exact contribution to
9 mitigation from the prevention of land conversion in particular has not been well quantified
10 (Thornbush et al. 2013). Suggestions from select studies in the US are that biomass decreases by half
11 in cases of conversion from forest to urban land uses (Briber et al. 2015), and a study in Bangkok
12 found a decline by half in carbon sinks in the urban area in the past 30 years (Ali et al. 2018).

13 There is no literature specifically on linkages between livelihood diversification and climate
14 mitigation benefits, although some forms of diversification that include agroforestry would likely
15 result in increased carbon sinks (Altieri et al. 2015; Descheemaeker et al. 2016). There is no literature
16 exploring linkages between local seeds and GHG emission reductions, although use of local seeds
17 likely reduces emissions associated with transport for commercial seeds, though the impact has not
18 been quantified.

19 While disaster risk management can presumably have mitigation co-benefits, as it can help reduce
20 food loss on-farm (e.g. crops destroyed before harvest or avoided animal deaths during droughts and
21 floods meaning reduced production losses and wasted emissions), there is no quantified global
22 estimate for this potential.

23 Risk sharing instruments could have some mitigation co-benefits if they buffer household losses and
24 reduce the need to expand agricultural lands after experiencing risks. However, the overall impacts of
25 these are unknown. Further, commercial insurance may induce producers to bring additional land into
26 crop production, particularly marginal or land with other risks that may be more environmentally
27 sensitive (Claassen et al. 2011). Policies to deny crop insurance to farmers who have converted
28 grasslands in the US resulted in a 9% drop in conversion, which likely has positive mitigation impacts
29 (Claassen et al. 2011). Estimates of emissions from cropland conversion in the US in 2016 were 23.8
30 Mt CO₂e, only some of which could be attributed to insurance as a driver.

31 Table 6.20 summarises the mitigation potentials for risk management options, with confidence
32 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
33 exhaustive) references upon which the evidence is based.

2 **6.3.2 Potential of the integrated response options for delivering adaptation**

3 In this section, the impacts of integrated response options on climate change adaptation are assessed.

4 **6.3.2.1 Integrated response options based on land management**

5 In this section, the impacts on climate change adaptation of integrated response options based on land
6 management are assessed.

7 **6.3.2.1.1 Integrated response options based on land management in agriculture**

8 Increasing food productivity by practices such as sustainable intensification improves farm incomes
9 and allows households to build assets for use in times of stress, thereby improving resilience
10 (Campbell et al. 2014). By reducing pressure on land and increasing food production, increased food
11 productivity could be beneficial for adaptation (Chapter 2; Section 6.3; Campbell et al. 2014). Pretty
12 et al. (2018) report that 163 million farms occupying 4.53 Mkm² have passed a redesign threshold for
13 application of sustainable intensification, suggesting the minimum number of people benefiting from
14 increased productivity and adaptation benefits under sustainable intensification is >163 million, with
15 the total likely to be far higher (Table 6.21).

16 Improved cropland management is a key climate adaptation option, potentially affecting more than 25
17 million people, including a wide range of technological decisions by farmers. Actions towards
18 adaptation fall into two broad overlapping areas: (1) accelerated adaptation to progressive climate
19 change over decadal time scales, for example integrated packages of technology, agronomy and
20 policy options for farmers and food systems, including changing planting dates and zones, tillage
21 systems, crop types and varieties, and (2) better management of agricultural risks associated with
22 increasing climate variability and extreme events, for example improved climate information services
23 and safety nets (Vermeulen et al. 2012b; Challinor et al. 2014; Lipper et al. 2014; Lobell 2014). In the
24 same way, improved livestock management is another technological adaptation option potentially
25 benefiting 1–25 million people. Crop and animal diversification are considered the most promising
26 adaptation measures (Porter et al. 2014; Rojas-Downing et al. 2017a). In grasslands and rangelands,
27 regulation of stocking rates, grazing field dimensions, establishment of exclosures and locations of
28 drinking fountains and feeders are strategic decisions by farmers to improve grazing management
29 (Taboada et al. 2011; Mekuria and Aynekulu 2013; Porter et al. 2014).

30 Around 30% of the world's rural population use trees across 46% of all agricultural landscapes (Lasco
31 et al. 2014), meaning that up to 2.3 billion people benefit from agroforestry, globally (Table 6.21).

32 Agricultural diversification is key to achieve climatic resilience (Campbell et al. 2014; Cohn et al.
33 2017). Crop diversification is one important adaptation option to progressive climate change
34 (Vermeulen et al. 2012) and it can improve resilience by engendering a greater ability to suppress pest
35 outbreaks and dampen pathogen transmission, as well as by buffering crop production from the effects
36 of greater climate variability and extreme events (Lin 2011).

37 Reduced conversion of grassland to cropland may lead to adaptation benefits by stabilising soils in the
38 face of extreme climatic events (Lal 2001b), thereby increasing resilience, but since it would likely
39 have a negative impact on food production / security (since croplands produce more food per unit area
40 than grasslands), the wider adaptation impacts would likely be negative. However, there is no
41 literature quantifying the global impact of avoidance of conversion of grassland to cropland on
42 adaptation.

