Date of draft: 07 August 2019

Drafting Authors:

Almut Arneth (Germany), Humberto Barbosa (Brazil), Tim Benton (United Kingdom), Katherine Calvin (The United States of America), Eduardo Calvo (Peru), Sarah Connors (United Kingdom), Annette Cowie (Australia), Edouard Davin (France/Switzerland), Fatima Denton (The Gambia), Renée van Diemen (The Netherlands/United Kingdom), Fatima Driouech (Morocco), Aziz Elbehri (Morocco), Jason Evans (Australia), Marion Ferrat (France), Jordan Harold (United Kingdom), Eamon Haughey (Ireland), Mario Herrero (Australia/Costa Rica), Joanna House (United Kingdom), Mark Howden (Australia), Margot Hurlbert (Canada), Gensuo Jia (China), Tom Gabriel Johansen (Norway), Jagdish Krishnaswamy (India), Werner Kurz (Canada), Christopher Lennard (South Africa), Soojeong Myeong (Republic of Korea); Nagmeldin Mahmoud (Sudan), Valérie Masson-Delmotte (France), Cheikh Mbow (Senegal), Pamela McElwee (The United States of America), Alisher Mirzabaev (Germany/Uzbekistan), Angela Morelli (Norway/Italy), Wilfran Moufouma-Okia (France), Dalila Nedjraoui (Algeria), Suvadip Neogi (India), Johnson Nkem (Cameroon), Nathalie De Noblet-Ducoudré (France), Lennart Olsson (Sweden), Minal Pathak (India), Jan Petzold (Germany), Ramón Pichs-Madruga (Cuba), Elvira Poloczanska (United Kingdom/Australia), Alexander Popp (Germany), Hans-Otto Pörtner (Germany), Joana Portugal Pereira (United Kingdom), Prajal Pradhan (Nepal/Germany), Andy Reisinger (New Zealand), Debra C. Roberts (South Africa), Cynthia Rosenzweig (The United States of America), Mark Rounsevell (United Kingdom/Germany), Elena Shevliakova (The United States of America), Priyadarshi Shukla (India), Jim Skea (United Kingdom), Raphael Slade (United Kingdom), Pete Smith (United Kingdom), Youba Sokona (Mali), Denis Jean Sonwa (Cameroon), Jean-Francois Soussana (France), Francesco Tubiello (The United States of America/Italy), Louis Verchot (The United States of America/Colombia), Koko Warner (The United States of America/Germany), Nora Weyer (Germany), Jianguo Wu (China), Noureddine Yassaa (Algeria), Panmao Zhai (China), Zinta Zommers (Latvia).

Introduction

This Special Report on Climate Change and Land¹ responds to the Panel decision in 2016 to prepare three Special Reports² during the Sixth Assessment cycle, taking account of proposals from governments and observer organizations³. This report addresses greenhouse gas (GHG) fluxes in land-based ecosystems, land use and sustainable land management⁴ in relation to climate change adaptation and mitigation, desertification⁵, land degradation⁶ and food security⁷. This report follows the publication of other recent reports, including the IPCC *Special Report on Global Warming of 1.5°C* (SR15), the thematic assessment of the Intergovernmental Science Policy Platform on Biodiversity and Ecosystem Services (IPBES) on Land Degradation and Restoration, the IPBES Global Assessment Report on Biodiversity and Ecosystem Services, and the Global Land Outlook of the UN Convention to Combat Desertification (UNCCD). This report provides an updated assessment of the current state of knowledge⁸ while striving for coherence and complementarity with other recent reports.

This Summary for Policymakers (SPM) is structured in four parts: *A) People, land and climate in a warming world; B) Adaptation and mitigation response options; C) Enabling response options; and D) Action in the near-term.*

Confidence in key findings is indicated using the IPCC calibrated language⁹; the underlying scientific basis of each key finding is indicated by references to the main report.

¹ The terrestrial portion of the biosphere that comprises the natural resources (soil, near-surface air, vegetation and other biota, and water), the ecological processes, topography, and human settlements and infrastructure that operate within that system.

² The three Special reports are: “Global Warming of 1.5°C. An IPCC special report on the impacts of global warming of 1.5°C above pre-industrial levels and related global greenhouse gas emission pathways, in the context of strengthening the global response to the threat of climate change, sustainable development, and efforts to eradicate poverty.”; “Climate Change and Land: an IPCC Special Report on Climate Change, Desertification, Land Degradation, Sustainable Land Management, Food Security, and Greenhouse gas fluxes in Terrestrial Ecosystems”; “The Ocean and Cryosphere in a Changing Climate”

³ related proposals were: climate change and desertification; desertification with regional aspects; land degradation – an assessment of the interlinkages and integrated strategies for mitigation and adaptation; agriculture, forestry and other landuse; food and agriculture; and food security and climate change.

⁴ Sustainable Land Management is defined in this report as “the stewardship and use of land resources, including soils, water, animals and plants, to meet changing human needs, while simultaneously ensuring the long-term productive potential of these resources and the maintenance of their environmental functions”.

⁵ Desertification is defined in this report as ‘land degradation in arid, semi-arid, and dry sub-humid areas resulting from many factors, including climatic variations and human activities’.

⁶ Land degradation is defined in this report as ‘a negative trend in land condition, caused by direct or indirect human induced processes, including anthropogenic climate change, expressed as long-term reduction and as loss of at least one of the following: biological productivity, ecological integrity, or value to humans’.

⁷ Food security is defined in this report as ‘a situation that exists when all people, at all times, have physical, social, and economic access to sufficient, safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life’.

⁸ The assessment covers literature accepted for publication by 7th April 2019.

⁹ Each finding is grounded in an evaluation of underlying evidence and agreement. A level of confidence is expressed using five qualifiers: very low, low, medium, high and very high, and typeset in italics, for example, medium

A. People, land and climate in a warming world

A1. Land provides the principal basis for human livelihoods and well-being including the supply of food, freshwater and multiple other ecosystem services, as well as biodiversity. Human use directly affects more than 70% (*likely 69-76%*) of the global, ice-free land surface (*high confidence*). Land also plays an important role in the climate system. {1.1, 1.2, 2.3, 2.4, Figure SPM.1}

A1.1. People currently use one quarter to one third of land's potential net primary production¹⁰ for food, feed, fibre, timber and energy. Land provides the basis for many other ecosystem functions and services¹¹, including cultural and regulating services, that are essential for humanity (*high confidence*). In one economic approach, the world's terrestrial ecosystem services have been valued on an annual basis to be approximately equivalent to the annual global Gross Domestic Product¹² (*medium confidence*). {1.1, 1.2, 3.2, 4.1, 5.1, 5.5, Figure SPM.1}

A1.2. Land is both a source and a sink of greenhouse gases (GHGs) and plays a key role in the exchange of energy, water and aerosols between the land surface and atmosphere. Land ecosystems and biodiversity are vulnerable to ongoing climate change and weather and climate extremes, to different extents. Sustainable land management can contribute to reducing the negative impacts of multiple stressors, including climate change, on ecosystems and societies (*high confidence*). {1.1, 1.2, 3.2, 4.1, 5.1, 5.5, Figure SPM.1}

A1.3. Data available since 1961¹³ show that global population growth and changes in per capita consumption of food, feed, fibre, timber and energy have caused unprecedented rates of land and freshwater use (*very high confidence*) with agriculture currently accounting for ca. 70% of global fresh-water use (*medium confidence*). Expansion of areas under agriculture and forestry, including commercial production, and enhanced agriculture and forestry productivity have supported consumption and food availability for a growing population (*high confidence*). With

confidence. The following terms have been used to indicate the assessed likelihood of an outcome or a result: virtually certain 99–100% probability, very likely 90–100%, likely 66–100%, about as likely as not 33–66%, unlikely 0–33%, very unlikely 0–10%, exceptionally unlikely 0–1%. Additional terms (extremely likely 95–100%, more likely than not >50–100%, more unlikely than likely 0–<50%, extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, for example, very likely. This is consistent with IPCC AR5.

¹⁰ Land's potential net primary production (NPP) is defined in this report as the amount of carbon accumulated through photosynthesis minus the amount lost by plant respiration over a specified time period that would prevail in the absence of land use.

¹¹ In its conceptual framework, IPBES uses “nature’s contribution to people” in which it includes ecosystem goods and services.

¹² i.e. estimated at \$75 trillion for 2011, based on US dollars for 2007.

¹³ This statement is based on the most comprehensive data from national statistics available within FAOSTAT, which starts in 1961. This does not imply that the changes started in 1961. Land use changes have been taking place from well before the pre-industrial period to the present.

large regional variation, these changes have contributed to increasing net GHG emissions (*very high confidence*), loss of natural ecosystems (e.g. forests, savannahs, natural grasslands and wetlands) and declining biodiversity (*high confidence*). {1.1, 1.3, 5.1, 5.5, Figure SPM.1}

A1.4. Data available since 1961 shows the per capita supply of vegetable oils and meat has more than doubled and the supply of food calories per capita has increased by about one third (*high confidence*). Currently, 25-30% of total food produced is lost or wasted (*medium confidence*). These factors are associated with additional GHG emissions (*high confidence*). Changes in consumption patterns have contributed to about 2 billion adults now being overweight or obese (*high confidence*). An estimated 821 million people are still undernourished (*high confidence*). {1.1, 1.3, 5.1, 5.5, Figure SPM.1}

A1.5. About a quarter of the Earth's ice-free land area is subject to human-induced degradation (*medium confidence*). Soil erosion from agricultural fields is estimated to be currently 10 to 20 times (no tillage) to more than 100 times (conventional tillage) higher than the soil formation rate (*medium confidence*). Climate change exacerbates land degradation, particularly in low-lying coastal areas, river deltas, drylands and in permafrost areas (*high confidence*). Over the period 1961-2013, the annual area of drylands in drought has increased, on average by slightly more than 1% per year, with large inter-annual variability. In 2015, about 500 (380-620) million people lived within areas which experienced desertification between the 1980s and 2000s. The highest numbers of people affected are in South and East Asia, the circum Sahara region including North Africa, and the Middle East including the Arabian peninsula (*low confidence*). Other dryland regions have also experienced desertification. People living in already degraded or desertified areas are increasingly negatively affected by climate change (*high confidence*). {1.1, 1.2, 3.1, 3.2, 4.1, 4.2, 4.3, Figure SPM.1}

Land use and observed climate change

A. Observed temperature change relative to 1850-1900

Since the pre-industrial period (1850-1900) the observed mean land surface air temperature has risen considerably more than the global mean surface (land and ocean) temperature (GMST).

CHANGE in TEMPERATURE rel. to 1850-1900 (°C)

B. GHG emissions

An estimated 23% of total anthropogenic greenhouse gas emissions (2007-2016) derive from Agriculture, Forestry and Other Land Use (AFOLU).

CHANGE in emissions rel. to 1961

- 1 Net CO₂ emissions from FOLU (Gt CO₂/yr)
- 2 CH₄ emissions from Agriculture (Gt CO₂eq/yr)
- 3 N₂O emissions from Agriculture (Gt CO₂eq/yr)

Gt CO₂eq/yr

C. Global land use in circa 2015

The bar chart depicts shares of different uses of the global, ice-free land area. Bars are ordered along a gradient of decreasing land-use intensity from left to right.

D. Agricultural production

Land use change and rapid land use intensification have supported the increasing production of food, feed and fibre. Since 1961, the total production of food (cereal crops) has increased by 240% (until 2017) because of land area expansion and increasing yields. Fibre production (cotton) increased by 162% (until 2013).

CHANGE in % rel. to 1961

- 1 Inorganic N fertiliser use
- 2 Cereal yields
- 3 Irrigation water volume
- 4 Total number of ruminant livestock

E. Food demand

Increases in production are linked to consumption changes.

CHANGE in % rel. to 1961 and 1975

- 1 Population
- 2 Prevalence of overweight + obese
- 3 Total calories per capita
- 4 Prevalence of underweight

F. Desertification and land degradation

Land-use change, land-use intensification and climate change have contributed to desertification and land degradation.

CHANGE in % rel. to 1961 and 1970

- 1 Population in areas experiencing desertification
- 2 Dryland areas in drought annually
- 3 Inland wetland extent

Figure SPM.1: Land use and observed climate change

A representation of the land use and observed climate change covered in this assessment report. Panels A-F show the status and trends in selected land use and climate variables that represent many of the core topics covered in this report. The annual time series in B and D-F are based on the most comprehensive, available data from national statistics, in most cases from FAOSTAT which starts in 1961. Y-axes in panels D-F are expressed relative to the starting year of the time series (rebased to zero). Data sources and notes: **A:** The warming curves are averages of four datasets {2.1; Figure 2.2; Table 2.1} **B:** N₂O and CH₄ from agriculture are from FAOSTAT; Net CO₂ emissions from FOLU using the mean of two bookkeeping models (including emissions from peatland fires since 1997). All values expressed in units of CO₂-eq are based on AR5 100 year Global Warming Potential values without climate-carbon feedbacks (N₂O=265; CH₄=28). {see Table SPM.1, 1.1, 2.3} **C:** Depicts shares of different uses of the global, ice-free land area for approximately the year 2015, ordered along a gradient of decreasing land-use intensity from left to right. Each bar represents a broad land cover category; the numbers on top are the total % of the ice-free area covered, with uncertainty ranges in brackets. Intensive pasture is defined as having a livestock density greater than 100 animals/km². The area of ‘forest managed for timber and other uses’ was calculated as total forest area minus ‘primary/intact’ forest area. {1.2, Table 1.1, Figure 1.3} **D:** Note that fertiliser use is shown on a split axis. The large percentage change in fertiliser use reflects the low level of use in 1961 and relates to both increasing fertiliser input per area as well as the expansion of fertilised cropland and grassland to increase food production. {1.1, Figure 1.3} **E:** Overweight population is defined as having a body mass index (BMI) > 25 kg m⁻²; underweight is defined as BMI < 18.5 kg m⁻². {5.1, 5.2} **F:** Dryland areas were estimated using TerraClimate precipitation and potential evapotranspiration (1980-2015) to identify areas where the Aridity Index is below 0.65. Population data are from the HYDE3.2 database. Areas in drought are based on the 12-month accumulation Global Precipitation Climatology Centre Drought Index. The inland wetland extent (including peatlands) is based on aggregated data from more than 2000 time series that report changes in local wetland area over time. {3.1, 4.2, 4.6}

A 2. Since the pre-industrial period, the land surface air temperature has risen nearly twice as much as the global average temperature (*high confidence*). Climate change, including increases in frequency and intensity of extremes, has adversely impacted food security and terrestrial ecosystems as well as contributed to desertification and land degradation in many regions (*high confidence*). {2.2, 3.2, 4.2, 4.3, 4.4, 5.1, 5.2, Executive Summary Chapter 7, 7.2}

A2.1. Since the pre-industrial period (1850-1900) the observed mean land surface air temperature has risen considerably more than the global mean surface (land and ocean) temperature (GMST) (*high confidence*). From 1850-1900 to 2006-2015 mean land surface air temperature has increased by 1.53°C (very likely range from 1.38°C to 1.68°C) while GMST increased by 0.87°C (likely range from 0.75°C to 0.99°C). {2.2.1, Figure SPM.1}

A2.2. Warming has resulted in an increased frequency, intensity and duration of heat-related events, including heat waves¹⁴ in most land regions (*high confidence*). Frequency and intensity of droughts has increased in some regions (including the Mediterranean, west Asia, many parts of South America, much of Africa, and north-eastern Asia) (*medium confidence*) and there

¹⁴ A heatwave is defined in this report as ‘a period of abnormally hot weather. Heatwaves and warm spells have various and in some cases overlapping definitions’.

has been an increase in the intensity of heavy precipitation events at a global scale (*medium confidence*). {2.2.5, 4.2.3, 5.2}

A2.3. Satellite observations¹⁵ have shown vegetation greening¹⁶ over the last three decades in parts of Asia, Europe, South America, central North America, and southeast Australia. Causes of greening include combinations of an extended growing season, nitrogen deposition, CO₂ fertilisation¹⁷, and land management (*high confidence*). Vegetation browning¹⁸ has been observed in some regions including northern Eurasia, parts of North America, Central Asia and the Congo Basin, largely as a result of water stress (*medium confidence*). Globally, vegetation greening has occurred over a larger area than vegetation browning (*high confidence*). {2.2.3, Box 2.3, 2.2.4, 3.2.1, 3.2.2, 4.3.1, 4.3.2, 4.6.2, 5.2.2}

A2.4. The frequency and intensity of dust storms have increased over the last few decades due to land use and land cover changes and climate-related factors in many dryland areas resulting in increasing negative impacts on human health, in regions such as the Arabian Peninsula and broader Middle East, Central Asia (*high confidence*)¹⁹. {2.4.1, 3.4.2}

A2.5. In some dryland areas, increased land surface air temperature and evapotranspiration and decreased precipitation amount, in interaction with climate variability and human activities, have contributed to desertification. These areas include Sub-Saharan Africa, parts of East and Central Asia, and Australia. (*medium confidence*) {2.2, 3.2.2, 4.4.1}

A2.6. Global warming has led to shifts of climate zones in many world regions, including expansion of arid climate zones and contraction of polar climate zones (*high confidence*). As a consequence, many plant and animal species have experienced changes in their ranges, abundances, and shifts in their seasonal activities (*high confidence*). {2.2, 3.2.2, 4.4.1}

A2.7. Climate change can exacerbate land degradation processes (*high confidence*) including through increases in rainfall intensity, flooding, drought frequency and severity, heat stress, dry spells, wind, sea-level rise and wave action, permafrost thaw with outcomes being

¹⁵ The interpretation of satellite observations can be affected by insufficient ground validation and sensor calibration. In addition their spatial resolution can make it difficult to resolve small-scale changes.

¹⁶ Vegetation greening is defined in this report as an increase in photosynthetically active plant biomass which is inferred from satellite observations.

¹⁷ CO₂ fertilization is defined in this report as the enhancement of plant growth as a result of increased atmospheric carbon dioxide (CO₂) concentration. The magnitude of CO₂ fertilization depends on nutrients and water availability.

¹⁸ Vegetation browning is defined in this report as a decrease in photosynthetically active plant biomass which is inferred from satellite observations.