43 Integrated water management provides large co-benefits for adaptation (Dillon and Arshad 2016) by
44 improving the resilience of food crop production systems to future climate change (Chapter 2; Table
45 6.7; Porter et al. 2014). Improving irrigation systems and integrated water resource management, such
46 as enhancing urban and rural water supplies and reducing water evaporation losses (Dillon and

Arshad 2016), are significant options for enhancing climate adaptation. Many technical innovations (e.g., precision water management) can lead to beneficial adaptation outcomes by increasing water availability and the reliability of agricultural production, using different techniques of water harvesting, storage, and its judicious utilisation through farm ponds, dams, and community tanks in rainfed agriculture areas. Integrated water management response options that use freshwater would be expected to have few adverse side effects in regions where water is plentiful, but large adverse side effects in regions where water is scarce (Grey and Sadoff 2007; Liu et al. 2017; Scott et al. 2011).

Table 6.21 summarises the potentials for adaptation for agricultural response options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence is based.

Table 6.21 Adaptation effects of response options based on land management in agriculture

Integrated water management	250 million people	Low confidence	Dillon and Arshad 2016; Liu et al. 2017

6.3.2.1.2 Integrated response options based on land management in forestry

Improved forest management positively impacts adaptation through limiting the negative effects associated with pollution (of air and fresh water), infections and other diseases, exposure to extreme weather events and natural disasters, and poverty (e.g., Smith et al. 2014c). There is high agreement on the fact that reduced deforestation and forest degradation positively impact adaptation and resilience of coupled human-natural systems. Based on the number of people affected by natural disasters (CRED 2015), the number of people depending to varying degrees on forests for their livelihoods (World Bank et al. 2009) and the current deforestation rate (Keenan et al. 2015), the estimated global potential effect for adaptation is large positive for improved forest management, and moderate positive for reduced deforestation when cumulated till the end of the century (Table 6.22). The uncertainty of these global estimates is high, e.g. the impact of reduced deforestation may be higher when the large biophysical impacts on the water cycle (and thus drought) from deforestation (e.g. Alkama & Cescatti 2016, etc) are taken into account (see Chapter 2).

More robust qualitative and some quantitative estimates are available at local and regional level. According to Karjalainen et al. (2009), reducing deforestation and habitat alteration contributes to limiting infectious diseases such as malaria in Africa, Asia, and Latin America, thus lowering the expenses associated with healthcare treatments. Bhattacharjee and Behera (2017) found that human lives lost due to floods increase with reducing forest cover and increasing deforestation rates in India. In addition, maintaining forest cover in urban contexts reduces air pollution and therefore avoids mortality of about one person per year per city in US, and up to 7.6 people per year in New York City

1 (Nowak et al. 2014). There is also evidence that reducing deforestation and degradation in mangrove
 2 plantations potentially improves soil stabilisation, and attenuates the impact of tropical cyclones and
 3 typhoons along the coastal areas in South and Southeast Asia (Chow 2018). At local scale, co-benefits
 4 between REDD+ and adaptation of local communities can potentially be substantial (Long 2013;
 5 Morita & Matsumoto 2017), even if often difficult to quantify, and not explicitly acknowledged
 6 (McElwee et al. 2017b).

7 Forest restoration may facilitate the adaptation and resilience of forests to climate change by
 8 enhancing connectivity between forest areas and conserving biodiversity hotspots (Locatelli et al.
 9 2011, 2015c; Ellison et al. 2017; Dooley and Kartha 2018b). Furthermore, forest restoration may
 10 improve ecosystem functionality and services, provide microclimatic regulation for people and crops,
 11 wood and fodder as safety nets, soil erosion protection and soil fertility enhancement for agricultural
 12 resilience, coastal area protection, water and flood regulation (Locatelli et al. 2015c).

13 Afforestation and reforestation are important climate change adaptation response options (Reyer et al.
 14 2009; Ellison et al. 2017a; Locatelli et al. 2015c), and can potentially help a large proportion of the
 15 global population to adapt to climate change and to associated natural disasters (Table 6.22). For
 16 example, trees general mitigate summer mean warming and temperature extremes (Findell et al. 2017;
 17 Sonntag et al. 2016).

18 Table 6.22 summarises the potentials for adaptation for forest response options, with confidence
 19 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
 20 exhaustive) references upon which the evidence is based.

22

23 **6.3.2.1.3 Integrated response options based on land management of soils**

24 Soil organic carbon increase is promoted as an action for climate change adaptation. Since increasing
 25 soil organic matter content is a measure to address land degradation (see Section 6.2.1), and restoring
 26 degraded land helps to improve resilience to climate change, soil carbon increase is an important
 27 option for climate change adaptation. With around 120 thousand km² lost to degradation every year,
 28 and over 3.2 billion people negatively impacted by land degradation globally (IPBES 2018), practices
 29 designed to increase soil organic carbon have a large potential to address adaptation challenges (Table
 30 6.23).

31 Since soil erosion control prevents land degradation and desertification, it improves the resilience of
 32 agriculture to climate change and increases food production (Lal 1998; IPBES 2018), though the
 33 global number of people benefiting from improved resilience to climate change has not been reported

1 in the literature. Using figures from (FAO et al. 2015), Scholes et al. (2018) estimates that land losses
 2 due to erosion are equivalent to 1.5 Mkm² of land used for crop production to 2050, or 45 thousand
 3 km² yr⁻¹ (Foley et al. 2011). Control of soil erosion (water and wind) could benefit 11 Mkm² of
 4 degraded land (Lal 2014), and improve the resilience of at least some of the 3.2 billion people affected
 5 by land degradation (IPBES 2018), suggesting positive impacts on adaptation. Management of
 6 erosion is an important climate change adaptation measure, since it reduces the vulnerability of soils
 7 to loss under climate extremes, thereby increasing resilience to climate change (Garbrecht et al. 2015).

8 Prevention and/or reversion of topsoil salinisation may require a combined management of
 9 groundwater, irrigation techniques, drainage, mulching and vegetation, with all of these considered
 10 relevant for adaptation (Qadir et al. 2013; UNCTAD 2011; Dagar et al. 2016b). Taking into account
 11 the widespread diffusion of salinity problems, many people can benefit from its implementation by
 12 farmers. The relation between compaction prevention and/or reversion and climate adaption is less
 13 evident, and can be related to better hydrological soil functioning (Chamen et al. 2015; Epron et al.
 14 2016; Tullberg et al. 2018b).

15 Biochar has potential to benefit climate adaptation by improving the resilience of food crop
 16 production systems to future climate change by increasing yield in some regions and improving water
 17 holding capacity (Chapter 2; Section 6.4; Woolf et al. 2010; Sohi 2012). By increasing yield by 25%
 18 in the tropics (Jeffery et al. 2017), this could increase food production for 3.2 billion people affected
 19 by land degradation (IPBES 2018), thereby potentially improving their resilience to climate change
 20 shocks (Table 6.23). A requirement for large areas of land to provide feedstock for biochar could
 21 adversely impact adaptation, though the impact has not been quantified globally.

22 Table 6.23 summarises the potentials for adaptation for soil-based response options, with confidence
 23 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
 24 exhaustive) references upon which the evidence is based.

25 **Table 6.23 Adaptation effects of response options based on land management of soils**

26 **6.3.2.1.4 Integrated response options based on land management across all/other ecosystems**

27 For fire management, Doerr et al. (2016) showed the number of people killed by wildfire was 1940,
 28 and the total number of people affected was 5.8 million from 1984 to 2013, globally. Johnston et al.
 29 (2012) showed the average mortality attributable to landscape fire smoke exposure was 339 thousand
 30 deaths annually. The regions most affected were sub-Saharan Africa (157 thousand) and Southeast
 31 Asia (110 thousand). Estimated annual mortality during La Niña was 262 thousand, compared with
 32 around 100 thousand excess deaths across Indonesia, Malaysia and Singapore (Table 6.24).
 33

34 Management of landslides and natural hazards are usually listed among planned adaptation options in
 35 mountainous and sloped hilly areas, where uncontrolled runoff and avalanches may cause climatic

1 disasters, affecting millions of people from both urban and rural areas. Landslide control requires both
2 increasing plant cover and engineering practices (see Table 6.8).

3 For management of pollution, including acidification, Anenberg et al. (2012) estimated that, for
4 PM_{2.5} and ozone, respectively, fully implementing reduction measures could reduce global
5 population-weighted average surface concentrations by 23–34% and 7–17% and avoid 0.6–4.4 and
6 0.04–0.52 million annual premature deaths globally in 2030. UNEP and WMO (2011) considered
7 emission control measures to reduce ozone and black carbon (BC) and estimated that 2.4 million
8 annual premature deaths (with a range of 0.7 to 4.6 million) from outdoor air pollution could be
9 avoided. West et al. (2013) estimated global GHG mitigation brings co-benefits for air quality and
10 would avoid 0.5±0.2, 1.3±0.5, and 2.2±0.8 million premature deaths in 2030, 2050, and 2100,
11 respectively.

12 There are no global data on the impacts of management of invasive species / encroachment on
13 adaptation.

14 Coastal wetlands provide a natural defence against coastal flooding and storm surges by dissipating
15 wave energy, reducing erosion and by helping to stabilise shore sediments, so restoration may provide
16 significant benefits for adaptation. The Ramsar Convention on Wetlands covers 1.5 Mkm² across
17 1674 sites Keddy et al. (2009). Coastal floods currently affect 93–310 million people (in 2010)
18 globally, and this could rise to 600 million people in 2100 with sea level rise, unless adaptation
19 measures are taken (Hinkel et al. 2014). The proportion of the flood-prone population that could avoid
20 these impacts through restoration of coastal wetlands has not been quantified, but this sets an upper
21 limit.