¹⁹ Evidence relative to such trends in dust storms and health impacts in other regions is limited in the literature assessed in this report.

modulated by land management. Ongoing coastal erosion is intensifying and impinging on more regions with sea level rise adding to land use pressure in some regions (*medium confidence*). {4.2.1, 4.2.2, 4.2.3, 4.4.1, 4.4.2, 4.9.6, Table 4.1, 7.2.1, 7.2.2}

A2.8. Climate change has already affected food security due to warming, changing precipitation patterns, and greater frequency of some extreme events (*high confidence*). In many lower-latitude regions, yields of some crops (e.g., maize and wheat) have declined, while in many higher-latitude regions, yields of some crops (e.g., maize, wheat and sugar beets) have increased over recent decades (*high confidence*). Climate change has resulted in lower animal growth rates and productivity in pastoral systems in Africa (*high confidence*). There is robust evidence that agricultural pests and diseases have already responded to climate change resulting in both increases and decreases of infestations (*high confidence*). Based on indigenous and local knowledge, climate change is affecting food security in drylands, particularly those in Africa, and high mountain regions of Asia and South America²⁰. {5.2.1, 5.2.2, 7.2.2}

A 3. Agriculture, Forestry and Other Land Use (AFOLU) activities accounted for around 13% of CO₂, 44% of methane (CH₄), and 82% of nitrous oxide (N₂O) emissions from human activities globally during 2007-2016, representing 23% (12.0 +/- 3.0 GtCO₂e yr⁻¹) of total net anthropogenic emissions of GHGs²¹ (*medium confidence*). The natural response of land to human-induced environmental change caused a net sink of around 11.2 GtCO₂ yr⁻¹ during 2007-2016 (equivalent to 29% of total CO₂ emissions) (*medium confidence*); the persistence of the sink is uncertain due to climate change (*high confidence*). If emissions associated with pre- and post-production activities in the global food system²² are included, the emissions are estimated to be 21-37% of total net anthropogenic GHG emissions (*medium confidence*). {2.3, Table 2.2, 5.4}.

A3.1. Land is simultaneously a source and a sink of CO₂ due to both anthropogenic and natural drivers, making it hard to separate anthropogenic from natural fluxes (*very high confidence*). Global models estimate net CO₂ emissions of 5.2 ± 2.6 GtCO₂ yr⁻¹ (*likely range*) from land use and land-use change during 2007-16. These net emissions are mostly due to deforestation, partly offset by afforestation/reforestation, and emissions and removals by other land use activities

²⁰ The assessment covered literature whose methodologies included interviews and surveys with indigenous peoples and local communities.

²¹ This assessment only includes CO₂, CH₄ and N₂O.

²² Global food system in this report is defined as ‘all the elements (environment, people, inputs, processes, infrastructures, institutions, etc.) and activities that relate to the production, processing, distribution, preparation and consumption of food, and the output of these activities, including socioeconomic and environmental outcomes at the global level’. These emissions data are not directly comparable to the national inventories prepared according to the 2006 IPCC Guidelines for National Greenhouse Gas.

(*very high confidence*) (Table SPM.1)²³. There is no clear trend in annual emissions since 1990 (*medium confidence*) (Figure SPM.1). {1.1, 2.3, Table 2.2, Table 2.3}

A3.2. The natural response of land to human-induced environmental changes such as increasing atmospheric CO₂ concentration, nitrogen deposition, and climate change, resulted in global net removals of 11.2 +/- 2.6 Gt CO₂ yr⁻¹ (*likely range*) during 2007-2016 (Table SPM.1). The sum of the net removals due to this response and the AFOLU net emissions gives a total net land-atmosphere flux that removed 6.0 +/- 2.6 GtCO₂ yr⁻¹ during 2007-2016 (*likely range*). Future net increases in CO₂ emissions from vegetation and soils due to climate change are projected to counteract increased removals due to CO₂ fertilisation and longer growing seasons (*high confidence*). The balance between these processes is a key source of uncertainty for determining the future of the land carbon sink. Projected thawing of permafrost is expected to increase the loss of soil carbon (*high confidence*). During the 21st century, vegetation growth in those areas may compensate in part for this loss (*low confidence*). {Box 2.3, 2.3.1, 2.5.3, 2.7; Table 2.3}

A3.3. Global models and national GHG inventories use different methods to estimate anthropogenic CO₂ emissions and removals for the land sector. Both produce estimates that are in close agreement for land-use change involving forest (e.g., deforestation, afforestation), and differ for managed forest. Global models consider as managed forest those lands that were subject to harvest whereas, consistent with IPCC guidelines, national GHG inventories define managed forest more broadly. On this larger area, inventories can also consider the natural response of land to human-induced environmental changes as anthropogenic, while the global model approach {Table SPM.1} treats this response as part of the non-anthropogenic sink. For illustration, from 2005 to 2014, the sum of the national GHG inventories net emission estimates is 0.1±1.0 GtCO₂yr⁻¹, while the mean of two global bookkeeping models is 5.1±2.6 GtCO₂yr⁻¹ (*likely range*). Consideration of differences in methods can enhance understanding of land sector net emission estimates and their applications.

²³ The net anthropogenic flux of CO₂ from “bookkeeping” or “carbon accounting” models is composed of two opposing gross fluxes: gross emissions (about 20 GtCO₂ yr⁻¹) are from deforestation, cultivation of soils, and oxidation of wood products; gross removals (about 14 GtCO₂ yr⁻¹) are largely from forest growth following wood harvest and agricultural abandonment (*medium confidence*).

Table SPM1. Net anthropogenic emissions due to Agriculture, Forestry, and other Land Use (AFOLU) and non-AFOLU (Panel 1) and global food systems (average for 2007-2016)¹ (Panel 2). Positive value represents emissions; negative value represents removals.

		Direct Anthropogenic							
		Net anthropogenic emissions due to Agriculture, Forestry, and Other Land Use (AFOLU)			Non-AFOLU anthropogenic GHG emissions ⁶	Total net anthropogenic emissions (AFOLU + non-AFOLU) by gas	AFOLU as a % of total net anthropogenic emissions, by gas	Natural response of land to human-induced environmental change ⁷	Net land – atmosphere flux from all lands
Panel 1: Contribution of AFOLU

Data sources and notes:

¹ Estimates are only given until 2016 as this is the latest date when data are available for all gases.

² Net anthropogenic flux of CO₂ due to land cover change such as deforestation and afforestation, and land management including wood harvest and regrowth, as well as peatland burning, based on two bookkeeping models as used in the Global Carbon Budget and for AR5. Agricultural soil carbon stock change under the same land use is not considered in these models. {2.3.1.2.1, Table 2.2, Box 2.2}

³ Estimates show the mean and assessed uncertainty of two databases, FAOSTAT and USEPA 2012 {2.3; Table 2.2}

⁴ Based on FAOSTAT. Categories included in this value are “net forest conversion” (net deforestation), drainage of organic soils (cropland and grassland), biomass burning (humid tropical forests, other forests, organic soils). It excludes “forest land” (forest management plus net forest expansion), which is primarily a sink due to afforestation. Note: total FOLU emissions from FAOSTAT are 2.8 (±1.4) Gt CO₂ yr⁻¹ for the period 2007-2016. {Table 2.2, Table 5.4}

⁵ CO₂ emissions induced by activities not included in the AFOLU sector, mainly from energy (e.g. grain drying), transport (e.g. international trade), and industry (e.g. synthesis of inorganic fertilizers) part of food systems, including agricultural production activities (e.g. heating in greenhouses), pre-production (e.g. manufacturing of farm inputs) and post-production (e.g. agri-food processing) activities. This estimate is land based and hence excludes emissions from fisheries. It includes emissions from fibre and other non-food agricultural products since these are not separated from food use in data bases. The CO₂ emissions related to food system in other sectors than AFOLU are 6-13% of total anthropogenic CO₂ emissions. These emissions are typically low in smallholder subsistence farming. When added to AFOLU emissions, the estimated share of food systems in global anthropogenic emissions is 21-37%. {5.4.5, Table 5.4}

⁶ Total non-AFOLU emissions were calculated as the sum of total CO₂e emissions values for energy, industrial sources, waste and other emissions with data from the Global Carbon Project for CO₂, including international aviation and shipping and from the PRIMAP database for CH₄ and N₂O averaged over 2007-2014 only as that was the period for which data were available {2.3; Table 2.2}.

⁷ The natural response of land to human-induced environmental changes is the response of vegetation and soils to environmental changes such as increasing atmospheric CO₂ concentration, nitrogen deposition, and climate change. The estimate shown represents the average from Dynamic Global Vegetation Models {2.3.1.2.4, Box 2.2, Table 2.3}

⁸ All values expressed in units of CO₂e are based on AR5 100 year Global Warming Potential (GWP) values without climate-carbon feedbacks (N₂O = 265; CH₄ = 28). Note that the GWP has been used across fossil fuel and biogenic sources of methane. If a higher GWP for fossil fuel CH₄ (30 per AR5), then total anthropogenic CH₄ emissions expressed in CO₂e would be 2% greater.

⁹ This estimate is land based and hence excludes emissions from fisheries and emissions from aquaculture (except emissions from feed produced on land and used in aquaculture), and also includes non-food use (e.g. fibre and bioenergy) since these are not separated from food use in databases. It excludes non-CO₂ emissions associated with land use change (FOLU category) since these are from fires in forests and peatlands.

¹⁰ Emissions associated with food loss and waste are included implicitly, since emissions from food system are related to food produced, including food consumed for nutrition and to food loss and waste. The latter is estimated at 8-10% of total anthropogenic emissions in CO₂e. {5.5.2.5}

¹¹ No global data are available for agricultural CO₂ emissions

A3.4. Global AFOLU emissions of methane in the period 2007-2016 were 162 ± 49 Mt CH₄ yr⁻¹ (4.5 ± 1.4 GtCO₂eq yr⁻¹) (*medium confidence*). The globally averaged atmospheric concentration of methane shows a steady increase between the mid-1980s and early 1990s, slower growth thereafter until 1999, a period of no growth between 1999-2006, followed by a resumption of growth in 2007 (*high confidence*). Biogenic sources make up a larger proportion of emissions than they did before 2000 (*high confidence*). Ruminants and the expansion of rice cultivation are important contributors to the rising concentration (*high confidence*). {Table 2.2, 2.3.2, 5.4.2, 5.4.3, Figure SPM.1}.

A3.5. Anthropogenic AFOLU N₂O emissions are rising, and were 8.3 ± 2.5 MtN₂O yr⁻¹ (2.3 ± 0.7 GtCO₂eq yr⁻¹) during the period 2007-2016. Anthropogenic N₂O emissions (Figure SPM.1, Table SPM.1) from soils are primarily due to nitrogen application including inefficiencies (over-application or poorly synchronised with crop demand timings) (*high confidence*). Cropland soils emitted around 3 Mt N₂O yr⁻¹ (around 795 MtCO₂-eq yr⁻¹) during the period 2007-2016 (*medium confidence*). There has been a major growth in emissions from managed pastures due to increased manure deposition (*medium confidence*). Livestock on managed pastures and rangelands accounted for more than one half of total anthropogenic N₂O emissions from agriculture in 2014 (*medium confidence*). {Table 2.1, 2.3.3, 5.4.2, 5.4.3}

A3.6. Total net GHG emissions from agriculture, forestry, and other land use (AFOLU) emissions represent 12.0 ± 3.0 GtCO₂eq yr⁻¹ during 2007-2016. This represents 23% of total net anthropogenic emissions²⁴ (Table SPM.1). Other approaches, such as global food system, include agricultural emissions and land use change (i.e., deforestation and peatland degradation), as well as outside farm gate emissions from energy, transport and industry sectors for food production. Emissions within farm gate and from agricultural land expansion contributing to the global food system represent 16-27% of total anthropogenic emissions (*medium confidence*). Emissions outside the farm gate represent 5-10% of total anthropogenic emissions (*medium confidence*). Given the diversity of food systems, there are large regional differences in the contributions from different components of the food system (*very high confidence*). Emissions from agricultural production are projected to increase (*high confidence*), driven by population and income growth and changes in consumption patterns (*medium confidence*). {5.5, Table 5.4}

A 4. Changes in land conditions²⁵, either from land-use or climate change, affect global and regional climate (*high confidence*). At the regional scale, changing land conditions can reduce or accentuate warming and affect the intensity, frequency and duration of extreme events. The magnitude and direction of these changes vary with location and season (*high confidence*). {Executive Summary Chapter 2, 2.3, 2.4, 2.5, 3.3}

A4.1. Since the pre-industrial period, changes in land cover due to human activities have led to both a net release of CO₂ contributing to global warming (*high confidence*), and an increase in global land albedo²⁶ causing surface cooling (*medium confidence*). Over the historical period, the resulting net effect on globally averaged surface temperature is estimated to be small (*medium confidence*). {2.4, 2.6.1, 2.6.2}

²⁴ This assessment only includes CO₂, CH₄ and N₂O.

²⁵ Land conditions encompass changes in land cover (e.g. deforestation, afforestation, urbanisation), in land use (e.g. irrigation), and in land state (e.g. degree of wetness, degree of greening, amount of snow, amount of permafrost)

²⁶ Land with high albedo reflects more incoming solar radiation than land with low albedo.

A4.2. The likelihood, intensity and duration of many extreme events can be significantly modified by changes in land conditions, including heat related events such as heat waves (*high confidence*) and heavy precipitation events (*medium confidence*). Changes in land conditions can affect temperature and rainfall in regions as far as hundreds of kilometres away (*high confidence*). {2.5.1, 2.5.2, 2.5.4, 3.3; Cross-Chapter Box 4 in Chapter 2}

A4.3. Climate change is projected to alter land conditions with feedbacks on regional climate. In those boreal regions where the treeline migrates northward and/or the growing season lengthens, winter warming will be enhanced due to decreased snow cover and albedo while warming will be reduced during the growing season because of increased evapotranspiration (*high confidence*). In those tropical areas where increased rainfall is projected, increased vegetation growth will reduce regional warming (*medium confidence*). Drier soil conditions resulting from climate change can increase the severity of heat waves, while wetter soil conditions have the opposite effect (*high confidence*). {2.5.2, 2.5.3}

A4.4. Desertification amplifies global warming through the release of CO₂ linked with the decrease in vegetation cover (*high confidence*). This decrease in vegetation cover tends to increase local albedo, leading to surface cooling (*high confidence*). {3.3}

A4.5. Changes in forest cover for example from afforestation, reforestation and deforestation, directly affect regional surface temperature through exchanges of water and energy²⁷ (*high confidence*). Where forest cover increases in tropical regions cooling results from enhanced evapotranspiration (*high confidence*). Increased evapotranspiration can result in cooler days during the growing season (*high confidence*) and can reduce the amplitude of heat related events (*medium confidence*). In regions with seasonal snow cover, such as boreal and some temperate, increased tree and shrub cover also has a wintertime warming influence due to reduced surface albedo²⁸ (*high confidence*). {2.3, 2.4.3, 2.5.1, 2.5.2, 2.5.4}

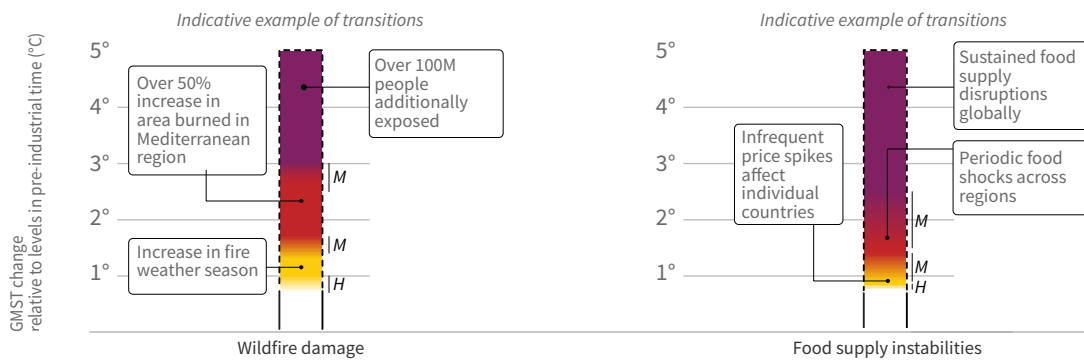

A4.6. Both global warming and urbanisation can enhance warming in cities and their surroundings (heat island effect), especially during heat related events, including heat waves (*high confidence*). Night-time temperatures are more affected by this effect than daytime temperatures (*high confidence*). Increased urbanisation can also intensify extreme rainfall events over the city or downwind of urban areas (*medium confidence*). {2.5.1, 2.5.2, 2.5.3, 4.9.1, Cross-Chapter Box 4 in Chapter 2}

²⁷ The literature indicates that forest cover changes can also affect climate through changes in emissions of reactive gases and aerosols {2.4, 2.5}.

²⁸ Emerging literature shows that boreal forest-related aerosols may counteract at least partly the warming effect of surface albedo {2.4.3}.

A. Risks to humans and ecosystems from changes in land-based processes as a result of climate change

Increases in global mean surface temperature (GMST), relative to pre-industrial levels, affect processes involved in **desertification** (water scarcity), **land degradation** (soil erosion, vegetation loss, wildfire, permafrost thaw) and **food security** (crop yield and food supply instabilities). Changes in these processes drive risks to food systems, livelihoods, infrastructure, the value of land, and human and ecosystem health. Changes in one process (e.g. wildfire or water scarcity) may result in compound risks. Risks are location-specific and differ by region.

B. Different socioeconomic pathways affect levels of climate related risks

Socio-economic choices can reduce or exacerbate climate related risks as well as influence the rate of temperature increase. The **SSP1** pathway illustrates a world with low population growth, high income and reduced inequalities, food produced in low GHG emission systems, effective land use regulation and high adaptive capacity. The **SSP3** pathway has the opposite trends. Risks are lower in SSP1 compared with SSP3 given the same level of GMST increase.

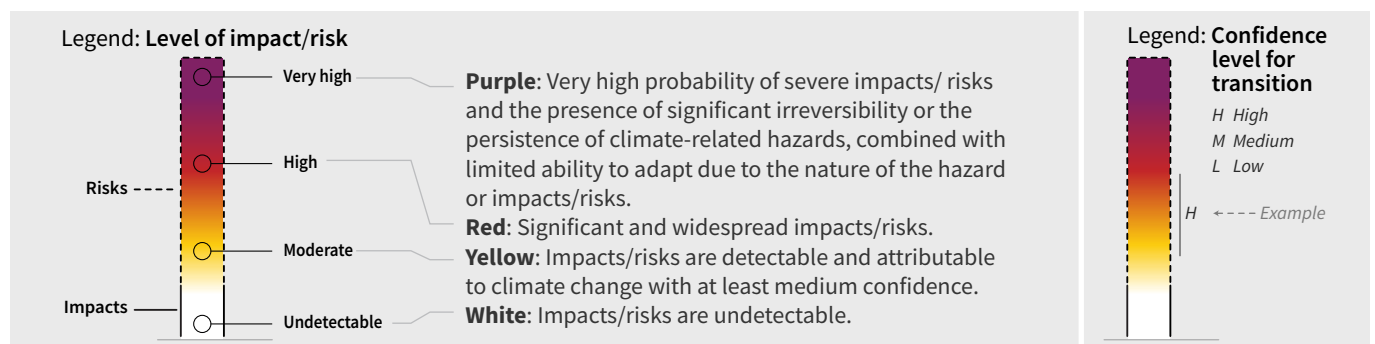

Figure SPM. 2 Risks to land-related human systems and ecosystems from global climate change, socio-economic development and mitigation choices in terrestrial ecosystems.