22 Avoided peat impacts and peatland restoration can help to regulate water flow and prevent
23 downstream flooding (Munang et al. 2014), but the global potential (in terms of number of people
24 who could avoid flooding through peatland restoration) has not been quantified.

25 There are no global estimates about the potential of biodiversity conservation to improve the
26 adaptation and resilience of local communities to climate change, in terms of reducing the number of
27 people affected by natural disasters. Nevertheless, it is widely recognised that biodiversity, ecosystem
28 health and resilience improves the adaptation potential (Jones et al. 2012). For example, tree species
29 mixture improves the resistance of stands to natural disturbances, such as drought, fires, and
30 windstorms (Jactel et al. 2017), as well as stability against landslides (Kobayashi and Mori 2017).
31 Moreover, Protected Areas play a key role for improving adaptation (Watson et al. 2014; Lopoukhine
32 et al. 2012), through reducing water flow, stabilising rock movements, creating physical barriers to
33 coastal erosion, improving resistance to fires, and buffering storm damages (Dudley et al. 2010).
34 33 out of 105 of the largest urban areas worldwide rely on protected areas for some, or all, of their drinking
35 water (Secretariat of the Convention on Biological Diversity 2008), indicating that many millions are
36 likely benefit from conservation practices.

37 Table 6.24 summarises the potentials for adaptation for soil-based response options, with confidence
38 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
39 exhaustive) references upon which the evidence is based.

40 **Table 6.24 Adaptation effects of response options based on land management of soils**

Integrated response option	Potential	Confidence	Citation
Fire management	> 5.8 million people affected by wildfire; max. 0.5 million deaths per year by smoke	Medium confidence	Doerr and Santín 2016; Johnston et al. 2012; Shannon et al., 2016
Reduced landslides and natural hazards	>25 million people	Low confidence	Arnáez J et al. 2015; Gariano and Guzzetti 2016
Reduced pollution	Prevent 0.5–4.6 million annual	Medium	Anenberg et al. 2012;

including acidification	premature deaths globally	confidence	Shindell et al.; West et al. 2013; UNEP & WMO, 2011;
Management of invasive species / encroachment	No global estimates	No evidence	
Restoration and reduced conversion of coastal wetlands	up to 93-310 million people	Low confidence	Hinkel et al. 2014
Restoration and reduced conversion of peatlands	No global estimates	No evidence	
Biodiversity conservation	Likely many millions	Low confidence	CBD, 2008

2 **6.3.2.1.5 Integrated response options based on land management specifically for CDR**

3 Enhanced weathering of minerals has been proposed as a mechanism of improving soil health and
4 food security (Beerling et al. 2018), but there is no literature estimating the global adaptation benefits.

5 Large-scale bioenergy and BECCS can require substantial amounts of cropland (Popp et al. 2017;
6 Calvin et al. 2014a; Smith et al. 2016c), forestland (Baker et al. 2019b; Favero and Mendelsohn
7 2017), and water (Chaturvedi et al. 2013; Smith et al. 2016; Fuss et al. 2018; Popp et al. 2011; Hejazi
8 et al. 2015b) suggesting that bioenergy and BECCS could have adverse side-effects for adaptation. In
9 some contexts, e.g., low inputs of fossil fuels and chemicals, limited irrigation, heat/drought tolerant
10 species, and using marginal land, bioenergy can have co-benefits for adaptation (Dasgupta et al. 2014;
11 Noble et al. 2014). However, no studies were found that quantify the magnitude of the effect.

12 Table 6.25 summarises the impacts on adaptation of land management response options specifically
13 for CDR, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6,
14 and indicative (not exhaustive) references upon which the evidence is based.

17 **6.3.2.2 Integrated response options based on value chain management**

18 In this section, the impacts on climate change adaptation of integrated response options based on
19 value chain management are assessed.

20 **6.3.2.2.1 Integrated response options based on value chain management through demand 21 management**

22 Decreases in pressure on land and decreases in production intensity associated with sustainable
23 healthy diets or reduced food waste could also benefit adaptation; however, the size of this effect is
24 not well quantified (Muller et al. 2017b).

25 Reducing food waste losses can relieve pressure on the global freshwater resource, thereby aiding
26 adaptation. Food losses account for 215 km³ yr⁻¹ of freshwater resources, which (Kummu et al. 2012)
27 report to be about 12–15% of the global consumptive water use. Given that 35% of the global
28 population is living under high water stress or shortage (Kummu et al. 2010), reducing food waste
29 could benefit 320–400 million people (12–15% of the 2681 million people affected by water stress /
30 shortage).

1 While no studies report quantitative estimates of the effect of material substitution on adaptation, the
 2 effects are expected to be similar to reforestation and afforestation if the amount of material
 3 substitution leads to an increase in forest area. Additionally, some studies indicate that wooden
 4 buildings, if properly constructed, could reduce fire risk compared to steel, which softens when
 5 burned (Gustavsson et al. 2006; Ramage et al. 2017a).