As in previous IPCC reports the literature was used to make expert judgements to assess the levels of global warming at which levels of risk are undetectable, moderate, high or very high, as described further in Chapter 7 and other parts of the underlying report. The figure indicates assessed risks at approximate warming levels which may be influenced by a variety of factors, including adaptation responses. The assessment considers adaptive capacity consistent with the SSP pathways as described below. **Panel A:** Risks to selected elements of the land system as a function of global mean surface temperature {2.1; Box 2.1; 3.5; 3.7.1.1; 4.4.1.1; 4.4.1.2; 4.4.1.3; 5.2.2; 5.2.3; 5.2.4; 5.2.5; 7.2;7.3, Table SM7.1}. Links to broader systems are illustrative and not intended to be comprehensive. Risk levels are estimated assuming medium exposure and vulnerability driven by moderate trends in socioeconomic conditions broadly consistent with an SSP2 pathway. {Table SM7.4}. **Panel B:** Risks associated with desertification, land degradation and food security due to climate change and patterns of socio-economic development. Increasing risks associated with desertification include population exposed and vulnerable to water scarcity in drylands. Risks related to land degradation include increased habitat degradation, population exposed to wildfire and floods and costs of floods. Risks to food security include availability and access to food, including population at risk of hunger, food price increases and increases in disability adjusted life years attributable due to childhood underweight. Risks are assessed for two contrasted socio-economic pathways (SSP1 and SSP3 {SPM Box 1}) excluding the effects of targeted mitigation policies {3.5; 4.2.1.2; 5.2.2; 5.2.3; 5.2.4; 5.2.5; 6.1.4; 7.2, Table SM7.5}. Risks are not indicated beyond 3°C because SSP1 does not exceed this level of temperature change. **All panels:** As part of the assessment, literature was compiled and data extracted into a summary table. A formal expert elicitation protocol (based on modified-Delphi technique and the Sheffield Elicitation Framework), was followed to identify risk transition thresholds. This included a multi-round elicitation process with two rounds of independent anonymous threshold judgement, and a final consensus discussion. Further information on methods and underlying literature can be found in Chapter 7 Supplementary Material.

BOX SPM.1: Shared Socioeconomic Pathways (SSPs)

In this report the implications of future socio-economic development on climate change mitigation, adaptation and land-use are explored using shared socio-economic pathways (SSPs). The SSPs span a range of challenges to climate change mitigation and adaptation.

- SSP1 includes a peak and decline in population (~7 billion in 2100), high income and reduced inequalities, effective land-use regulation, less resource intensive consumption, including food produced in low-GHG emission systems and lower food waste, free trade and environmentally-friendly technologies and lifestyles. Relative to other pathways, SSP1 has low challenges to mitigation and low challenges to adaptation (i.e., high adaptive capacity).
- SSP2 includes medium population growth (~9 billion in 2100), medium income; technological progress, production and consumption patterns are a continuation of past trends, and only gradual reduction in inequality occurs. Relative to other pathways, SSP2 has medium challenges to mitigation and medium challenges to adaptation (i.e., medium adaptive capacity).

- SSP3 includes high population (~13 billion in 2100), low income and continued inequalities, material-intensive consumption and production, barriers to trade, and slow rates of technological change. Relative to other pathways, SSP3 has high challenges to mitigation and high challenges to adaptation (i.e., low adaptive capacity).
- SSP4 includes medium population growth (~9 billion in 2100), medium income, but significant inequality within and across regions. Relative to other pathways, SSP4 has low challenges to mitigation, but high challenges to adaptation (i.e., low adaptive capacity).
- SSP5 includes a peak and decline in population (~7 billion in 2100), high income, reduced inequalities, and free trade. This pathway includes resource-intensive production, consumption and lifestyles. Relative to other pathways, SSP5 has high challenges to mitigation, but low challenges to adaptation (i.e., high adaptive capacity).

The SSPs can be combined with Representative Concentration Pathways (RCPs) which imply different levels of mitigation, with implications for adaptation. Therefore, SSPs can be consistent with different levels of global mean surface temperature rise as projected by different SSP-RCP combinations. However, some SSP-RCP combinations are not possible; for instance RCP2.6 and lower levels of future global mean surface temperature rise (e.g., 1.5°C) are not possible in SSP3 in modelled pathways. {1.2.2, Cross-Chapter Box 1 in Chapter 1, 6.1.4, Cross-Chapter Box 9 in Chapter 6}

A 5. Climate change creates additional stresses on land, exacerbating existing risks to livelihoods, biodiversity, human and ecosystem health, infrastructure, and food systems (*high confidence*). Increasing impacts on land are projected under all future GHG emission scenarios (*high confidence*). Some regions will face higher risks, while some regions will face risks previously not anticipated (*high confidence*). Cascading risks with impacts on multiple systems and sectors also vary across regions (*high confidence*). {2.2, 3.5, 4.2, 4.4, 4.7, 5.1, 5.2, 5.8, 6.1, 7.2, 7.3, Cross-Chapter Box 9 in Chapter 6, Figure SPM.2}

A5.1. With increasing warming, the frequency, intensity and duration of heat related events including heat waves are projected to continue to increase through the 21st century (*high confidence*). The frequency and intensity of droughts are projected to increase particularly in the Mediterranean region and southern Africa (*medium confidence*). The frequency and intensity of extreme rainfall events are projected to increase in many regions (*high confidence*). {2.2.5, 3.5.1, 4.2.3, 5.2}

A5.2. With increasing warming, climate zones are projected to further shift poleward in the middle and high latitudes (*high confidence*). In high-latitude regions, warming is projected to increase disturbance in boreal forests, including drought, wildfire, and pest outbreaks (*high confidence*). In tropical regions, under medium and high GHG emissions scenarios, warming is projected to result in the emergence of unprecedented²⁹ climatic conditions by the mid to late 21st century (*medium confidence*). {2.2.4, 2.2.5, 2.5.3, 4.3.2}

A5.3. Current levels of global warming are associated with moderate risks from increased dryland water scarcity, soil erosion, vegetation loss, wildfire damage, permafrost thawing, coastal degradation and tropical crop yield decline (*high confidence*). Risks, including cascading risks, are projected to become increasingly severe with increasing temperatures. At around 1.5°C of global warming the risks from dryland water scarcity, wildfire damage, permafrost degradation and food supply instabilities are projected to be high (*medium confidence*). At around 2°C of global warming the risk from permafrost degradation and food supply instabilities are projected to be very high (*medium confidence*). Additionally, at around 3°C of global warming risk from vegetation loss, wildfire damage, and dryland water scarcity are also projected to be very high (*medium confidence*). Risks from droughts, water stress, heat related events such as heatwaves and habitat degradation simultaneously increase between 1.5°C and 3°C warming (*low confidence*). {Figure SPM.2, 7.2.2, Cross-Chapter Box 9 in Chapter 6, Chapter 7 supplementary material}

A5.4. The stability of food supply³⁰ is projected to decrease as the magnitude and frequency of extreme weather events that disrupt food chains increases (*high confidence*). Increased atmospheric CO₂ levels can also lower the nutritional quality of crops (*high confidence*). In SSP2, global crop and economic models project a median increase of 7.6% (range of 1 to 23%) in cereal prices in 2050 due to climate change (RCP6.0), leading to higher food prices and increased risk of food insecurity and hunger (*medium confidence*). The most vulnerable people will be more severely affected (*high confidence*). {5.2.3, 5.2.4, 5.2.5, 5.8.1, 7.2.2.2, 7.3.1}

A5.5. In drylands, climate change and desertification are projected to cause reductions in crop and livestock productivity (*high confidence*), modify the plant species mix and reduce biodiversity (*medium confidence*). Under SSP2, the dryland population vulnerable to water stress, drought intensity and habitat degradation is projected to reach 178 million people by 2050 at 1.5°C warming, increasing to 220 million people at 2°C warming, and 277 million people at 3°C warming (*low confidence*). {3.5.1, 3.5.2, 3.7.3}

²⁹ Unprecedented climatic conditions are defined in this report as not having occurred anywhere during the 20th century. They are characterized by high temperature with strong seasonality and shifts in precipitation. In the literature assessed, the effect of climatic variables other than temperature and precipitation were not considered.

³⁰ The supply of food is defined in this report as encompassing availability and access (including price). Food supply instability refers to variability that influences food security through reducing access.

A5.6. Asia and Africa³¹ are projected to have the highest number of people vulnerable to increased desertification. North America, South America, Mediterranean, southern Africa and central Asia may be increasingly affected by wildfire. The tropics and subtropics are projected to be most vulnerable to crop yield decline. Land degradation resulting from the combination of sea level rise and more intense cyclones is projected to jeopardise lives and livelihoods in cyclone prone areas (*very high confidence*). Within populations, women, the very young, elderly and poor are most at risk (*high confidence*). {3.5.1, 3.5.2, 4.4, Table 4.1, 5.2.2, 7.2.2, Cross-Chapter Box 3 in Chapter 2}

A5.7. Changes in climate can amplify environmentally induced migration both within countries and across borders (*medium confidence*), reflecting multiple drivers of mobility and available adaptation measures (*high confidence*). Extreme weather and climate or slow-onset events may lead to increased displacement, disrupted food chains, threatened livelihoods (*high confidence*), and contribute to exacerbated stresses for conflict (*medium confidence*). {3.4.2, 4.7.3, 5.2.3, 5.2.4, 5.2.5, 5.8.2, 7.2.2, 7.3.1}

A5.8. Unsustainable land management has led to negative economic impacts (*high confidence*). Climate change is projected to exacerbate these negative economic impacts (*high confidence*). {4.3.1, 4.4.1, 4.7, 4.8.5, 4.8.6, 4.9.6, 4.9.7, 4.9.8, 5.2, 5.8.1, 7.3.4, 7.6.1, Cross-Chapter Box 10 in Chapter 7}

A6. The level of risk posed by climate change depends both on the level of warming and on how population, consumption, production, technological development, and land management patterns evolve (*high confidence*). Pathways with higher demand for food, feed, and water, more resource-intensive consumption and production, and more limited technological improvements in agriculture yields result in higher risks from water scarcity in drylands, land degradation, and food insecurity (*high confidence*). {5.1.4, 5.2.3, 6.1.4, 7.2, Cross-Chapter Box 9 in Chapter 6, Figure SPM.2b}

A6.1. Projected increases in population and income, combined with changes in consumption patterns, result in increased demand for food, feed, and water in 2050 in all SSPs (*high confidence*). These changes, combined with land management practices, have implications for land-use change, food insecurity, water scarcity, terrestrial GHG emissions, carbon sequestration potential, and biodiversity (*high confidence*). Development pathways in which incomes increase and the demand for land conversion is reduced, either through reduced

³¹ West Africa has a high number of people vulnerable to increased desertification and yield decline. North Africa is vulnerable to water scarcity.

agricultural demand or improved productivity, can lead to reductions in food insecurity (*high confidence*). All assessed future socio-economic pathways result in increases in water demand and water scarcity (*high confidence*). SSPs with greater cropland expansion result in larger declines in biodiversity (*high confidence*). {6.1.4}

A6.2. Risks related to water scarcity in drylands are lower in pathways with low population growth, less increase in water demand, and high adaptive capacity, as in Shared Socio-economic Pathway 1 (SSP1) (See BOX SPM.1). In these scenarios the risk from water scarcity in drylands is moderate even at global warming of 3°C (*low confidence*). By contrast, risks related to water scarcity in drylands are greater for pathways with high population growth, high vulnerability, higher water demand, and low adaptive capacity, such as SSP3. In SSP3 the transition from moderate to high risk occurs between 1.2°C and 1.5°C (*medium confidence*). {7.2, Figure SPM.2b, BOX SPM.1}

A6.3. Risks related to climate change driven land degradation are higher in pathways with a higher population, increased land-use change, low adaptive capacity and other barriers to adaptation (e.g., SSP3). These scenarios result in more people exposed to ecosystem degradation, fire, and coastal flooding (*medium confidence*). For land degradation, the projected transition from moderate to high risk occurs for global warming between 1.8°C and 2.8°C in SSP1 (*low confidence*) and between 1.4°C and 2°C in SSP3 (*medium confidence*). The projected transition from high to very high risk occurs between 2.2°C and 2.8°C for SSP3 (*medium confidence*). {4.4, 7.2, Figure SPM.2b}

A6.4. Risks related to food security are greater in pathways with lower income, increased food demand, increased food prices resulting from competition for land, more limited trade, and other challenges to adaptation (e.g., SSP3) (*high confidence*). For food security, the transition from moderate to high risk occurs for global warming between 2.5°C and 3.5°C in SSP1 (*medium confidence*) and between 1.3°C and 1.7°C in SSP3 (*medium confidence*). The transition from high to very high risk occurs between 2°C and 2.7°C for SSP3 (*medium confidence*). {7.2, Figure SPM.2b}

A6.5 Urban expansion is projected to lead to conversion of cropland leading to losses in food production (*high confidence*). This can result in additional risks to the food system. Strategies for reducing these impacts can include urban and peri-urban food production and management of urban expansion, as well as urban green infrastructure that can reduce climate risks in cities³² (*high confidence*). {4.9.1, 5.5, 5.6, 6.3, 6.4, 7.5.6} (Figure SPM3)

³² The land systems considered in this report do not include urban ecosystem dynamics in detail. Urban areas, urban expansion, and other urban processes and their relation to land-related processes are extensive, dynamic, and complex.

B. Adaptation and mitigation response options

B 1. Many land-related responses that contribute to climate change adaptation and mitigation can also combat desertification and land degradation and enhance food security. The potential for land-related responses and the relative emphasis on adaptation and mitigation is context specific, including the adaptive capacities of communities and regions. While land-related response options can make important contributions to adaptation and mitigation, there are some barriers to adaptation and limits to their contribution to global mitigation. (*very high confidence*) {2.6, 4.8, 5.6, 6.1, 6.3, 6.4, Figure SPM.3}

B1.1. Some land-related actions are already being taken that contribute to climate change adaptation, mitigation and sustainable development. The response options were assessed across adaptation, mitigation, combating desertification and land degradation, food security and sustainable development, and a select set of options deliver across all of these challenges. These options include, but are not limited to, sustainable food production, improved and sustainable forest management, soil organic carbon management, ecosystem conservation and land restoration, reduced deforestation and degradation, and reduced food loss and waste (*high confidence*). These response options require integration of biophysical, socioeconomic and other enabling factors. {6.3, 6.4.5; Cross-Chapter Box 10 in Chapter 7}

B1.2. While some response options have immediate impact, others take decades to deliver measurable results. Examples of response options with immediate impacts include the conservation of high-carbon ecosystems such as peatlands, wetlands, rangelands, mangroves and forests. Examples that provide multiple ecosystem services and functions, but take more time to deliver, include afforestation and reforestation as well as the restoration of high-carbon ecosystems, agroforestry, and the reclamation of degraded soils (*high confidence*). {6.4.5; Cross-Chapter Box 10 in Chapter 7}

B1.3. The successful implementation of response options depends on consideration of local environmental and socio-economic conditions. Some options such as soil carbon management are potentially applicable across a broad range of land use types, whereas the efficacy of land management practices relating to organic soils, peatlands and wetlands, and those linked to freshwater resources, depends on specific agro-ecological conditions (*high confidence*). Given

Several issues addressed in this report such as population, growth, incomes, food production and consumption, food security, and diets have close relationships with these urban processes. Urban areas are also the setting of many processes related to land-use change dynamics, including loss of ecosystem functions and services, that can lead to increased disaster risk. Some specific urban issues are assessed in this report.

the site-specific nature of climate change impacts on food system components and wide variations in agroecosystems, adaptation and mitigation options and their barriers are linked to environmental and cultural context at regional and local levels (*high confidence*). Achieving land degradation neutrality depends on the integration of multiple responses across local, regional and national scales, multiple sectors including agriculture, pasture, forest and water (*high confidence*). {4.8, 6.2, 6.3, 6.4.4}

B1.4. Land based options that deliver carbon sequestration in soil or vegetation, such as afforestation, reforestation, agroforestry, soil carbon management on mineral soils, or carbon storage in harvested wood products do not continue to sequester carbon indefinitely (*high confidence*). Peatlands, however, can continue to sequester carbon for centuries (*high confidence*). When vegetation matures or when vegetation and soil carbon reservoirs reach saturation, the annual removal of CO₂ from the atmosphere declines towards zero, while carbon stocks can be maintained (*high confidence*). However, accumulated carbon in vegetation and soils is at risk from future loss (or sink reversal) triggered by disturbances such as flood, drought, fire, or pest outbreaks, or future poor management (*high confidence*). {6.4.1}

B 2. Most of the response options assessed contribute positively to sustainable development and other societal goals (*high confidence*). Many response options can be applied without competing for land and have the potential to provide multiple co-benefits (*high confidence*). A further set of response options has the potential to reduce demand for land, thereby enhancing the potential for other response options to deliver across each of climate change adaptation and mitigation, combating desertification and land degradation, and enhancing food security (*high confidence*). {4.8, 6.2, 6.3.6, 6.4.3; Figure SPM.3}

B2.1. A number of land management options, such as improved management of cropland and grazing lands, improved and sustainable forest management, and increased soil organic carbon content, do not require land use change and do not create demand for more land conversion (*high confidence*). Further, a number of response options such as increased food productivity, dietary choices and food losses and waste reduction, can reduce demand for land conversion, thereby potentially freeing land and creating opportunities for enhanced implementation of other response options (*high confidence*). Response options that reduce competition for land are possible and are applicable at different scales, from farm to regional (*high confidence*). {4.8, 6.3.6, 6.4; Figure SPM.3}

B2.2. A wide range of adaptation and mitigation responses, e.g. preserving and restoring natural ecosystems such as peatland, coastal lands and forests, biodiversity conservation, reducing competition for land, fire management, soil management, and most risk management options (e.g. use of local seeds, disaster risk management, risk sharing instruments) have the potential to make

positive contributions to sustainable development, enhancement of ecosystem functions and services and other societal goals (*medium confidence*). Ecosystem-based adaptation can, in some contexts, promote nature conservation while alleviating poverty and even provide co-benefits by removing greenhouse gases and protecting livelihoods (e.g. mangroves) (*medium confidence*). {6.4.3, 7.4.6.2}

B2.3. Most of the land management-based response options that do not increase competition for land, and almost all options based on value chain management (e.g. dietary choices, reduced post-harvest losses, reduced food waste) and risk management, can contribute to eradicating poverty and eliminating hunger while promoting good health and wellbeing, clean water and sanitation, climate action, and life on land (*medium confidence*). {6.4.3}