6 Table 6.26 summarises the impacts on adaptation of demand management options, with confidence
 7 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
 8 exhaustive) references upon which the evidence is based.

Material substitution	No global estimates	No evidence	

10
 11 **6.3.2.2.2 Integrated response options based on value chain management through supply
 12 management**

13 It is estimated that 500 million smallholder farmers depend on agricultural businesses in developing
 14 countries (World Bank, 2017), meaning that better promotion of value-added products and improved
 15 efficiency and sustainability of food processing and retailing could potentially help up to 500 million
 16 people to adapt to climate change. However, figures on how sustainable sourcing in general could
 17 help farmers and forest management is mostly unquantified. More than 1 million farmers have
 18 currently been certified through various schemes (Tayleur et al. 2017), but how much this has helped
 19 them prepare for adaptation is unknown.

20 Management of supply chains has the potential to reduce vulnerability to price volatility. Consumers
 21 in lower income countries are most affected by price volatility, with sub-Saharan Africa and South
 22 Asia at highest risk (Regmi and Meade 2013; Fujimori et al. 2018a). However, understanding of the
 23 stability of food supply is one of the weakest links in global food system research (Wheeler and von
 24 Braun 2013) as instability is driven by a confluence of factors (Headey and Fan 2008). Food price
 25 spikes in 2007 increased the number of people under the poverty line by between 100 million people
 26 (Ivanic and Martin 2008) and 450 million people (Brinkman et al. 2009), and caused welfare losses of
 27 3% or more for poor households in many countries (Zezza et al. 2009). Food price stabilisation by
 28 China, India and Indonesia alone in 2007/2008 led to reduced staple food price for 2 billion people
 29 (Timmer 2009). Presumably, spending less on food frees up money for other activities, including
 30 adaptation, but it is unknown how much (Zezza et al. 2009; Ziervogel and Ericksen 2010). One
 31 example of reduction in staple food price costs to consumers in Bangladesh from food stability
 32 policies saved rural households USD887 million total (Torlesse et al. 2003b). Food supply stability
 33 through improved supply chains also potentially reduces conflicts (by avoiding food price riots, which
 34 occurred in countries with over 100 million total in population in 2007/2008), and thus increases
 35 adaptation capacity (Raleigh et al. 2015a).

36 There are no global estimates of the contribution of improved food transport and distribution, or of
 37 urban food systems, in contributing to adaptation, but since the urban population in 2018 was 4.2
 38 billion people, this sets the upper limit on those that could benefit.

39 Given that 65% (760 million) of poor working adults make a living through agriculture, increased
 40 energy efficiency in agriculture could benefit this 760 million people.

1 Table 6.27 summarises the impacts on adaptation of supply management options, with confidence
 2 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
 3 exhaustive) references upon which the evidence is based.

6 **6.3.2.3 Integrated response options based on risk management**

7 In this section, the impacts on climate change adaptation of integrated response options based on risk
 8 management are assessed.

9 Reducing urban sprawl is likely to provide adaptation co-benefits *via* improved human health
 10 (Frumkin 2002; Anderson 2017), as sprawl contributes to reduced physical activity, worse air
 11 pollution, and exacerbation of urban heat island effects and extreme heat waves (Stone et al. 2010).
 12 The most sprawling cities in the US have experienced extreme heat waves more than double those of
 13 denser cities, and “urban albedo and vegetation enhancement strategies have significant potential to
 14 reduce heat-related health impacts” (Stone et al. 2010). Other adaption co-benefits are less well
 15 understood. There are likely to be cost savings from managing planning growth (one study found 2%
 16 savings in metropolitan budgets, which can be then spent on adaptation planning) (Deal and Schunk
 17 2004).

18 Diversification is a major adaptation strategy and form of risk management, as it can help households
 19 smooth out income fluctuations and provide a broader range of options for the future (Osbaahr et al.
 20 2008; Adger et al. 2011; Thornton and Herrero 2014). Surveys of farmers in climate variable areas
 21 find that livelihood diversification is increasingly favoured as an adaptation option (Bryan et al.
 22 2013), although it is not always successful, since it can increase exposure to climate variability (Adger
 23 et al. 2011). There are over 570 million small farms in the world (Lowder et al. 2016), and many
 24 millions of smallholder agriculturalists already practice livelihood diversification by engaging in
 25 multiple forms of off-farm income (Rigg 2006). It is not clear, however, how many farmers have not
 26 yet practiced diversification and thus how many would be helped by supporting this response option.

27 Currently, millions of farmers still rely to some degree on local seeds. Use of local seeds can facilitate
 28 adaptation for many smallholders, as moving to use of commercial seeds can increase costs for
 29 farmers (Howard 2015). Seed networks and banks protect local agrobiodiversity and landraces, which
 30 are important to facilitate adaptation, as local landraces may be resilient to some forms of climate
 31 change (Coomes et al. 2015a; van Niekerk and Wynberg 2017a; Vasconcelos et al. 2013).