B 3. Although most response options can be applied without competing for available land, some can increase demand for land conversion (*high confidence*). At the deployment scale of several GtCO₂yr⁻¹, this increased demand for land conversion could lead to adverse side effects for adaptation, desertification, land degradation and food security (*high confidence*). If applied on a limited share of total land and integrated into sustainably managed landscapes, there will be fewer adverse side-effects and some positive co-benefits can be realised (*high confidence*). {4.5, 6.2, 6.4; Cross-Chapter Box 7 in Chapter 6; Figure SPM.3}

B3.1. If applied at scales necessary to remove CO₂ from the atmosphere at the level of several GtCO₂yr⁻¹, afforestation, reforestation and the use of land to provide feedstock for bioenergy with or without carbon capture and storage, or for biochar, could greatly increase demand for land conversion (*high confidence*). Integration into sustainably managed landscapes at appropriate scale can ameliorate adverse impacts (*medium confidence*). Reduced grassland conversion to croplands, restoration and reduced conversion of peatlands, and restoration and reduced conversion of coastal wetlands affect smaller land areas globally, and the impacts on land use change of these options are smaller or more variable (*high confidence*). {Cross-Chapter Box 7 in Chapter 6; 6.4; Figure SPM.3}

B3.2. While land can make a valuable contribution to climate change mitigation, there are limits to the deployment of land-based mitigation measures such as bioenergy crops or afforestation. Widespread use at the scale of several millions of km² globally could increase risks for desertification, land degradation, food security and sustainable development (*medium confidence*). Applied on a limited share of total land, land-based mitigation measures that displace other land uses have fewer adverse side-effects and can have positive co-benefits for adaptation, desertification, land degradation or food security. (*high confidence*) {4.2, 4.5, 6.4; Cross-Chapter Box 7 in Chapter 6, Figure SPM3}

B3.3 The production and use of biomass for bioenergy can have co-benefits, adverse side effects, and risks for land degradation, food insecurity, GHG emissions and other environmental and sustainable development goals (*high confidence*). These impacts are context specific and depend on the scale of deployment, initial land use, land type, bioenergy feedstock, initial carbon stocks, climatic region and management regime, and other land-demanding response options can have a similar range of consequences (*high confidence*). The use of residues and organic waste as bioenergy feedstock can mitigate land use change pressures associated with bioenergy deployment, but residues are limited and the removal of residues that would otherwise be left on the soil could lead to soil degradation (*high confidence*). {2.6.1.5; Cross-Chapter Box 7 in Chapter 6; Figure SPM3}

B3.4. For projected socioeconomic pathways with low population, effective land-use regulation, food produced in low-GHG emission systems and lower food loss and waste (SSP1), the transition from low to moderate risk to food security, land degradation and water scarcity in dry lands occur between 1 and 4 million km² of bioenergy or BECCS (*medium confidence*). By contrast, in pathways with high population, low income and slow rates of technological change (SSP3), the transition from low to moderate risk occurs between 0.1 and 1 million km² (*medium confidence*). {6.4; Cross-Chapter Box 7 in Chapter 6; Table SM7.6; Box SPM1}

B 4. Many activities for combating desertification can contribute to climate change adaptation with mitigation co-benefits, as well as to halting biodiversity loss with sustainable development co-benefits to society (*high confidence*). Avoiding, reducing and reversing desertification would enhance soil fertility, increase carbon storage in soils and biomass, while benefitting agricultural productivity and food security (*high confidence*). Preventing desertification is preferable to attempting to restore degraded land due to the potential for residual risks and maladaptive outcomes (*high confidence*). {3.6.1, 3.6.2, 3.6.3, 3.6.4, 3.7.1, 3.7.2}

B4.1. Solutions that help adapt to and mitigate climate change while contributing to combating desertification are site and regionally specific and include *inter alia*: water harvesting and micro-irrigation, restoring degraded lands using drought-resilient ecologically appropriate plants; agroforestry and other agroecological and ecosystem-based adaptation practices (*high confidence*). {3.3, 3.6.1, 3.7.2, 3.7.5, 5.2, 5.6}

B4.2. Reducing dust and sand storms and sand dune movement can lessen the negative effects of wind erosion and improve air quality and health (*high confidence*). Depending on water availability and soil conditions, afforestation, tree planting and ecosystem restoration programs,

which aim for the creation of windbreaks in the form of “green walls”, and “green dams” using native and other climate resilient tree species with low water needs, can reduce sand storms, avert wind erosion, and contribute to carbon sinks, while improving micro-climates, soil nutrients and water retention (*high confidence*). {3.3, 3.6.1, 3.7.2, 3.7.5}

B4.3. Measures to combat desertification can promote soil carbon sequestration (*high confidence*). Natural vegetation restoration and tree planting on degraded land enriches, in the long term, carbon in the topsoil and subsoil (*medium confidence*). Modelled rates of carbon sequestration following the adoption of conservation agriculture practices in drylands depend on local conditions (*medium confidence*). If soil carbon is lost, it may take a prolonged period of time for carbon stocks to recover. {3.1.4, 3.3, 3.6.1, 3.6.3, 3.7.1, 3.7.2}

B4.4 Eradicating poverty and ensuring food security can benefit from applying measures promoting land degradation neutrality (including avoiding, reducing and reversing land degradation) in rangelands, croplands and forests, which contribute to combating desertification, while mitigating and adapting to climate change within the framework of sustainable development. Such measures include avoiding deforestation and locally suitable practices including management of rangeland and forest fires (*high confidence*). {3.4.2, 3.6.1, 3.6.2, 3.6.3, 4.8.5}.

B4.5 Currently there is a lack of knowledge of adaptation limits and potential maladaptation to combined effects of climate change and desertification. In the absence of new or enhanced adaptation options, the potential for residual risks and maladaptive outcomes is high (*high confidence*). Even when solutions are available, social, economic and institutional constraints could pose barriers to their implementation (*medium confidence*). Some adaptation options can become maladaptive due to their environmental impacts, such as irrigation causing soil salinisation or over extraction leading to ground-water depletion (*medium confidence*). Extreme forms of desertification can lead to the complete loss of land productivity, limiting adaptation options or reaching the limits to adaptation (*high confidence*). {Executive Summary Chapter 3, 3.6.4, 3.7.5, 7.4.9}

B4.6. Developing, enabling and promoting access to cleaner energy sources and technologies can contribute to adaptation and mitigating climate change and combating desertification and forest degradation through decreasing the use of traditional biomass for energy while increasing the diversity of energy supply (*medium confidence*). This can have socioeconomic and health benefits, especially for women and children. (*high confidence*). The efficiency of wind and solar energy infrastructures is recognized; the efficiency can be affected in some regions by dust and sand storms (*high confidence*). {3.5.3, 3.5.4, 4.4.4, 7.5.2, Cross-Chapter Box 12 in Chapter 7}

B 5. Sustainable land management³³, including sustainable forest management³⁴, can prevent and reduce land degradation, maintain land productivity, and sometimes reverse the adverse impacts of climate change on land degradation (*very high confidence*). It can also contribute to mitigation and adaptation (*high confidence*). Reducing and reversing land degradation, at scales from individual farms to entire watersheds, can provide cost effective, immediate, and long-term benefits to communities and support several Sustainable Development Goals (SDGs) with co-benefits for adaptation (*very high confidence*) and mitigation (*high confidence*). Even with implementation of sustainable land management, limits to adaptation can be exceeded in some situations (*medium confidence*). {1.3.2, 4.1.5, 4.8, Table 4.2}

B5.1. Land degradation in agriculture systems can be addressed through sustainable land management, with an ecological and socioeconomic focus, with co-benefits for climate change adaptation. Management options that reduce vulnerability to soil erosion and nutrient loss include growing green manure crops and cover crops, crop residue retention, reduced/zero tillage, and maintenance of ground cover through improved grazing management (*very high confidence*). {4.8}

B5.2. The following options also have mitigation co-benefits. Farming systems such as agroforestry, perennial pasture phases and use of perennial grains, can substantially reduce erosion and nutrient leaching while building soil carbon (*high confidence*). The global sequestration potential of cover crops would be about 0.44 +/- 0.11 GtCO₂ yr⁻¹ if applied to 25% of global cropland (*high confidence*). The application of certain biochars can sequester carbon (*high confidence*), and improve soil conditions in some soil types/climates (*medium confidence*). {4.8.1.1, 4.8.1.3, 4.9.2, 4.9.5, 5.5.1, 5.5.4; Cross-Chapter Box 6 in Chapter 5}

B5.3. Reducing deforestation and forest degradation lowers GHG emissions (*high confidence*), with an estimated technical mitigation potential of 0.4–5.8 GtCO₂ yr⁻¹. By providing long-term livelihoods for communities, sustainable forest management can reduce the extent of

³³ Sustainable land management is defined in this report as the stewardship and use of land resources, including soils, water, animals and plants, to meet changing human needs, while simultaneously ensuring the long-term productive potential of these resources and the maintenance of their environmental functions. Examples of options include inter alia agroecology (including agroforestry), conservation agriculture and forestry practices, crop and forest species diversity, appropriate crop and forest rotations, organic farming, integrated pest management, the conservation of pollinators, rain water harvesting, range and pasture management, and precision agriculture systems.

³⁴ Sustainable forest management is defined in this report as the stewardship and use of forests and forest lands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity, vitality, and their potential to fulfill now and in the future, relevant ecological, economic and social functions at local, national and global levels and that does not cause damage to other ecosystems.

forest conversion to non-forest uses (e.g., cropland or settlements) (*high confidence*). Sustainable forest management aimed at providing timber, fibre, biomass, non-timber resources and other ecosystem functions and services, can lower GHG emissions and can contribute to adaptation. (*high confidence*). {2.6.1.2, 4.1.5, 4.3.2, 4.5.3, 4.8.1.3, 4.8.3, 4.8.4}

B5.4. Sustainable forest management can maintain or enhance forest carbon stocks, and can maintain forest carbon sinks, including by transferring carbon to wood products, thus addressing the issue of sink saturation (*high confidence*). Where wood carbon is transferred to harvested wood products, these can store carbon over the long-term and can substitute for emissions-intensive materials reducing emissions in other sectors (*high confidence*). Where biomass is used for energy, e.g., as a mitigation strategy, the carbon is released back into the atmosphere more quickly (*high confidence*). {2.6.1, 2.7, 4.1.5, 4.8.4, 6.4.1, Figure SPM.3, Cross-Chapter Box 7 in Chapter 6}

B5.5. Climate change can lead to land degradation, even with the implementation of measures intended to avoid, reduce or reverse land degradation (*high confidence*). Such limits to adaptation are dynamic, site specific and are determined through the interaction of biophysical changes with social and institutional conditions (*very high confidence*). In some situations, exceeding the limits of adaptation can trigger escalating losses or result in undesirable transformational changes (*medium confidence*), such as forced migration (*low confidence*), conflicts (*low confidence*) or poverty (*medium confidence*). Examples of climate change induced land degradation that may exceed limits to adaptation include coastal erosion exacerbated by sea level rise where land disappears (*high confidence*), thawing of permafrost affecting infrastructure and livelihoods (*medium confidence*), and extreme soil erosion causing loss of productive capacity (*medium confidence*). {4.7, 4.8.5, 4.8.6, 4.9.6, 4.9.7, 4.9.8}

B 6. Response options throughout the food system, from production to consumption, including food loss and waste, can be deployed and scaled up to advance adaptation and mitigation (*high confidence*). The total technical mitigation potential from crop and livestock activities, and agroforestry is estimated as 2.3-9.6 GtCO₂e.yr⁻¹ by 2050 (*medium confidence*). The total technical mitigation potential of dietary changes is estimated as 0.7-8 GtCO₂e.yr⁻¹ by 2050 (*medium confidence*). {5.3, 5.5, 5.6}

B6.1. Practices that contribute to climate change adaptation and mitigation in cropland include increasing soil organic matter, erosion control, improved fertiliser management, improved crop management, for example, paddy rice management, and use of varieties and genetic improvements for heat and drought tolerance. For livestock, options include better grazing land management, improved manure management, higher-quality feed, and use of breeds and genetic improvement. Different farming and pastoral systems can achieve reductions in the emissions

intensity of livestock products. Depending on the farming and pastoral systems and level of development, reductions in the emissions intensity of livestock products may lead to absolute reductions in GHG emissions (*medium confidence*). Many livestock related options can enhance the adaptive capacity of rural communities, in particular, of smallholders and pastoralists. Significant synergies exist between adaptation and mitigation, for example through sustainable land management approaches (*high confidence*). {4.8, 5.3.3, 5.5.1, 5.6}

B6.2. Diversification in the food system (e.g., implementation of integrated production systems, broad-based genetic resources, and diets) can reduce risks from climate change (*medium confidence*). Balanced diets, featuring plant-based foods, such as those based on coarse grains, legumes, fruits and vegetables, nuts and seeds, and animal-sourced food produced in resilient, sustainable and low-GHG emission systems, present major opportunities for adaptation and mitigation while generating significant co-benefits in terms of human health (*high confidence*). By 2050, dietary changes could free several Mkm² (*medium confidence*) of land and provide a technical mitigation potential of 0.7 to 8.0 GtCO_{2e} yr⁻¹, relative to business as usual projections (*high confidence*). Transitions towards low-GHG emission diets may be influenced by local production practices, technical and financial barriers and associated livelihoods and cultural habits (*high confidence*). {5.3, 5.5.2, 5.5, 5.6}

B6.3. Reduction of food loss and waste can lower GHG emissions and contribute to adaptation through reduction in the land area needed for food production (*medium confidence*). During 2010-2016, global food loss and waste contributed 8-10% of total anthropogenic GHG emissions (*medium confidence*). Currently, 25-30% of total food produced is lost or wasted (*medium confidence*). Technical options such as improved harvesting techniques, on-farm storage, infrastructure, transport, packaging, retail and education can reduce food loss and waste across the supply chain. Causes of food loss and waste differ substantially between developed and developing countries, as well as between regions (*medium confidence*). {5.5.2} By 2050, reduced food loss and waste can free several Mkm² of land (*low confidence*). {6.3.6}

B 7. Future land use depends, in part, on the desired climate outcome and the portfolio of response options deployed (*high confidence*). All assessed modelled pathways that limit warming to 1.5°C or well below 2°C require land-based mitigation and land-use change, with most including different combinations of reforestation, afforestation, reduced deforestation, and bioenergy (*high confidence*). A small number of modelled pathways achieve 1.5°C with reduced land conversion (*high confidence*) and, thus, reduced consequences for desertification, land degradation, and food security (*medium confidence*). {2.6, 6.4, 7.4, 7.6; Cross-Chapter Box 9 in Chapter 6; Figure SPM.4}

B7.1. Modelled pathways limiting global warming to 1.5°C³⁵ include more land-based mitigation than higher warming level pathways (*high confidence*), but the impacts of climate change on land systems in these pathways are less severe (*medium confidence*). {2.6, 6.4, 7.4, Cross-Chapter Box 9 in Chapter 6, Figure SPM.2, Figure SPM.4}

B7.2. Modelled pathways limiting global warming to 1.5°C and 2°C project a 2 million km² reduction to a 12 million km² increase in forest area in 2050 relative to 2010 (*medium confidence*). 3°C pathways project lower forest areas, ranging from a 4 million km² reduction to a 6 million km² increase (*medium confidence*). {2.5, 6.3, 7.3, 7.5; Cross-Chapter Box 9 in Chapter 6; Figure SPM.3, Figure SPM.4}

B7.3. The land area needed for bioenergy in modelled pathways varies significantly depending on the socioeconomic pathway, the warming level, and the feedstock and production system used (*high confidence*). Modelled pathways limiting global warming to 1.5°C use up to 7 million km² for bioenergy in 2050; bioenergy land area is smaller in 2°C (0.4 to 5 million km²) and 3°C pathways (0.1 to 3 million km²) (*medium confidence*). Pathways with large levels of land conversion may imply adverse side-effects impacting water scarcity, biodiversity, land degradation, desertification, and food security, if not adequately and carefully managed, whereas best practice implementation at appropriate scales can have co-benefits, such as management of dryland salinity, enhanced biocontrol and biodiversity and enhancing soil carbon sequestration (*high confidence*). {2.6, 6.1, 6.4, 7.2; Cross-Chapter Box 7 in Chapter 6, Figure SPM.3}

B7.4. Most mitigation pathways include substantial deployment of bioenergy technologies. A small number of modelled pathways limit warming to 1.5°C with reduced dependence on bioenergy and BECCS (land area below <1 million km² in 2050) and other carbon dioxide removal (CDR) options (*high confidence*). These pathways have even more reliance on rapid and far-reaching transitions in energy, land, urban systems and infrastructure, and on behavioural and lifestyle changes compared to other 1.5°C pathways. {2.6.2, 5.5.1, 6.4, Cross-Chapter Box 7 in Chapter 6}

B7.5. These modelled pathways do not consider the effects of climate change on land or CO₂ fertilisation. In addition, these pathways include only a subset of the response options assessed in this report (*high confidence*); the inclusion of additional response options in models could reduce the projected need for bioenergy or CDR that increases the demand for land. {6.4.4, Cross-Chapter Box 9 in Chapter 6}

³⁵ In this report references to pathways limiting global warming to a particular level are based on a 66% probability of staying below that temperature level in 2100 using the MAGICC model.

Potential global contribution of response options to mitigation, adaptation, combating desertification and land degradation, and enhancing food security

Panel A shows response options that can be implemented without or with limited competition for land, including some that have the potential to reduce the demand for land. Co-benefits and adverse side effects are shown quantitatively based on the high end of the range of potentials assessed. Magnitudes of contributions are categorised using thresholds for positive or negative impacts. Letters within the cells indicate confidence in the magnitude of the impact relative to the thresholds used (see legend). Confidence in the direction of change is generally higher.

Response options based on land management		Mitigation	Adaptation	Desertification	Land Degradation	Food Security	Cost

Potential global contribution of response options to mitigation, adaptation, combating desertification and land degradation, and enhancing food security

Panel B shows response options that rely on additional land-use change and could have implications across three or more land challenges under different implementation contexts. For each option, the first row (high level implementation) shows a quantitative assessment (as in Panel A) of implications for global implementation at scales delivering CO₂ removals of more than 3 GtCO₂ yr⁻¹ using the magnitude thresholds shown in Panel A. The red hatched cells indicate an increasing pressure but unquantified impact. For each option, the second row (best practice implementation) shows qualitative estimates of impact if implemented using best practices in appropriately managed landscape systems that allow for efficient and sustainable resource use and supported by appropriate governance mechanisms. In these qualitative assessments, green indicates a positive impact, grey indicates a neutral interaction.