32 Disaster risk management is an essential part of adaptation strategies. The Famine Early Warning
 33 System funded by the USAID has operated across 3 continents since the 1980s, and many millions of
 34 people across 34 countries have access to early information on drought. Such information can assist
 35 communities and households in adapting to onset conditions (Hillbruner and Moloney 2012).

1 However, concerns have been raised as to how many people are actually reached by disaster risk
2 management and early warning systems; for example, less than 50% of respondents in Bangladesh
3 had heard a cyclone warning before it hit, even though an early warning system existed (Mahmud and
4 Prowse 2012). Further, there are concerns that current early warning systems “tend to focus on
5 response and recovery rather than on addressing livelihood issues as part of the process of reducing
6 underlying risk factors,” (Birkmann et al. 2015a), leading to less adaptation potential being realised.

7 Local risk sharing instruments like rotating credit or loan groups can help buffer farmers against
8 climate impacts and help facilitate adaptation. Both index and commercial crop insurance offers some
9 potential for adaptation, as it provides a means of buffering and transferring weather risk, saving
10 farmers the cost of crop losses (Meze-Hausken et al. 2009; Patt et al. 2010). However, overly
11 subsidised insurance can undermine the market’s role in pricing risks and thus depress more rapid
12 adaptation strategies (Skees and Collier 2012; Jaworski 2016) and increase the riskiness of decision-
13 making (McLeman and Smit 2006). For example, availability of crop insurance was observed to
14 reduce farm-level diversification in the US, a factor cited as increasing adaptive capacity (Sanderson
15 et al. 2013b) and crop insurance-holding soybean farmers in the US have been less likely to adapt to
16 extreme weather events than those not holding insurance (Annan and Schlenker 2015). It is unclear
17 how many people worldwide use insurance as an adaptation strategy; (Platteau et al. 2017) suggest
18 less than 30% of smallholders take out any form of insurance), but it is likely in the millions.

19 Table 6.28 summarises the impacts on adaptation of risk management options, with confidence
20 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
21 exhaustive) references upon which the evidence is based.

22 **Table 6.28 Adaptation effects of response options based on risk management**

Integrated response option	Potential	Confidence	Citation

Livelihood diversification	>100 million likely	Low confidence	Morton 2007; Rigg 2006
Use of local seeds	Unquantified but likely to be many millions	Low confidence	Louwaars 2002; Santilli 2012
Disaster risk management	>100 million	High confidence	Hillbruner and Moloney 2012
Risk sharing instruments	Unquantified but likely to be several million	Low confidence	Platteau et al. 2017

24 **6.3.3 Potential of the integrated response options for addressing desertification**

25 In this section, the impacts of integrated response options on desertification are assessed.

26 **6.3.3.1 Integrated response options based on land management**

27 In this section, the impacts on desertification of integrated response options based on land
28 management are assessed.

29 **6.3.3.1.1 Integrated response options based on land management in agriculture**

30 Burney et al. (2010) estimated that an additional global cropland area of 11.11–15.14 Mkm² would
31 have been needed if productivity had not increased between 1961 and 2000. Given that agricultural
32 expansion is a main driver of desertification (FAO et al. 2015), increased food productivity could
33 have prevented up to 11.11–15.14 Mkm² from exploitation and desertification (Table 6.10).

34 Improved cropland, livestock and grazing land management are strategic options aiming at prevention
35 of desertification, and may include crop and animal selection, optimised stocking rates, changed

1 tillage and/or cover crops, to land use shifting from cropland to rangeland, in general targeting
2 increases in ground cover by vegetation, and protection against wind erosion (Schwilch et al. 2014;
3 Bestelmeyer et al. 2015). Considering the widespread distribution of deserts and desertified lands
4 globally, more than 10 Mkm² could benefit from improved management techniques.

5 Agroforestry can help stabilise soils to prevent desertification (Section 6.3.2.1.1), so given that there
6 are is around 10 Mkm² of land with more than 10% tree cover (Garrity, 2012), agroforestry could
7 benefit up to 10 Mkm² of land.

8 Agricultural diversification to prevent desertification may include the use of crops with manures,
9 legumes, fodder legumes and cover crops combined with conservation tillage systems (Schwilch et al.
10 2014). These practices can be considered to be part of improved crop management options (see
11 above) and aim at increasing ground coverage by vegetation and controlling wind erosion losses.

12 Since shifting from grassland to the annual cultivation of crops increases erosion and soil loss, there
13 are significant benefits for desertification control, by stabilising soils in arid areas (Chapter 3).
14 Cropland expansion during 1985 to 2005 was 359 thousand km², or 17.4 thousand km² yr⁻¹ (Foley et
15 al. 2011). Not all of this expansion will be from grasslands or in desertified areas, but this value sets
16 the maximum contribution of prevention of conversion of grasslands to croplands, a small global
17 benefit for desertification control (Table 6.10).