Bioenergy and BECCS

High level: Impacts on adaptation, desertification, land degradation and food security are maximum potential impacts, assuming carbon dioxide removal by BECCS at a scale of 11.3 GtCO₂ yr⁻¹ in 2050, and noting that bioenergy without CCS can also achieve emissions reductions of up to several GtCO₂ yr⁻¹ when it is a low carbon energy source {2.7.1.5; 6.4.1.1.5}. Studies linking bioenergy to food security estimate an increase in the population at risk of hunger to up to 150 million people at this level of implementation {6.4.5.1.5}. The red hatched cells for desertification and land degradation indicate that while up to 15 million km² of additional land is required in 2100 in 2°C scenarios which will increase pressure for desertification and land degradation, the actual area affected by this additional pressure is not easily quantified {6.4.3.1.5; 6.4.4.1.5}.

Best practice: The sign and magnitude of the effects of bioenergy and BECCS depends on the scale of deployment, the type of bioenergy feedstock, which other response options are included, and where bioenergy is grown (including prior land use and indirect land use change emissions). For example, limiting bioenergy production to marginal lands or abandoned cropland would have negligible effects on biodiversity, food security, and potentially co-benefits for land degradation; however, the benefits for mitigation could also be smaller. {Table 6.58}

Reforestation and forest restoration

High level: Impacts on adaptation, desertification, land degradation and food security are maximum potential impacts assuming implementation of reforestation and forest restoration (partly overlapping with afforestation) at a scale of 10.1 GtCO₂ yr⁻¹ removal {6.4.1.1.2}. Large-scale afforestation could cause increases in food prices of 80% by 2050, and more general mitigation measures in the AFOLU sector can translate into a rise in undernourishment of 80–300 million people; the impact of reforestation is lower {6.4.5.1.2}.

Best practice: There are co-benefits of reforestation and forest restoration in previously forested areas, assuming small scale deployment using native species and involving local stakeholders to provide a safety net for food security. Examples of sustainable implementation include, but are not limited to, reducing illegal logging and halting illegal forest loss in protected areas, reforesting and restoring forests in degraded and desertified lands {Box6.1C; Table 6.6}.

Afforestation

High level: Impacts on adaptation, desertification, land degradation and food security are maximum potential impacts assuming implementation of afforestation (partly overlapping with reforestation and forest restoration) at a scale of 8.9 GtCO₂ yr⁻¹ removal {6.4.1.1.2}. Large-scale afforestation could cause increases in food prices of 80% by 2050, and more general mitigation measures in the AFOLU sector can translate into a rise in undernourishment of 80–300 million people {6.4.5.1.2}.

Best practice: Afforestation is used to prevent desertification and to tackle land degradation. Forested land also offers benefits in terms of food supply, especially when forest is established on degraded land, mangroves, and other land that cannot be used for agriculture. For example, food from forests represents a safety-net during times of food and income insecurity {6.4.5.1.2}.

Biochar addition to soil

High level: Impacts on adaptation, desertification, land degradation and food security are maximum potential impacts assuming implementation of afforestation at a scale of 6.6 GtCO₂ yr⁻¹ removal {6.4.1.1.3}. Dedicated energy crops required for feedstock production could occupy 0.4–2.6 Mkm² of land, equivalent to around 20% of the global cropland area, which could potentially have a large effect on food security for up to 100 million people {6.4.5.1.3}.

Best practice: When applied to land, biochar could provide moderate benefits for food security by improving yields by 25% in the tropics, but with more limited impacts in temperate regions, or through improved water holding capacity and nutrient use efficiency. Abandoned cropland could be used to supply biomass for biochar, thus avoiding competition with food production; 5-9 Mkm² of land is estimated to be available for biomass production without compromising food security and biodiversity, considering marginal and degraded land and land released by pasture intensification {6.4.5.1.3}.

Figure SPM.3 Potential global contribution of response options to mitigation, adaptation, combating desertification and land degradation, and enhancing food security.

This Figure is based on an aggregation of information from studies with a wide variety of assumptions about how response options are implemented and the contexts in which they occur. Response options implemented differently at local to global scales could lead to different outcomes. **Magnitude of potential:** For panel A, magnitudes are for the technical potential of response options globally. For each land challenge, magnitudes are set relative to a marker level as follows. For mitigation, potentials are set relative to the approximate potentials for the response options with the largest individual impacts (~3 GtCO₂-eq yr⁻¹). The threshold for the “large” magnitude category is set at this level. For adaptation, magnitudes are set relative to the 100 million lives estimated to be affected by climate change and a carbon-based economy between 2010 and 2030. The threshold for the “large” magnitude category represents 25% of this total. For desertification and land degradation, magnitudes are set relative to the lower end of current estimates of degraded land, 10-60 million km². The threshold for the “large” magnitude category represents 30% of the lower estimate. For food security, magnitudes are set relative to the approximately 800 million people who are currently undernourished. The threshold for the “large” magnitude category represents 12.5% of this total. For panel B, for the first row (high level implementation) for each response option, the magnitude and thresholds are as defined for panel A. In the second row (best practice implementation) for each response option, the qualitative assessments that are green denote potential positive impacts, and those shown in grey indicate neutral interactions. Increased food production is assumed to be achieved through sustainable intensification rather than through injudicious application of additional external inputs such as agrochemicals. **Levels of confidence:** Confidence in the magnitude category (high, medium or low) into which each option falls for mitigation, adaptation, combating desertification and land degradation, and enhancing food security. *High confidence* means that there is a high level of agreement and evidence in the literature to support the categorisation as high, medium or low magnitude. *Low confidence* denotes that the categorisation of magnitude is based on few studies. *Medium confidence* reflects medium evidence and agreement in the magnitude of response. **Cost ranges:** Cost estimates are based on aggregation of often regional studies and vary in the components of costs that are included. In panel B, cost estimates are not provided for best practice implementation. One coin indicates low cost (<USD10 tCO₂-eq⁻¹ or <USD20 ha⁻¹), two coins indicate medium cost (USD10-USD100 tCO₂-eq⁻¹ or USD20-USD200 ha⁻¹), and three coins indicate high cost (>USD100 tCO₂-eq⁻¹ or >USD200 ha⁻¹). Thresholds in USD ha⁻¹ are chosen to be comparable, but precise conversions will depend on the response option. **Supporting evidence:** Supporting evidence for the magnitude of the quantitative potential for land management-based response options can be found as follows: for mitigation tables 6.13 to 6.20, with further evidence in Section 2.7.1; for adaptation tables 6.21 to 6.28; for combating desertification tables 6.29 to 6.36, with further evidence in Chapter 3; for combating degradation tables 6.37 to 6.44, with further evidence in Chapter 4; for enhancing food security tables 6.45 to 6.52, with further evidence in Chapter 5. Other synergies and trade-offs not shown here are discussed in Chapter 6. Additional supporting evidence for the qualitative assessments in the second row for each option in panel B can be found in the tables 6.6, 6.55, 6.56 and 6.58, section 6.3.5.1.3, and Box 6.1c.

C. Enabling response options

C 1. Appropriate design of policies, institutions and governance systems at all scales can contribute to land-related adaptation and mitigation while facilitating the pursuit of climate-adaptive development pathways (*high confidence*). Mutually supportive climate and land policies have the potential to save resources, amplify social resilience, support ecological restoration, and foster engagement and collaboration between multiple stakeholders (*high confidence*). {Figure SPM.1, Figure SPM.2, Figure SPM.3; 3.6.2, 3.6.3, 4.8, 4.9.4, 5.7, 6.3, 6.4, 7.2.2, 7.3, 7.4, 7.4.7, 7.4.8, 7.5, 7.5.5, 7.5.6, 7.6.6; Cross-Chapter Box 10 in Chapter 7}

C1.1. Land-use zoning, spatial planning, integrated landscape planning, regulations, incentives (such as payment for ecosystem services), and voluntary or persuasive instruments (such as environmental farm planning, standards and certification for sustainable production, use of scientific, local and indigenous knowledge and collective action), can achieve positive adaptation and mitigation outcomes (*medium confidence*). They can also contribute revenue and provide incentive to rehabilitate degraded lands and adapt to and mitigate climate change in certain contexts (*medium confidence*). Policies promoting the target of land degradation neutrality can also support food security, human wellbeing and climate change adaptation and mitigation (*high confidence*). {Figure SPM.2; 3.4.2, 4.1.6, 4.7, 4.8.5, 5.1.2, 5.7.3, 7.3, 7.4.6, 7.4.7, 7.5}

C1.2. Insecure land tenure affects the ability of people, communities and organisations to make changes to land that can advance adaptation and mitigation (*medium confidence*). Limited recognition of customary access to land and ownership of land can result in increased vulnerability and decreased adaptive capacity (*medium confidence*). Land policies (including recognition of customary tenure, community mapping, redistribution, decentralisation, co-management, regulation of rental markets) can provide both security and flexibility response to climate change (*medium confidence*). {3.6.1, 3.6.2, 5.3, 7.2.4, 7.6.4, Cross-Chapter Box 6 in Chapter 5}

C1.3. Achieving land degradation neutrality will involve a balance of measures that avoid and reduce land degradation, through adoption of sustainable land management, and measures to reverse degradation through rehabilitation and restoration of degraded land. Many interventions to achieve land degradation neutrality commonly also deliver climate change adaptation and mitigation benefits. The pursuit of land degradation neutrality provides impetus to address land degradation and climate change simultaneously (*high confidence*). {4.5.3, 4.8.5, 4.8.7, 7.4.5}

C1.4. Due to the complexity of challenges and the diversity of actors involved in addressing land challenges, a mix of policies, rather than single policy approaches, can deliver improved results in addressing the complex challenges of sustainable land management and climate change (*high confidence*). Policy mixes can strongly reduce the vulnerability and exposure of human and natural systems to climate change (*high confidence*). Elements of such policy mixes may include weather and health insurance, social protection and adaptive safety nets, contingent finance and reserve funds, universal access to early warning systems combined with effective contingency plans (*high confidence*). {1.2, 4.8, 4.9.2, 5.3.2, 5.6, 5.6.6, 5.7.2, 7.3.2, 7.4, 7.4.2, 7.4.6, 7.4.7, 7.4.8, 7.5.5, 7.5.6, 7.6.4, Figure SPM.4}

C2. Policies that operate across the food system, including those that reduce food loss and waste and influence dietary choices, enable more sustainable land-use management, enhanced food security and low emissions trajectories (*high confidence*). Such policies can contribute to climate change adaptation and mitigation, reduce land degradation, desertification and poverty as well as improve public health (*high confidence*). The adoption of sustainable land management and poverty eradication can be enabled by improving access to markets, securing land tenure, factoring environmental costs into food, making payments for ecosystem services, and enhancing local and community collective action (*high confidence*). {1.1.2, 1.2.1, 3.6.3, 4.7.1, 4.7.2, 4.8, 5.5, 6.4, 7.4.6, 7.6.5}

C2.1. Policies that enable and incentivise sustainable land management for climate change adaptation and mitigation include improved access to markets for inputs, outputs and financial services, empowering women and indigenous peoples, enhancing local and community collective action, reforming subsidies and promoting an enabling trade system (*high confidence*). Land restoration and rehabilitation efforts can be more effective when policies support local management of natural resources, while strengthening cooperation between actors and institutions, including at the international level. {3.6.3, 4.1.6, 4.5.4, 4.8.2, 4.8.4, 5.7, 7.2}

C2.2. Reflecting the environmental costs of land-degrading agricultural practices can incentivise more sustainable land management (*high confidence*). Barriers to the reflection of environmental costs arise from technical difficulties in estimating these costs and those embodied in foods. {3.6.3, 5.5.1, 5.5.2, 5.6.6, 5.7, 7.4.4, Cross-Chapter Box 10 in Chapter 7}

C2.3. Adaptation and enhanced resilience to extreme events impacting food systems can be facilitated by comprehensive risk management, including risk sharing and transfer mechanisms (*high confidence*). Agricultural diversification, expansion of market access, and preparation for increasing supply chain disruption can support the scaling up of adaptation in food systems (*high confidence*). {5.3.2, 5.3.3, 5.3.5}

C2.4. Public health policies to improve nutrition, such as increasing the diversity of food sources in public procurement, health insurance, financial incentives, and awareness-raising campaigns, can potentially influence food demand, reduce healthcare costs, contribute to lower GHG emissions and enhance adaptive capacity (*high confidence*). Influencing demand for food, through promoting diets based on public health guidelines, can enable more sustainable land management and contribute to achieving multiple SDGs (*high confidence*). {3.4.2, 4.7.2, 5.1, 5.7, 6.3, 6.4}

C 3. Acknowledging co-benefits and trade-offs when designing land and food policies can overcome barriers to implementation (*medium confidence*). Strengthened multilevel, hybrid and cross-sectoral governance, as well as policies developed and adopted in an iterative, coherent, adaptive and flexible manner can maximise co-benefits and minimise trade-offs, given that land management decisions are made from farm level to national scales, and both climate and land policies often range across multiple sectors, departments and agencies (*high confidence*). {Figure SPM.3; 4.8.5, 4.9, 5.6, 6.4, 7.3, 7.4.6, 7.4.8, 7.4.9, 7.5.6, 7.6.2}

C3.1. Addressing desertification, land degradation, and food security in an integrated, coordinated and coherent manner can assist climate resilient development and provides numerous potential co-benefits (*high confidence*). {3.7.5, 4.8, 5.6, 5.7, 6.4, 7.2.2, 7.3.1, 7.3.4, 7.4.7, 7.4.8, 7.5.6, 7.5.5}

C3.2. Technological, biophysical, socio-economic, financial and cultural barriers can limit the adoption of many land-based response options, as can uncertainty about benefits (*high confidence*). Many sustainable land management practices are not widely adopted due to insecure land tenure, lack of access to resources and agricultural advisory services, insufficient and unequal private and public incentives, and lack of knowledge and practical experience (*high confidence*). Public discourse, carefully designed policy interventions, incorporating social learning and market changes can together help reduce barriers to implementation (*medium confidence*). {3.6.1, 3.6.2, 5.3.5, 5.5.2, 5.6, 6.2, 6.4, 7.4, 7.5, 7.6}

C3.3. The land and food sectors face particular challenges of institutional fragmentation and often suffer from a lack of engagement between stakeholders at different scales and narrowly focused policy objectives (*medium confidence*). Coordination with other sectors, such as public health, transportation, environment, water, energy and infrastructure, can increase co-benefits, such as risk reduction and improved health (*medium confidence*). {5.6.3, 5.7, 6.2, 6.4.4, 7.1, 7.3, 7.4.8, 7.6.2, 7.6.3}

C3.4. Some response options and policies may result in trade-offs, including social impacts, ecosystem functions and services damage, water depletion, or high costs, that cannot be well-managed, even with institutional best practices (*medium confidence*). Addressing such trade-offs helps avoid maladaptation (*medium confidence*). Anticipation and evaluation of potential trade-offs and knowledge gaps supports evidence-based policymaking to weigh the costs and benefits of specific responses for different stakeholders (*medium confidence*). Successful management of trade-offs often includes maximising stakeholder input with structured feedback processes, particularly in community-based models, use of innovative fora like facilitated dialogues or spatially explicit mapping, and iterative adaptive management that allows for continuous readjustments in policy as new evidence comes to light (*medium confidence*). {5.3.5, 6.4.2, 6.4.4, 6.4.5, 7.5.6; Cross-Chapter Box 13 in Chapter 7}

C 4. The effectiveness of decision-making and governance is enhanced by the involvement of local stakeholders (particularly those most vulnerable to climate change including indigenous peoples and local communities, women, and the poor and marginalised) in the selection, evaluation, implementation and monitoring of policy instruments for land-based climate change adaptation and mitigation (*high confidence*). Integration across sectors and scales increases the chance of maximising co-benefits and minimising trade-offs (*medium confidence*). {1.4, 3.1, 3.6, 3.7, 4.8, 4.9, 5.1.3, Box 5.1, 7.4, 7.6}

C4.1. Successful implementation of sustainable land management practices requires accounting for local environmental and socio-economic conditions (*very high confidence*). Sustainable land management in the context of climate change is typically advanced by involving all relevant stakeholders in identifying land-use pressures and impacts (such as biodiversity decline, soil loss, over-extraction of groundwater, habitat loss, land-use change in agriculture, food production and forestry) as well as preventing, reducing and restoring degraded land (*medium confidence*). {1.4.1, 4.1.6, 4.8.7, 5.2.5, 7.2.4, 7.6.2, 7.6.4}

C4.2. Inclusiveness in the measurement, reporting and verification of the performance of policy instruments can support sustainable land management (*medium confidence*). Involving stakeholders in the selection of indicators, collection of climate data, land modelling and land-use planning, mediates and facilitates integrated landscape planning and choice of policy (*medium confidence*). {3.7.5, 5.7.4, 7.4.1, 7.4.4, 7.5.3, 7.5.4, 7.5.5, 7.6.4, 7.6.6}

C4.3. Agricultural practices that include indigenous and local knowledge can contribute to overcoming the combined challenges of climate change, food security, biodiversity conservation, and combating desertification and land degradation (*high confidence*). Coordinated action across a range of actors including businesses, producers, consumers, land managers and policymakers in partnership with indigenous peoples and local communities enable conditions for

the adoption of response options (*high confidence*) {3.1.3, 3.6.1, 3.6.2, 4.8.2, 5.5.1, 5.6.4, 5.7.1, 5.7.4, 6.2, 7.3, 7.4.6, 7.6.4}

C4.4. Empowering women can bring synergies and co-benefits to household food security and sustainable land management (*high confidence*). Due to women's disproportionate vulnerability to climate change impacts, their inclusion in land management and tenure is constrained. Policies that can address land rights and barriers to women's participation in sustainable land management include financial transfers to women under the auspices of anti-poverty programmes, spending on health, education, training and capacity building for women, subsidised credit and program dissemination through existing women's community-based organisations (*medium confidence*). {1.4.1, 4.8.2, 5.1.3, Box 5.1, Cross-Chapter Box 11 in Chapter 7}.

A. Pathways linking socioeconomic development, mitigation responses and land

Socioeconomic development and land management influence the evolution of the land system including the relative amount of land allocated to **CROPLAND**, **PASTURE**, **BIOENERGY CROPLAND**, **FOREST**, and **NATURAL LAND**. The lines show the median across Integrated Assessment Models (IAMs) for three alternative shared socioeconomic pathways (**SSP1**, **SSP2** and **SSP5** at **RCP1.9**); shaded areas show the range across models. Note that pathways illustrate the effects of climate change mitigation but not those of climate change impacts or adaptation.

A. Sustainability-focused (SSP1)

Sustainability in land management, agricultural intensification, production and consumption patterns result in reduced need for agricultural land, despite increases in per capita food consumption. This land can instead be used for reforestation, afforestation, and bioenergy.

B. Middle of the road (SSP2)

Societal as well as technological development follows historical patterns. Increased demand for land mitigation options such as bioenergy, reduced deforestation or afforestation decreases availability of agricultural land for food, feed and fibre.

C. Resource intensive (SSP5)

Resource-intensive production and consumption patterns, results in high baseline emissions. Mitigation focuses on technological solutions including substantial bioenergy and BECCS. Intensification and competing land uses contribute to declines in agricultural land.