18 Integrated water management strategies such as water-use efficiency and irrigation, improve soil
19 health through increase in soil organic matter content, thereby delivering benefits for prevention or
20 reversal of desertification (Chapter 3; Baumhardt et al. 2015; Datta et al. 2000; Evans and Sadler
21 2008; He et al. 2015). Climate change will amplify existing stress on water availability and on
22 agricultural systems, particularly in semi-arid environments (AR5; Chapter 3). In 2011, semiarid
23 ecosystems in the southern hemisphere contributed 51% of the global net carbon sink (Poulter et al.,
24 2014). These results suggest that arid ecosystems could be an important global carbon sink, depending
25 on soil water availability.

26 Table 6.29 summarises the impacts on desertification of agricultural options, with confidence
27 estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not
28 exhaustive) references upon which the evidence is based.

29 **Table 6.29 Effects on desertification of response options in agriculture**

Integrated response option	Potential	Confidence	Citation
Increased food productivity	11.1-15.1 Mkm ²	Low confidence	Burney et al. 2010
Improved cropland management	10 Mkm ²	Low confidence	Schwilch et al. 2014

30

31 **6.3.3.1.2 Integrated response options based on land management in forestry**

32 Forests are important to help to stabilise land and regulate water and microclimate (Locatelli et al.
33 2015c). Based on the extent of dry forest at risk of desertification (Núñez et al. 2010; Bastin et al.

1 2017), the estimated global potential effect for avoided desertification is large for both improved
 2 forest management and for reduced deforestation and forest degradation when cumulated for at least
 3 20 years (Table 6.30). The uncertainty of these global estimates is high. More robust qualitative and
 4 some quantitative estimates are available at regional level. For example, it has been simulated that
 5 human activity (i.e., land management) contributed to 26% of the total land reverted from
 6 desertification in Northern China between 1981 and 2010 (Xu et al. 2018). In Thailand, it was found
 7 that the desertification risk is reduced when the land use is changed from bare lands to agricultural
 8 lands and forests, and from non-forests to forests; conversely, the desertification risk increases when
 9 converting forests and denuded forests to bare lands (Wijitkosum 2016).

10 Afforestation, reforestation and forest restoration are land management response options that are used
 11 to prevent desertification. Forests tend to maintain water and soil quality by reducing runoff and
 12 trapping sediments and nutrients (Idris Medugu et al. 2010a; Salvati et al. 2014a), but planting of non-
 13 native species in semi-arid regions can deplete soil water resources if they have high
 14 evapotranspiration rates (Feng et al.; Yang et al.). Afforestation and reforestation programmes can be
 15 deployed over large areas of the Earth, so can create synergies in areas prone to desertification. Global
 16 estimates of land potentially available for afforestation are up to 25.8 Mkm² by the end of the century,
 17 depending on a variety of assumptions on socio-economic developments and climate policies
 18 (Griscom et al. 2017; Kreidenweis et al. 2016a; Popp et al. 2017). The higher end of this range is
 19 achieved under the assumption of a globally uniform reward for carbon uptake in the terrestrial
 20 biosphere, and it is halved by considering tropical and subtropical areas only to minimise albedo
 21 feedbacks (Kreidenweis et al. 2016a). When safeguards are introduced (e.g., excluding existing
 22 cropland for food security, boreal areas, etc.), the area available declines to about 6.8 Mkm² (95%
 23 confidence interval of 2.3 and 11.25 Mkm²), of which about 4.72 Mkm² is in the tropics and 2.06
 24 Mkm² is in temperate regions (Griscom et al. 2017a; Table 6.30).

25 Table 6.30 summarises the impacts on desertification of forestry options, with confidence estimates
 26 based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive)
 27 references upon which the evidence is based.

28 **Table 6.30 Effects on desertification of response options in forests**

Integrated response option	Potential	Confidence	Citation

Reduced deforestation and degradation	> 3 Mkm ² (effects cumulated for at least 20 years)	Low confidence	Bastin et al. 2017; Keenan et al. 2015; Núñez et al. 2010
Reforestation and forest restoration	See afforestation		
Afforestation	2-25.8 Mkm ² by the end of the century	Medium confidence	Griscom et al. 2017a; Kreidenweis et al. 2016a; Popp et al. 2017

30 **6.3.3.1.3 Integrated response options based on land management of soils**

31 With over 2.7 billion people affected globally by desertification (IPBES 2018), practices to increase
 32 soil organic carbon content are proposed as actions to address desertification, and could be applied to
 33 an estimated 11.37 Mkm² of desertified soils (Lal 2001a; Table 6.31).

34 Control of soil erosion could have large benefits for desertification control. Using figures from (FAO
 35 et al. 2015), Scholes et al. (2018) estimated that land losses due to erosion to 2050 are equivalent to
 36 1.5 Mkm² of land from crop production, or 45 thousand km² yr⁻¹ (Foley et al. 2011), so soil erosion
 37 control could benefit up to 1.50 Mkm² of land in the coming decades. Lal (2001a) estimated that
 38 desertification control (using soil erosion control as one intervention) could benefit 11.37 Mkm² of
 39 desertified land globally (Table 6.10).

1 Oldeman et al. (1991) estimated the global extent soil affected by salinisation is 0.77 Mkm² yr⁻¹,
 2 which sets the upper limit on the area that could benefit from measures to address soil salinisation
 3 (Table 6.31).

4 In degraded arid grasslands, shrublands and rangelands, desertification can be reversed by alleviation
 5 of soil compaction through installation of enclosures and removal of domestic livestock (Allington et
 6 al. 2010), but there are no global estimates of potential (Tale 6.31).

7 Biochar could potentially deliver benefits in efforts to address desertification though improving water
 8 holding capacity (Woolf et al. 2010; Sohi 2012), but the global effect is not quantified.

9 Table 6.31 summarises the impacts on desertification of soil-based options, with confidence estimates
 10 based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive)
 11 references upon which the evidence in based.

Reduced soil compaction	No global estimates	No evidence	FAO and ITPS 2015; Hamza and Anderson 2005b
Biochar addition to soil	No global estimates	No evidence	

13

14 **6.3.3.1.4 Integrated response options based on land management across all/other ecosystems**

15 For fire management, Arora and Melton (2018) estimated, using models and GFED4.1s0 data, that
 16 burned area over the 1997–2014 period was 4.834–4.855 Mkm² yr⁻¹. Randerson et al. (2012) estimated
 17 small fires increased total burned area globally by 35% from 3.45 to 4.64 Mkm² yr⁻¹ during the period
 18 2001–2010. Tansey et al. (2004) estimated over 3.5 Mkm² yr⁻¹ of burned areas were detected in the
 19 year 2000 (Table 6.32).

20 Although slope and slope aspect are predictive factors of desertification occurrence, the factors with
 21 the greatest influence are land cover factors, such as normalised difference vegetation index (NDVI)
 22 and rangeland classes (Djeddaoui et al. 2017). Therefore, prevention of landslides and natural hazards
 23 exert indirect influence on the occurrence of desertification.

24 The global extent of chemical soil degradation (salinisation, pollution, and acidification) is about 1.03
 25 Mkm² yr⁻¹ (Oldeman et al. 1991), giving the maximum extent of land that could benefit from the
 26 management of pollution and acidification.

27 There are no global data on the impacts of management of invasive species / encroachment on
 28 desertification, though the impact is presumed to be positive. There are no studies examining the
 29 potential role of restoration and avoided conversion of coastal wetlands on desertification.

30 There are no impacts of peatland restoration for prevention of desertification, as peatlands occur in
 31 wet areas and deserts in arid areas, so they are not connected.

32 For management of pollution, including acidification, Oldeman et al. (1991) estimated global extent
 33 of chemical soil degradation, with 0.77 Mkm² yr⁻¹ affected by salinisation, 0.21 Mkm² yr⁻¹ affected by
 34 pollution, and 0.06 Mkm² yr⁻¹ affected by pollution (total: 1.03 Mkm² yr⁻¹), so this is the area that
 35 could potentially benefit from pollution management measures.

1 Biodiversity conservation measures can interact with desertification, but the literature contains no
2 global estimates of potential.

3 Table 6.32 summarises the impacts on desertification of options on all/other ecosystems, with
4 confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative
5 (not exhaustive) references upon which the evidence is based.

6 **Table 6.32 Effects on desertification of response options on all/other ecosystems**

Integrated response option	Potential	Confidence	Citation
Fire management	Up to 3.5-4.9 Mkm ² yr ⁻¹	Medium confidence	Arora and Melton 2018; Randerson et al. 2012; Tansey et al. 2004
Reduced landslides and natural hazards	>0	Low confidence	Djeddaoui et al.; Noble et al. 2014
Reduced pollution including acidification	1.03 Mkm ² yr ⁻¹	Low confidence	Oldeman et al. 1991
Management of invasive species / encroachment	No global estimates	No evidence	
Restoration and reduced conversion of coastal wetlands	No global estimates	No evidence	
Restoration and reduced conversion of peatlands	No impact		
Biodiversity conservation	No global estimates	No evidence	

7

8 **6.3.3.1.5 Integrated response options based on land management specifically for CDR**

9 While spreading of crushed minerals onto land as part of enhanced weathering may provide soil /
10 plant nutrients in nutrient-depleted soils (Beerling et al. 2018), there is no literature reporting on the
11 potential global impacts of this in addressing desertification.

12 Large-scale production of bioenergy can require significant amounts of land (Smith et al. 2016d;
13 Clarke and Jiang 2014a; Popp et al. 2017), with as much as 15 Mkm² in 2100 in 2°C scenarios (Popp
14 et al. 2017), increasing pressures for desertification (Table 6.33).