SSP1 Sustainability-focused
Change in Land from 2010 (Mkm²)

SSP2 Middle of the road
Change in Land from 2010 (Mkm²)

SSP5 Resource intensive

* Count of models included / Count of models attempted. One model did not provide land data and is excluded from all entries.

** One model could reach RCP1.9 with SSP4, but did not provide land data

Figure SPM.4 Pathways linking socioeconomic development, mitigation responses and land

Future scenarios provide a framework for understanding the implications of mitigation and socioeconomics on land. The Shared Socioeconomic Pathways (SSPs) span a range of different socioeconomic assumptions (Box SPM.1). They are combined with Representative Concentration Pathways (RCPs)³⁶ which imply different levels of mitigation. The changes in cropland, pasture, bioenergy cropland, forest, and natural land from 2010 are shown. For this figure: Cropland includes all land in food, feed, and fodder crops, as well as other arable land (cultivated area). This category includes 1st generation non-forest bioenergy crops (e.g. corn for ethanol, sugar cane for ethanol, soybeans for biodiesel), but excludes 2nd generation bioenergy crops. Pasture includes categories of pasture land, not only high quality rangeland, and is based on FAO definition of "permanent meadows and pastures". Bioenergy cropland includes land dedicated to 2nd generation energy crops (e.g., switchgrass, miscanthus, fast-growing wood species). Forest includes managed and unmanaged forest. Natural land includes other grassland, savannah, and shrubland. **Panel A:** This panel shows integrated assessment model (IAM)³⁷ results for SSP1, SSP2 and SSP5 at RCP1.9³⁸. For each pathway, the shaded areas show the range across all IAMs; the line indicates the median across models. For RCP1.9, SSP1, SSP2 and SSP5 include results from five, four and two IAMs respectively. **Panel B:** Land use and land cover change are indicated for various SSP-RCP combinations, showing multi-model median and range (min, max). {Box SPM.1, 1.3.2, Cross-Chapter Box 1 in Chapter 1, 2.7.2, Cross-Chapter Box 9 in Chapter 6, 6.1, 6.4.4, 7.4.2, 7.4.4, 7.4.5, 7.4.6, 7.4.7, 7.4.8, 7.5.3, 7.5.6; Cross-Chapter Box 9 in Chapter 6}

D. Action in the near-term

D 1. Actions can be taken in the near-term, based on existing knowledge, to address desertification, land degradation and food security while supporting longer-term responses that enable adaptation and mitigation to climate change. These include actions to build individual and institutional capacity, accelerate knowledge transfer, enhance technology transfer and deployment, enable financial mechanisms, implement early warning systems, undertake risk management and address gaps in implementation and upscaling (*high confidence*). {3.6.1, 3.6.2, 3.7.2, 4.8, 5.3.3, 5.5, 5.6.4, 5.7, 6.2, 6.4, 7.3, 7.4.9, 7.6; Cross-Chapter Box 10 in Chapter 7}

D1.1. Near-term capacity-building, technology transfer and deployment, and enabling financial mechanisms can strengthen adaptation and mitigation in the land sector. Knowledge and technology transfer can help enhance the sustainable use of natural resources for food security under a changing climate (*medium confidence*). Raising awareness, capacity building and education about sustainable land management practices, agricultural extension and advisory

³⁶ Representative Concentration Pathways (RCPs) are scenarios that include timeseries of emissions and concentrations of the full suite of greenhouse gases (GHGs) and aerosols and chemically active gases, as well as land use/land cover³⁷.

³⁷ Integrated Assessment Models (IAMs) integrate knowledge from two or more domains into a single framework. In this figure, IAMs are used to assess linkages between economic, social and technological development and the evolution of the climate system.

³⁸ The RCP1.9 pathways assessed in this report have a 66% chance of limiting warming to 1.5C in 2100, but some of these pathways overshoot 1.5C of warming during the 21st century by >0.1C.

services, and expansion of access to agricultural services to producers and land users can effectively address land degradation (*medium confidence*). {3.1, 5.7.4, 7.2, 7.3.4, 7.5.4}

D1.2. Measuring and monitoring land use change including land degradation and desertification is supported by the expanded use of new information and communication technologies (cellphone based applications, cloud-based services, ground sensors, drone imagery), use of climate services, and remotely sensed land and climate information on land resources (*medium confidence*). Early warning systems for extreme weather and climate events are critical for protecting lives and property and enhancing disaster risk reduction and management (*high confidence*). Seasonal forecasts and early warning systems are critical for food security (famine) and biodiversity monitoring including pests and diseases and adaptive climate risk management (*high confidence*). There are high returns on investments in human and institutional capacities. These investments include access to observation and early warning systems, and other services derived from in-situ hydro-meteorological and remote sensing-based monitoring systems and data, field observation, inventory and survey, and expanded use of digital technologies (*high confidence*). {1.2, 3.6.2, 4.2.2, 4.2.4, 5.3.1, 5.3.6, 6.4, 7.3.4, 7.4.3, 7.5.4, 7.5.5, 7.6.4; Cross-Chapter Box 5 in Chapter 3}

D1.3. Framing land management in terms of risk management, specific to land, can play an important role in adaptation through landscape approaches, biological control of outbreaks of pests and diseases, and improving risk sharing and transfer mechanisms (*high confidence*). Providing information on climate-related risk can improve the capacity of land managers and enable timely decision making (*high confidence*). {5.3.2, 5.3.5, 5.6.2, 5.6.3; Cross-Chapter Box 6 in Chapter 5; 5.6.5, 5.7.1, 5.7.2, 7.2.4}

D1.4. Sustainable land management can be improved by increasing the availability and accessibility of data and information relating to the effectiveness, co-benefits and risks of emerging response options and increasing the efficiency of land use (*high confidence*). Some response options (e.g., improved soil carbon management) have been implemented only at small-scale demonstration facilities and knowledge, financial, and institutional gaps and challenges exist with upscaling and the widespread deployment of these options (*medium confidence*). {4.8, 5.5.1, 5.5.2, 5.6.1, 5.6.5, 5.7.5, 6.2, 6.4,}

D 2. Near-term action to address climate change adaptation and mitigation, desertification, land degradation and food security can bring social, ecological, economic and development co-benefits (*high confidence*). Co-benefits can contribute to poverty eradication and more resilient livelihoods for those who are vulnerable (*high confidence*). {3.4.2, 5.7, 7.5}

D2.1. Near-term actions to promote sustainable land management will help reduce land and food-related vulnerabilities, and can create more resilient livelihoods, reduce land degradation and desertification, and loss of biodiversity (*high confidence*). There are synergies between

sustainable land management, poverty eradication efforts, access to market, non-market mechanisms and the elimination of low-productivity practices. Maximising these synergies can lead to adaptation, mitigation, and development co-benefits through preserving ecosystem functions and services (*medium confidence*). {3.4.2, 3.6.3, Table 4.2, 4.7, 4.9, 4.10, 5.6, 5.7, 7.3, 7.4, 7.5, 7.6; Cross-Chapter Box 12 in Chapter 7}

D2.2. Investments in land restoration can result in global benefits and in drylands can have benefit-cost ratios of between three and six in terms of the estimated economic value of restored ecosystem services (*medium confidence*). Many sustainable land management technologies and practices are profitable within three to 10 years (*medium confidence*). While they can require upfront investment, actions to ensure sustainable land management can improve crop yields and the economic value of pasture. Land restoration and rehabilitation measures improve livelihood systems and provide both short-term positive economic returns and longer-term benefits in terms of climate change adaptation and mitigation, biodiversity and enhanced ecosystem functions and services (*high confidence*). {3.6.1, 3.6.3, 4.8.1, 7.2.4, 7.2.3, 7.3.1, 7.4.6, Cross-Chapter Box 10 in Chapter 7}

D2.3. Upfront investments in sustainable land management practices and technologies can range from about USD 20 ha⁻¹ to USD 5000 ha⁻¹, with a median estimated to be around USD 500 ha⁻¹. Government support and improved access to credit can help overcome barriers to adoption, especially those faced by poor smallholder farmers (*high confidence*). Near-term change to balanced diets (see B6.2) can reduce the pressure on land and provide significant health co-benefits through improving nutrition (*medium confidence*). {3.6.3, 4.8, 5.3, 5.5, 5.6, 5.7, 6.4, 7.4.7, 7.5.5; Cross-Chapter Box 9 in Chapter 6}

D 3. Rapid reductions in anthropogenic GHG emissions across all sectors following ambitious mitigation pathways reduce negative impacts of climate change on land ecosystems and food systems (*medium confidence*). Delaying climate mitigation and adaptation responses across sectors would lead to increasingly negative impacts on land and reduce the prospect of sustainable development (*medium confidence*). {Box SPM.1, Figure SPM.2, 2.5, 2.7, 5.2, 6.2, 6.4, 7.2, 7.3.1, 7.4.7, 7.4.8, 7.5.6; Cross-Chapter Box 9 in Chapter 6, Cross-Chapter Box 10 in Chapter 7}

D3.1. Delayed action across sectors leads to an increasing need for widespread deployment of land-based adaptation and mitigation options and can result in a decreasing potential for the array of these options in most regions of the world and limit their current and future effectiveness (*high confidence*). Acting now may avert or reduce risks and losses, and generate benefits to society (*medium confidence*). Prompt action on climate mitigation and

adaptation aligned with sustainable land management and sustainable development depending on the region could reduce the risk to millions of people from climate extremes, desertification, land degradation and food and livelihood insecurity (*high confidence*). {1.3.5, 3.4.2, 3.5.2, 4.1.6, 4.7.1, 4.7.2, 5.2.3, 5.3.1, 6.3, 6.5, 7.3.1}

D3.2. In future scenarios, deferral of GHG emissions reductions implies trade-offs leading to significantly higher costs and risks associated with rising temperatures (*medium confidence*). The potential for some response options, such as increasing soil organic carbon, decreases as climate change intensifies, as soils have reduced capacity to act as sinks for carbon sequestration at higher temperatures (*high confidence*). Delays in avoiding or reducing land degradation and promoting positive ecosystem restoration risk long-term impacts including rapid declines in productivity of agriculture and rangelands, permafrost degradation and difficulties in peatland rewetting (*medium confidence*). {1.3.1, 3.6.2, 4.8, 4.9, 4.9.1, 5.5.2, 6.3, 6.4, 7.2, 7.3; Cross-Chapter Box 10 in Chapter 7}

D3.3. Deferral of GHG emissions reductions from all sectors implies trade-offs including irreversible loss in land ecosystem functions and services required for food, health, habitable settlements and production, leading to increasingly significant economic impacts on many countries in many regions of the world (*high confidence*). Delaying action as is assumed in high emissions scenarios could result in some irreversible impacts on some ecosystems, which in the longer-term has the potential to lead to substantial additional GHG emissions from ecosystems that would accelerate global warming (*medium confidence*). {1.3.1, 2.5.3, 2.7, 3.6.2, 4.9, 4.10.1, 5.4.2.4, 6.3, 6.4, 7.2, 7.3; Cross-Chapter Box 9 in Chapter 6, Cross-Chapter Box 10 in Chapter 7}

Glossary

Coordinating Editor:

Renée van Diemen (Netherlands/UK)

Editorial Team:

Tim Benton (UK), Eduardo Calvo (Peru), Annette Cowie (Australia), Valérie Masson-Delmotte (France), Aziz Elbehri (Morocco), Karlheinz Erb (Italy), Giacomo Grassi (Italy), J.B. Robin Matthews (UK), Hans-Otto Pörtner (Germany), Andy Reisinger (New Zealand), Debra Roberts (South Africa), Priyadarshi Shukla (India), Andrey Sirin (Russian Federation), Jim Skea (UK), Murat Türkeş (Turkey), Nora M. Weyer (Germany), Sumaya Zakieldeen (Sudan), Panmao Zhai (China)

Notes:

Note that subterms are in italics beneath main terms

This glossary defines some specific terms as the Lead Authors intend them to be interpreted in the context of this report. Italicised words indicate that the term is defined in the Glossary.

1.5°C pathway

See *Pathways*.

2030 Agenda for Sustainable Development

A UN resolution in September 2015 adopting a plan of action for people, planet and prosperity in a new global development framework anchored in 17 *Sustainable Development Goals* (UN, 2015).

Acceptability of policy or system change

The extent to which a policy or system change is evaluated unfavourably or favourably, or rejected or supported, by members of the general public (public acceptability) or politicians or governments (political acceptability). Acceptability may vary from totally unacceptable/fully rejected to totally acceptable/fully supported; individuals may differ in how acceptable policies or system changes are believed to be.

Acclimatization

A change in functional or morphological traits occurring once or repeatedly (e.g., seasonally) during the lifetime of an individual organism in its natural environment. Through acclimatization the individual maintains performance across a range of environmental conditions. For a clear differentiation between findings in laboratory and field studies, the term acclimation is used in ecophysiology for the respective phenomena when observed in well-defined experimental settings. The term (adaptive) plasticity characterises the generally limited scope of changes in phenotype that an individual can reach through the process of acclimatization.

Activity

A practice or ensemble of practices that take place on a delineated area over a given period of time.

Activity data

Data on the magnitude of a human *activity* resulting in emissions or removals taking place during a given period of time. In the *Agriculture, Forestry and Other Land Use (AFOLU)* sector, data on area of different *land uses*, management systems, animal numbers, lime and fertiliser use are examples of activity data.

Adaptability

See *Adaptive capacity*.

Adaptation

In *human systems*, the process of adjustment to actual or expected *climate* and its effects, in order to moderate harm or exploit beneficial opportunities. In natural systems, the process of adjustment to actual climate and its effects; human intervention may facilitate adjustment to expected climate and its effects.

Incremental adaptation

Adaptation that maintains the essence and integrity of a system or process at a given scale (Park et al., 2012).

Transformational adaptation

Adaptation that changes the fundamental attributes of a *social-ecological system* in anticipation of *climate change* and its *impacts*.

Adaptation limits

The point at which an actor's objectives (or system needs) cannot be secured from intolerable risks through adaptive actions.

- Hard adaptation limit - No adaptive actions are possible to avoid intolerable risks.
- Soft adaptation limit - Options are currently not available to avoid intolerable risks through adaptive action.

See also *Adaptation options*, *Adaptive capacity*, and *Maladaptive actions (Maladaptation)*.

Adaptation behaviour

See *Human behaviour*.

Adaptation limits

See *Adaptation*.

Adaptation options

The array of strategies and measures that are available and appropriate for addressing *adaptation*. They include a wide range of actions that can be categorised as structural, institutional, ecological or behavioural.

See also *Adaptive capacity*, and *Maladaptive actions (Maladaptation)*.

Adaptation pathways

See *Pathways*.

Adaptive capacity

The ability of systems, *institutions*, humans and other organisms to adjust to potential damage, to take advantage of opportunities, or to respond to consequences (IPCC, 2014; MA, 2005).

See also *Adaptation*, *Adaptation options*, and *Maladaptive actions (Maladaptation)*.

Adaptive governance

See *Governance*.

Adverse side-effect

The negative effects that a policy or measure aimed at one objective might have on other objectives, without yet evaluating the net effect on overall social welfare. Adverse side-effects are often subject to uncertainty and depend on, among others, local circumstances and implementation practices.

See also *Co-benefits* and *Risk*.

Aerosol

A suspension of airborne solid or liquid particles, with a typical size between a few nanometres and 10 µm that reside in the *atmosphere* for at least several hours. The term aerosol, which includes both

the particles and the suspending gas, is often used in this report in its plural form to mean aerosol particles. Aerosols may be of either natural or *anthropogenic* origin. Aerosols may influence *climate* in several ways: through both interactions that scatter and/or absorb radiation and through interactions with cloud microphysics and other cloud properties, or upon deposition on snow or ice covered surfaces thereby altering their *albedo* and contributing to *climate feedback*. Atmospheric aerosols, whether natural or anthropogenic, originate from two different pathways: emissions of primary particulate matter (PM), and formation of secondary PM from gaseous *precursors*. The bulk of aerosols are of natural origin. Some scientists use group labels that refer to the chemical composition, namely: sea salt, organic carbon, *black carbon* (BC), mineral species (mainly desert dust), sulphate, nitrate, and ammonium. These labels are, however, imperfect as aerosols combine particles to create complex mixtures.

See also *Short-lived climate forcers (SLCF)*.

Afforestation

Conversion to *forest* of land that historically has not contained forests.

[Note: For a discussion of the term forest and related terms such as afforestation, *reforestation* and *deforestation*, in the context of reporting and accounting Article 3.3 and 3.4 activities under the *Kyoto Protocol*, see 2013 Revised Supplementary Methods and Good Practice Guidance Arising from the Kyoto Protocol.]

See also *Reforestation, Deforestation, Forest and Reducing Emissions from Deforestation and Forest Degradation (REDD+)*.

Agreement

In this report, the degree of agreement within the scientific body of knowledge on a particular finding is assessed based on multiple lines of *evidence* (e.g., mechanistic understanding, theory, data, models, expert judgement) and expressed qualitatively (Mastrandrea et al., 2010).

See also *Confidence, Likelihood, and Uncertainty*.

Agriculture, Forestry and Other Land Use (AFOLU)

In the context of national *greenhouse gas (GHG)* inventories under the *United Nations Convention on Climate Change (UNFCCC)*, AFOLU is the sum of the GHG inventory sectors Agriculture and Land Use, Land-Use Change and Forestry (LULUCF); see the 2006 IPCC Guidelines for National GHG Inventories for details. Given the difference in estimating the ‘anthropogenic’ *carbon dioxide (CO₂)* removals between countries and the global modelling community, the land-related net GHG emissions from global models included in this report are not necessarily directly comparable with LULUCF estimates in national GHG Inventories.

See also *Land-use change (LUC)* and *Land Use, Land-use change and Forestry (LULUCF)*.

Agrobiodiversity

‘The variety and variability of animals, plants and micro-organisms that are used directly or indirectly for food and agriculture, including crops, livestock, forestry and fisheries. It comprises the diversity of genetic resources (varieties, breeds) and species used for food, fodder, fibre, fuel and pharmaceuticals. It also includes the diversity of non-harvested species that support production (soil micro-organisms, predators, pollinators), and those in the wider environment that support agro-ecosystems (agricultural, pastoral, forest and aquatic) as well as the diversity of the agro-ecosystems’ (FAO, 2005).

Agroecology

‘The science and practice of applying ecological concepts, principles and knowledge (i.e., the interactions of, and explanations for, the diversity, abundance and activities of organisms) to the study, design and management of sustainable agroecosystems. It includes the roles of human beings as a central organism in agroecology by way of social and economic processes in farming systems. Agroecology examines the roles and interactions among all relevant biophysical, technical and socioeconomic components of farming systems and their surrounding landscapes’ (IPBES, 2019).

Agroforestry

Collective name for land-use systems and technologies where woody perennials (trees, shrubs, palms, bamboos, etc.) are deliberately used on the same land-management units as agricultural crops and/or animals, in some form of spatial arrangement or temporal sequence. In agroforestry systems there are both ecological and economical interactions between the different components. Agroforestry can also be defined as a dynamic, ecologically based, natural resource management system that, through the integration of trees on farms and in the agricultural landscape, diversifies and sustains production for increased social, economic and environmental benefits for land users at all levels (FAO, 2015a).

Air pollution

Degradation of air quality with negative effects on human health, the natural or built environment, due to the introduction by natural processes or human activity in the *atmosphere* of substances (gases, *aerosols*) which have a direct (primary pollutants) or indirect (secondary pollutants) harmful effect.

See also *Short-lived climate forcers (SLCF)*.

Albedo

The proportion of sunlight (solar radiation) reflected by a surface or object, often expressed as a percentage. Clouds, snow and ice usually have high albedo; soil surfaces cover the albedo range from high to low; vegetation in the dry season and/or in arid zones can have high albedo, whereas photosynthetically active vegetation and the ocean have low albedo. The Earth's planetary albedo changes mainly through varying cloudiness, snow, ice, leaf area and land cover changes.

Ambient persuasive technology

Technological systems and environments that are designed to change human cognitive processing, attitudes and behaviours without the need for the user's conscious attention.

Anomaly

The deviation of a variable from its value averaged over a *reference period*.

See also *Reference period*.

Anthromes

‘*Human systems*, with natural *ecosystems* embedded within them’ (Ellis and Ramankutty 2008). The anthrome classification system is based on human population density and *land use*, and comprises the following classes: dense settlements, villages, croplands, rangeland, forested (then broadened to seminatural) and wildlands (Ellis et al. 2010).

Anthropocene

A proposed new geological epoch resulting from significant human-driven changes to the structure and functioning of the Earth System, including the *climate system*. Originally proposed in the Earth System science community in 2000, the proposed new epoch is undergoing a formalization process within the geological community based on the stratigraphic *evidence* that human activities have changed the Earth System to the extent of forming geological deposits with a signature that is distinct from those of the *Holocene*, and which will remain in the geological record. Both the stratigraphic and Earth System approaches to defining the Anthropocene consider the mid-20th Century to be the most appropriate starting date, although others have been proposed and continue to be discussed. The Anthropocene concept has been taken up by a diversity of disciplines and the public to denote the substantive influence humans have had on the state, dynamics and future of the Earth System.

See also *Holocene*.

Anthropogenic

Resulting from or produced by human activities.

See also *Anthropogenic emissions*, and *Anthropogenic removals*.

Anthropogenic emissions

Emissions of *greenhouse gases* (GHGs), *precursors* of GHGs and *aerosols* caused by human activities. These activities include the burning of *fossil fuels*, *deforestation*, *land use and land use changes* (LULUC), livestock production, fertilisation, waste management, and industrial processes.

See also *Anthropogenic*, and *Anthropogenic removals*.

Anthropogenic removals

The withdrawal of *greenhouse gases* (GHGs) from the *atmosphere* as a result of deliberate human activities. These include enhancing biological *sinks* of CO₂ and using chemical engineering to achieve long term removal and storage. *Carbon capture and storage* (CCS) from industrial and energy-related sources, which alone does not remove CO₂ from the atmosphere, can help reduce atmospheric CO₂ if it is combined with *bioenergy production* (BECCS).

[Note: In the 2006 IPCC Guidelines for national GHG Inventories, which are used in reporting of emissions to the UNFCCC, ‘*anthropogenic*’ land-related GHG *fluxes* are defined as all those occurring on ‘*managed land*’, i.e. ‘where human interventions and practices have been applied to perform production, ecological or social functions’. However, some removals (e.g. removals associated with CO₂ fertilisation and N deposition) are not considered as ‘anthropogenic’, or are referred to as ‘indirect’ anthropogenic effects, in some of the scientific literature assessed in this report. As a consequence, the land-related net GHG emission estimates from global models included in this report are not necessarily directly comparable with LULUCF estimates in national GHG Inventories.]

See also *Anthropogenic emissions*, *Bioenergy with carbon dioxide capture and storage* (BECCS), *Carbon dioxide capture and storage* (CCS) and *Land use, Land-use change, and Forestry* (LULUCF).

Aridity

The state of a long-term climatic feature characterised by low average precipitation or available water in a region. Aridity generally arises from widespread persistent *atmospheric* subsidence or anticyclonic conditions, and from more localised subsidence in the lee side of mountains (adapted from Gbeckor-Kove, 1989; Türkeş, 1999).

Atmosphere

The gaseous envelope surrounding the Earth, divided into five layers — the *troposphere* which contains half of the Earth's atmosphere, the *stratosphere*, the mesosphere, the thermosphere, and the exosphere, which is the outer limit of the atmosphere. The dry atmosphere consists almost entirely of nitrogen (78.1% volume mixing ratio) and oxygen (20.9% volume mixing ratio), together with a number of trace gases, such as argon (0.93 % volume mixing ratio), helium and radiatively active *greenhouse gases (GHGs)* such as *carbon dioxide (CO₂)* (0.04% volume mixing ratio) and *ozone (O₃)*. In addition, the atmosphere contains the GHG water vapour (H₂O), whose amounts are highly variable but typically around 1% volume mixing ratio. The atmosphere also contains clouds and aerosols.

See also *Carbon dioxide (CO₂)*, *Ozone (O₃)*, *Troposphere*, *Stratosphere*, *Greenhouse gas (GHG)*, and *Hydrological cycle*.

Atmosphere-ocean general circulation model (AOGCM)

See *Climate model*.

Atmospheric boundary layer

The atmospheric layer adjacent to the Earth's surface that is affected by friction against that boundary surface, and possibly by transport of heat and other variables across that surface (AMS, 2000). The lowest 100 m of the boundary layer (about 10% of the boundary layer thickness), where mechanical generation of turbulence is dominant, is called the surface boundary layer or surface layer.

Attribution

See *Detection and attribution*.

Baseline scenario

In much of the literature the term is also synonymous with the term business-as-usual (BAU) *scenario*, although the term BAU has fallen out of favour because the idea of business as usual in century-long socio-economic *projections* is hard to fathom. In the context of *transformation pathways*, the term baseline scenarios refers to scenarios that are based on the assumption that no mitigation policies or measures will be implemented beyond those that are already in force and/or are legislated or planned to be adopted. Baseline scenarios are not intended to be predictions of the future, but rather counterfactual constructions that can serve to highlight the level of emissions that would occur without further policy effort. Typically, baseline scenarios are then compared to *mitigation scenarios* that are constructed to meet different goals for *greenhouse gas (GHG)* emissions, atmospheric concentrations or temperature change. The term baseline scenario is often used interchangeably with reference scenario and no policy scenario.

See also *Emission scenario*, and *Mitigation scenario*.

Biochar

Relatively stable, carbon-rich material produced by heating *biomass* in an oxygen-limited environment. Biochar is distinguished from charcoal by its application: biochar is used as a soil amendment with the intention to improve soil functions and to reduce *greenhouse gas (GHG)* emissions from biomass that would otherwise decompose rapidly (IBI, 2018).

Biodiversity

Biodiversity or biological diversity means the variability among living organisms from all sources including, among other things, terrestrial, marine and other aquatic *ecosystems* and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems (UN, 1992).

See also *Ecosystem*, and *Ecosystem service*.

Bioenergy

Energy derived from any form of *biomass* or its metabolic by-products.

See also *Biomass* and *Biofuel*.

Bioenergy with carbon dioxide capture and storage (BECCS)

Carbon dioxide capture and storage (CCS) technology applied to a *bioenergy* facility. Note that depending on the total emissions of the BECCS supply chain, *carbon dioxide (CO₂)* can be removed from the *atmosphere*.

See also *Bioenergy*, and *Carbon dioxide capture and storage (CCS)*.

Biofuel

A fuel, generally in liquid form, produced from *biomass*. Biofuels include bioethanol from sugarcane, sugar beet or maize, and biodiesel from canola or soybeans.

See also *Biomass*, and *Bioenergy*.

Biogeochemical effects

Processes through which land affects *climate*, excluding *biophysical effects*. These processes include changes in net emissions of *carbon dioxide (CO₂)* towards the *atmosphere*, net emissions of *aerosols* (mineral and organic), ozone deposition on *ecosystems*, and net emissions of biogenic volatile organic compounds (BVOCs) and their subsequent changes in atmospheric chemistry.

See also *Biophysical effects*.

Biomass

Organic material excluding the material that is fossilised or embedded in geological formations. Biomass may refer to the mass of organic matter in a specific area (ISO, 2014).

See also *Bioenergy*, and *Biofuel*.

Traditional biomass

The combustion of wood, charcoal, agricultural residues and/or animal dung for cooking or heating in open fires or in inefficient stoves as is common in low-income countries.

Biome

‘Global-scale zones, generally defined by the type of plant life that they support in response to average rainfall and temperature patterns. For example, tundra, coral reefs or savannas’ (IPBES, 2019).

Biophysical effects

The range of physical processes through which *land* affects *climate*. These processes include changes in hydrology (e.g. water vapor fluxes at the land/atmosphere interface), heat exchanges via convective *fluxes* (latent and sensible), radiation (solar and infra-red, absorbed and emitted), and momentum (e.g. affecting wind speed).

Black carbon (BC)

A relatively pure form of carbon, also known as soot, arising from the incomplete combustion of *fossil fuels*, *biofuel*, and *biomass*. It stays in the *atmosphere* only for days or weeks. Black carbon is a climate forcing agent with strong warming effect, both in the atmosphere and when deposited on snow or ice.

See also *Atmosphere*, and *Aerosol*.

Blue carbon

All biologically-driven carbon *fluxes* and storage in marine systems that are amenable to management can be considered as blue carbon. Coastal blue carbon focuses on rooted vegetation in the coastal zone, such as tidal marshes, mangroves and seagrasses. These *ecosystems* have high carbon burial rates on a per unit area basis and accumulate carbon in their soils and sediments. They provide many non-climatic benefits and can contribute to ecosystem-based adaptation. If degraded or lost, coastal blue carbon ecosystems are likely to release most of their carbon back to the *atmosphere*. There is current debate regarding the application of the blue carbon concept to other coastal and non-coastal processes and ecosystems, including the open ocean.

See also *Ecosystem services*, and *Carbon sequestration*.

Business as usual (BAU)

See *Baseline scenario*.

Carbon budget

Refers to three concepts in the literature: (1) an assessment of *carbon cycle sources* and *sinks* on a global level, through the synthesis of *evidence* for *fossil-fuel* and cement emissions, *land-use change* emissions, ocean and land CO₂ sinks, and the resulting atmospheric *carbon dioxide (CO₂)* growth rate. This is referred to as the global carbon budget; (2) the estimated cumulative amount of global carbon dioxide emissions that that is estimated to limit global surface temperature to a given level above a *reference period*, taking into account global surface temperature contributions of other *greenhouse gases (GHGs)* and climate forcers; (3) the distribution of the carbon budget defined under (2) to the regional, national, or sub-national level based on considerations of *equity*, costs or efficiency.

See also *Remaining carbon budget*.

Carbon cycle

The flow of carbon (in various forms, e.g., as *carbon dioxide (CO₂)*, carbon in *biomass*, and carbon dissolved in the ocean as carbonate and bicarbonate) through the *atmosphere*, hydrosphere, terrestrial and marine biosphere and lithosphere. In this report, the reference unit for the global carbon cycle is GtCO₂ or GtC (one Gigatonne = 1 Gt = 10¹⁵ grams; 1GtC corresponds to 3.667 GtCO₂).

Carbon dioxide (CO₂)

A naturally occurring gas, CO₂ is also a by-product of burning *fossil fuels* (such as oil, gas and coal), of burning *biomass*, of *land use changes (LUC)* and of industrial processes (e.g., cement production). It is the principal *anthropogenic* greenhouse gas (*GHG*) that affects the Earth's radiative balance. It is the reference gas against which other GHGs are measured and therefore has a Global Warming Potential (GWP) of 1.

See also *Greenhouse gas (GHG)*, *Land use, Land-use change*, and *Global Warming Potential (GWP)*.

Carbon dioxide capture and storage (CCS)

A process in which a relatively pure stream of *carbon dioxide (CO₂)* from industrial and energy-related sources is separated (captured), conditioned, compressed and transported to a storage location for long-term isolation from the atmosphere. Sometimes referred to as Carbon Capture and Storage.

See also *Carbon dioxide capture and utilisation (CCU)*, *Bioenergy with carbon dioxide capture and storage (BECCS)*, and *Sequestration*.

Carbon dioxide capture and utilisation (CCU)

A process in which *carbon dioxide (CO₂)* is captured and then used to produce a new product. If the CO₂ is stored in a product for a *climate-relevant* time horizon, this is referred to as carbon dioxide capture, utilisation and storage (CCUS). Only then, and only combined with CO₂ recently removed from the *atmosphere*, can CCUS lead to carbon dioxide removal. CCU is sometimes referred to as Carbon dioxide capture and use.

See also *Carbon dioxide capture and storage (CCS)*.

Carbon dioxide capture, utilisation and storage (CCUS)

See *Carbon dioxide capture and utilisation (CCU)*.

Carbon dioxide removal (CDR)

Anthropogenic activities removing CO₂ from the *atmosphere* and durably storing it in geological, terrestrial, or ocean reservoirs, or in products. It includes existing and potential anthropogenic enhancement of biological or geochemical sinks and direct air capture and storage, but excludes natural CO₂ *uptake* not directly caused by human activities.

See also *Mitigation (of climate change)*, *Greenhouse gas removal (GGR)*, *Negative emission technologies*, and *Sink*.

Carbon intensity

The amount of emissions of *carbon dioxide (CO₂)* released per unit of another variable such as *gross domestic product (GDP)*, output energy use or transport.

Carbon price

The price for avoided or released *carbon dioxide (CO₂)* or *CO₂-equivalent emissions*. This may refer to the rate of a carbon tax, or the price of emission permits. In many models that are used to assess the economic costs of *mitigation*, carbon prices are used as a proxy to represent the level of effort in mitigation policies.

See also *Mitigation*.

Carbon sequestration

The process of storing carbon in a carbon *pool*.

See also *Blue carbon*, *Carbon dioxide capture and storage (CCS)*, *Uptake*, and *Sink*.

Carbon sink

See *Sink*.

Carbon stock

The quantity of carbon in a carbon *pool*.

See also *Pool*, *carbon and nitrogen*.

Citizen science

A voluntary participation of the public in the collection and/or processing of data as part of a scientific study (Silvertown, 2009).

Clean Development Mechanism (CDM)

A mechanism defined under Article 12 of the *Kyoto Protocol* through which investors (governments or companies) from developed (Annex B) countries may finance *greenhouse gas (GHG)* emission reduction or removal projects in developing countries (Non-Annex B), and receive Certified Emission Reduction Units (CERs) for doing so. The CERs can be credited towards the commitments of the respective developed countries. The CDM is intended to facilitate the two objectives of promoting *sustainable development (SD)* in developing countries and of helping *industrialised countries* to reach their emissions commitments in a cost-effective way.

Climate

Climate in a narrow sense is usually defined as the average weather, or more rigorously, as the statistical description in terms of the mean and variability of relevant quantities over a period of time ranging from months to thousands or millions of years. The classical period for averaging these variables is 30 years, as defined by the World Meteorological Organization. The relevant quantities are most often surface variables such as temperature, precipitation and wind. Climate in a wider sense is the state, including a statistical description, of the *climate system*.

Climate change

A change in the state of the *climate* that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes or external *forcings* such as modulations of the solar cycles, volcanic eruptions and persistent *anthropogenic* changes in the composition of the *atmosphere* or in *land use*. Note that the *United Nations Framework Convention on Climate Change (UNFCCC)*, in its Article 1, defines climate change as: 'a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods'. The UNFCCC thus makes a distinction between climate change attributable to human activities altering the atmospheric composition and climate variability attributable to natural causes.

See also *Climate variability*, *Global warming*, *Ocean acidification*, and *Detection and attribution*.

Climate extreme (extreme weather or climate event)

The occurrence of a value of a weather or *climate* variable above (or below) a threshold value near the upper (or lower) ends of the range of observed values of the variable. For simplicity, both extreme weather events and extreme climate events are referred to collectively as ‘climate extremes.’

See also *Extreme weather event*.

Climate feedback

An interaction in which a perturbation in one *climate* quantity causes a change in a second and the change in the second quantity ultimately leads to an additional change in the first. A negative feedback is one in which the initial perturbation is weakened by the changes it causes; a positive feedback is one in which the initial perturbation is enhanced. The initial perturbation can either be externally forced or arise as part of internal variability.

Climate governance

See *Governance*.

Climate model

A numerical representation of the *climate system* based on the physical, chemical and biological properties of its components, their interactions and *feedback* processes and accounting for some of its known properties. The climate system can be represented by models of varying complexity; that is, for any one component or combination of components a spectrum or hierarchy of models can be identified, differing in such aspects as the number of spatial dimensions, the extent to which physical, chemical or biological processes are explicitly represented, or the level at which empirical parametrizations are involved. There is an evolution towards more complex models with interactive chemistry and biology. *Climate models* are applied as a research tool to study and simulate the *climate* and for operational purposes, including monthly, seasonal and interannual climate predictions.

See also *Earth system model (ESM)*.

Climate projection

Simulated response of the *climate system* to a *scenario* of future emissions or concentrations of *greenhouse gases (GHGs)* and *aerosols*, and changes in land use, generally derived using *climate models*. Climate projections are distinguished from climate predictions by their dependence on the emission/concentration/*radiative forcing* scenario used, which is in turn based on assumptions concerning, for example, future socioeconomic and technological developments that may or may not be realised.

Climate-resilient development pathways (CRDPs)

Trajectories that strengthen *sustainable development* and efforts to eradicate *poverty* and reduce inequalities while promoting *fair* and cross-scalar *adaptation* to and *resilience* in a changing *climate*. They raise the *ethics*, *equity*, and *feasibility* aspects of the deep *societal transformation* needed to drastically reduce emissions to limit *global warming* (e.g., to 2°C) and achieve desirable and liveable futures and *well-being* for all.

Climate-resilient pathways

Iterative processes for managing change within complex systems in order to reduce disruptions and enhance opportunities associated with *climate change*.

See also *Climate-resilient development pathways (CRDPs)*, *Development pathways*, *Pathways*, and *Transformation pathways*.

Climate sensitivity

The change in the annual *global mean surface temperature* in response to a change in the atmospheric *carbon dioxide (CO₂)* concentration or other radiative forcing.

Equilibrium climate sensitivity

The equilibrium (steady state) change in the globally-averaged near-surface temperature following a doubling of the atmospheric *carbon dioxide (CO₂)* concentration from pre-industrial conditions. The equilibrium climate sensitivity is often estimated through experiments in atmosphere-ocean general circulation model (AOGCMs) where CO₂ levels are either quadrupled or doubled from *pre-industrial* levels and which are integrated for 100-200 years. A related quantity, the climate feedback parameter (units: W m⁻² °C⁻¹) refers to the top of atmosphere budget change per degree of globally-averaged near-surface temperature change.

See also *Climate model*, and *Global mean surface temperature (GMST)*.

Effective climate sensitivity

An estimate of the *global mean surface temperature* response to a doubling of the atmospheric *carbon dioxide (CO₂)* concentration that is evaluated from model output or observations for evolving non-equilibrium conditions. It is a measure of the strengths of the *climate feedbacks* at a particular time and may vary with *forcing* history and *climate* state, and therefore may differ from *equilibrium climate sensitivity*.

Transient climate response

The change in the *global mean surface temperature*, averaged over a 20-year period, centred at the time of atmospheric *carbon dioxide (CO₂)* doubling, in a *climate model* simulation in which CO₂ increases at 1% yr⁻¹ from *pre-industrial*. It is a measure of the strength of *climate feedbacks* and the timescale of ocean heat uptake.

Climate services

Information and products that enhance users' knowledge and understanding about the *impacts* of *climate change* and/or *climate variability* so as to aid decision-making of individuals and organizations and enable preparedness and early climate change action. Such services involve high-quality data from national and international databases on temperature, rainfall, wind, soil moisture and ocean conditions, as well as maps, *risk* and *vulnerability* analyses, assessments, and long-term *projections* and *scenarios*. Depending on the user's needs, these data and information products may be combined with non-meteorological data, such as agricultural production, health trends, population distributions in high-risk areas, road and infrastructure maps for the delivery of goods, and other socio-economic variables (WMO, 2019).

Climate-smart agriculture (CSA)

An approach to agriculture that aims to transform and reorient agricultural systems to effectively support development and ensure *food security* in a changing climate by: sustainably increasing agricultural productivity and incomes; adapting and building resilience to climate change; and reducing and/or removing *greenhouse gas* emissions, where possible (FAO, 2018).

Climate system

The system consisting of five major components: the *atmosphere*, the hydrosphere, the cryosphere, the lithosphere and the biosphere and the interactions between them. The climate system evolves in time under the influence of its own internal dynamics and because of external *forcings* such as volcanic eruptions, solar variations, orbital forcing, and *anthropogenic* forcings such as the changing composition of the atmosphere and *land-use change*.

Climate target

A temperature limit, concentration level, or emissions reduction goal used towards the aim of avoiding dangerous *anthropogenic* interference with the *climate system*. For example, national climate targets may aim to reduce *greenhouse gas* emissions by a certain amount over a given time horizon, for example those under the *Kyoto Protocol*.

Climate variability

Variations in the mean state and other statistics (such as standard deviations, the occurrence of extremes, etc.) of the *climate* on all spatial and temporal scales beyond that of individual weather events. Variability may be due to natural internal processes within the *climate system* (internal variability), or to variations in natural or *anthropogenic* external *forcing* (external variability).

See also *Climate change*.

CO₂ equivalent (CO₂-eq) emission

The amount of *carbon dioxide* (CO₂) emission that would cause the same integrated *radiative forcing* or temperature change, over a given time horizon, as an emitted amount of a *greenhouse gas* (GHG) or a mixture of GHGs. There are a number of ways to compute such equivalent emissions and choose appropriate time horizons. Most typically, the CO₂-equivalent emission is obtained by multiplying the emission of a GHG by its Global Warming Potential (GWP) for a 100 year time horizon. For a mix of GHGs it is obtained by summing the CO₂-equivalent emissions of each gas. CO₂-equivalent emission is a common scale for comparing emissions of different GHGs but does not imply equivalence of the corresponding climate change responses. There is generally no connection between CO₂-equivalent emissions and resulting CO₂-equivalent concentrations.

Co-benefits

The positive effects that a policy or measure aimed at one objective might have on other objectives, thereby increasing the total benefits for society or the environment. Co-benefits are often subject to uncertainty and depend on local circumstances and implementation practices, among other factors. Co-benefits are also referred to as ancillary benefits.

See also *Adverse side-effects*, and *Risk*.

Collective action

A number of people working together voluntarily to achieve some common objective (Meinzen-Dick and Di Gregorio, 2004).

Conference of the Parties (COP)

The supreme body of UN conventions, such as the *United Nations Framework Convention on Climate Change* (UNFCCC), comprising parties with a right to vote that have ratified or acceded to the convention.

See also *United Nations Convention to Combat Desertification* (UNCCD).

Confidence

The robustness of a finding based on the type, amount, quality and consistency of *evidence* (e.g., mechanistic understanding, theory, data, models, expert judgment) and on the degree of *agreement* across multiple lines of evidence. In this report, confidence is expressed qualitatively (Mastrandrea et al., 2010).

See also *Likelihood*, and *Uncertainty*.

Convection

Vertical motion driven by buoyancy forces arising from static instability, usually caused by near-surface cooling or increases in salinity in the case of the ocean and near-surface warming or cloud-top radiative cooling in the case of the *atmosphere*. In the atmosphere, convection gives rise to cumulus clouds and precipitation and is effective at both scavenging and vertically transporting chemical species. In the ocean, convection can carry surface waters to deep within the ocean.

Coping capacity

The ability of people, *institutions*, organizations, and systems, using available skills, values, beliefs, resources, and opportunities, to address, manage, and overcome adverse conditions in the short to medium term. (UNISDR, 2009; IPCC, 2012a)

See also *Resilience*.

Cost-benefit analysis

Monetary assessment of all negative and positive impacts associated with a given action. Cost-benefit analysis enables comparison of different interventions, investments or strategies and reveal how a given investment or policy effort pays off for a particular person, company or country. Cost-benefit analyses representing society's point of view are important for *climate change* decision making, but there are difficulties in aggregating costs and benefits across different actors and across timescales.

See also *Discounting*.

Cost-effectiveness

A measure of the cost at which a policy goal or outcome is achieved. The lower the cost the greater the cost-effectiveness.

See also *Integrated models*.

Coupled Model Intercomparison Project (CMIP)

A climate modelling activity from the World Climate Research Programme (WCRP) which coordinates and archives *climate model* simulations based on shared model inputs by modelling groups from around the world. The CMIP3 multi-model data set includes *projections* using SRES scenarios. The CMIP5 data set includes projections using the *Representative Concentration Pathways (RCPs)*. The CMIP6 phase involves a suite of common model experiments as well as an ensemble of CMIP-endorsed model intercomparison projects (MIPs).

Cumulative emissions

The total amount of emissions released over a specified period of time.

See also *Carbon budget*.

Decarbonisation

Process by which countries, individuals or other entities aim to achieve zero fossil carbon existence. Typically refers to a reduction of the carbon emissions associated with electricity, industry and transport.

Decoupling

Decoupling (in relation to *climate change*) is where economic growth is no longer strongly associated with consumption of *fossil fuels*. Relative decoupling is where both grow but at different rates. Absolute decoupling is where economic growth happens but fossil fuels decline.

Deforestation

Conversion of *forest* to non-forest.

[Note: For a discussion of the term forest and related terms such as *afforestation*, *reforestation* and *deforestation* in the context of reporting and accounting Article 3.3 and 3.4 activities under the Kyoto Protocol, see 2013 Revised Supplementary Methods and Good Practice Guidance Arising from the Kyoto Protocol.]

See also *Reducing Emissions from Deforestation and Forest Degradation (REDD+)*.

Deliberative governance

See *Governance*.

Demand and supply-side measures*Demand-side measures*

Policies and programmes for influencing the demand for goods and/or services. In the energy sector, demand-side management aims at reducing the demand for electricity and other forms of energy required to deliver energy services.

Supply-side measures

Policies and programmes for influencing how a certain demand for goods and/or services is met. In the energy sector, for example, supply-side *mitigation measures* aim at reducing the amount of *greenhouse gas (GHG)* emissions emitted per unit of energy produced.

See also *Mitigation measures*.

Demand-side measures

See *Demand and supply-side measures*.

Desertification

Land degradation in arid, semi-arid, and dry sub-humid areas resulting from many factors, including climatic variations and human activities (UNCCD, 1994).

Detection

See *Detection and attribution*.

Detection and attribution

Detection of change is defined as the process of demonstrating that *climate* or a system affected by climate has changed in some defined statistical sense, without providing a reason for that change. An identified change is detected in observations if its *likelihood* of occurrence by chance due to internal variability alone is determined to be small, for example, <10%. Attribution is defined as the process of evaluating the relative contributions of multiple causal factors to a change or event with a formal assessment of *confidence*.

Development pathways

See *Pathways*.

Diet

‘The kinds of food that follow a particular pattern that a person or community eats’ (FAO, 2014).

See also *Dietary patterns*.

Dietary patterns

The quantities, proportions, variety or combinations of different foods and beverages in diets, and the frequency with which they are habitually consumed (Dietary Guidelines Advisory Committee, 2015).

See also *Diet*.

Dietary and nutrition transitions

Modernization, urbanisation, economic development, and increased wealth lead to predictable shifts in diet, referred to as ‘nutrition transitions’ (Misra and Khurana, 2008; Popkin, 2006). Over historical time there have been a number of dietary *transitions* but in recent decades the prime transition has been associated with changes from subsistence towards eating diets rich in calories and relatively poor in nutrition (the ‘westernised diet’) that are obesogenic. From a public health perspective, a new dietary transition is in focus, from the obesogenic diet to one promoting health.

Disaster

A ‘serious disruption of the functioning of a community or a society at any scale due to hazardous events interacting with conditions of exposure, vulnerability and capacity, leading to one or more of the following: human, material, economic and environmental losses and impacts’ (UNISDR, 2017).

See also *Exposure, Risk, Vulnerability* and *Hazard*.

Disaster risk management (DRM)

Processes for designing, implementing, and evaluating strategies, policies, and measures to improve the understanding of current and future *disaster* risk, foster disaster risk reduction and transfer, and promote continuous improvement in disaster preparedness, prevention and protection, response, and recovery practices, with the explicit purpose of increasing human security, *well-being*, quality of life, and *sustainable development* (UNISDR, 2017).

Discounting

A mathematical operation that aims to make monetary (or other) amounts received or expended at different times (years) comparable across time. The discounter uses a fixed or possibly time-varying discount rate from year to year that makes future value worth less today (if the discount rate is positive). The choice of discount rate(s) is debated as it is a judgement based on hidden and/or explicit values.

Discount rate

See *Discounting*.

(Internal) Displacement

The forced movement of people within the country they live in. Internally displaced persons (IDPs) are 'Persons or groups of persons who have been forced or obliged to flee or to leave their homes or places of habitual residence, in particular as a result of or in order to avoid the effects of armed conflict, situations of generalized violence, violations of human rights or natural or human-made *disasters*, and who have not crossed an internationally recognized State border' (UN, 1998).

See also *Migration*.

Displacement

In land system science, displacement denotes the increasing spatial separation between the location of agricultural and forestry production and the place of consumption of these products, as it occurs with trade. Displacement disconnects spatially environmental impacts from their socioeconomic drivers.

Downscaling

Method that derives local- to regional-scale (up to 100 km) information from larger-scale models or data analyses. Two main methods exist: dynamical downscaling and empirical/statistical downscaling. The dynamical method uses the output of regional *climate models*, global models with variable spatial resolution, or high-resolution global models. The empirical/statistical methods [are based on observations and] develop statistical relationships that link the large-scale atmospheric variables with local/ regional climate variables. In all cases, the quality of the driving model remains an important limitation on quality of the downscaled information. The two methods can be combined, e.g., applying empirical/statistical downscaling to the output of a regional climate model, consisting of a dynamical downscaling of a global climate model.'

Drainage

'Artificial lowering of the soil water table' (IPCC, 2013).

See also *Rewetting*.

Drought

A period of abnormally dry weather long enough to cause a serious hydrological imbalance. Drought is a relative term, therefore any discussion in terms of precipitation deficit must refer to the particular precipitation-related activity that is under discussion. For example, shortage of precipitation during the growing season impinges on crop production or *ecosystem* function in general (due to *soil moisture* drought, also termed agricultural drought), and during the *runoff* and percolation season primarily affects water supplies (hydrological drought). Storage changes in soil moisture and groundwater are also affected by increases in actual *evapotranspiration* in addition to reductions in

precipitation. A period with an abnormal precipitation deficit is defined as a meteorological drought.

Megadrought

A very lengthy and pervasive drought, lasting much longer than normal, usually a decade or more.

Early warning systems (EWS)

The set of technical, financial and *institutional capacities* needed to generate and disseminate timely and meaningful warning information to enable individuals, communities and organizations threatened by a *hazard* to prepare to act promptly and appropriately to reduce the possibility of harm or loss. Dependent upon context, EWS may draw upon scientific and/or *Indigenous knowledge*. EWS are also considered for ecological applications e.g., conservation, where the organisation itself is not threatened by hazard but the *ecosystem* under conservation is (an example is coral bleaching alerts), in agriculture (for example, warnings of ground frost, hailstorms) and in fisheries (storm and tsunami warnings) (UNISDR, 2009; IPCC, 2012a).

Earth system feedbacks

See *Climate feedback*.

Earth system model (ESM)

A coupled atmosphere–ocean general circulation model in which a representation of the *carbon cycle* is included, allowing for interactive calculation of atmospheric *carbon dioxide* (CO_2) or compatible emissions. Additional components (e.g., atmospheric chemistry, *ice sheets*, dynamic vegetation, nitrogen cycle, but also urban or crop models) may be included.

See also *Climate model*.

Ecological cascade

A series of secondary extinctions as a result of the extinction of a key species within an *ecosystem* (Soulé, 2010).

Ecosystem

A functional unit consisting of living organisms, their non-living environment and the interactions within and between them. The components included in a given ecosystem and its spatial boundaries depend on the purpose for which the ecosystem is defined: in some cases they are relatively sharp, while in others they are diffuse. Ecosystem boundaries can change over time. Ecosystems are nested within other ecosystems and their scale can range from very small to the entire biosphere. In the current era, most ecosystems either contain people as key organisms, or are influenced by the effects of human activities in their environment.

See also *Ecosystem services*.

Ecosystem services

Ecological processes or functions having monetary or non-monetary value to individuals or society at large. These are frequently classified as (1) supporting services such as productivity or *biodiversity* maintenance, (2) provisioning services such as food or fibre, (3) regulating services such as climate regulation or *carbon sequestration*, and (4) cultural services such as tourism or spiritual and aesthetic appreciation.

See also *Ecosystem*.

Effective climate sensitivity

See *Climate sensitivity*.

Effective radiative forcing

See *Radiative forcing*.

El Niño-Southern Oscillation (ENSO)

The term El Niño was initially used to describe a warm-water current that periodically flows along the coast of Ecuador and Peru, disrupting the local fishery. It has since become identified with warming of the tropical Pacific Ocean east of the dateline. This oceanic event is associated with a fluctuation of a global-scale tropical and subtropical surface pressure pattern called the Southern Oscillation. This coupled atmosphere–ocean phenomenon, with preferred time scales of two to about seven years, is known as the El Niño-Southern Oscillation (ENSO). It is often measured by the surface pressure anomaly difference between Tahiti and Darwin and/or the *sea surface temperatures* in the central and eastern equatorial Pacific. During an ENSO event, the prevailing trade winds weaken, reducing upwelling and altering ocean currents such that the sea surface temperatures warm, further weakening the trade winds. This phenomenon has a great impact on the wind, sea surface temperature and precipitation patterns in the tropical Pacific. It has climatic effects throughout the Pacific region and in many other parts of the world, through global *teleconnections*. The cold phase of ENSO is called La Niña.

Embodied (embedded) [emissions, water, land]

The total emissions [water use, *land use*] generated [used] in the production of goods and services regardless of the location and timing of those emissions [water use, land use] in the production process. This includes emissions [water use, land use] within the country used to produce goods or services for the country’s own use, but also includes the emissions [water use, land use] related to the production of such goods or services in other countries that are then consumed in another country through imports. Such emissions [water, land] are termed ‘embodied’ or ‘embedded’ emissions, or in some cases (particularly with water) as ‘virtual water use’ (David and Caldeira, 2010; Allan, 2005; MacDonald et al., 2015).

Emission scenario

A plausible representation of the future development of emissions of substances that are radiatively active (e.g., *greenhouse gases (GHGs)*, *aerosols*) based on a coherent and internally consistent set of assumptions about driving forces (such as demographic and socio-economic development, technological change, energy and *land use*) and their key relationships. Concentration *scenarios*, derived from emission scenarios, are often used as input to a *climate model* to compute *climate projections*.

See also *Baseline scenario*, *Mitigation scenario*, *Representative Concentration Pathways (RCPs) (under Pathways)*, *Shared socio-economic pathways (SSPs) (under Pathways)*, *Scenario*, *Socio-economic scenario*, and *Transformation pathway*.

Emission trajectories

A *projected* development in time of the emission of a *greenhouse gas (GHG)* or group of GHGs, *aerosols*, and *GHG precursors*.

See also *Pathways*.

Energy access

Access to clean, reliable and affordable energy services for cooking and heating, lighting, communications, and productive uses (with special reference to *Sustainable Development Goal 7*) (AGECC, 2010).

See also *Traditional biomass*.

Enabling conditions (for adaptation and mitigation options)

Conditions that affect the *feasibility* of *adaptation* and *mitigation* options, and can accelerate and scale-up systemic transitions that would limit temperature increase and enhance capacities of systems and societies to adapt to the associated *climate change*, while achieving *sustainable development*, eradicating *poverty* and reducing *inequalities*. Enabling conditions include finance, technological innovation, strengthening policy instruments, *institutional capacity*, *multi-level governance*, and changes in *human behaviour* and lifestyles. They also include inclusive processes, attention to power asymmetries and unequal opportunities for development and reconsideration of values.

Energy efficiency

The ratio of output or useful energy or energy services or other useful physical outputs obtained from a system, conversion process, transmission or storage activity to the input of energy (measured as kWh kWh⁻¹, tonnes kWh⁻¹ or any other physical measure of useful output like tonne-km transported). Energy efficiency is often described by energy intensity. In economics, energy intensity describes the ratio of economic output to energy input. Most commonly energy efficiency is measured as input energy over a physical or economic unit, i.e. kWh USD⁻¹ (energy intensity), kWh tonne⁻¹. For buildings, it is often measured as kWh m⁻², and for vehicles as km liter⁻¹ or liter km⁻¹. Very often in policy ‘energy efficiency’ is intended as the measures to reduce energy demand through technological options such as insulating buildings, more efficient appliances, efficient lighting, efficient vehicles, etc.

Energy security

The goal of a given country, or the global community as a whole, to maintain an adequate, stable and predictable energy supply. Measures encompass safeguarding the sufficiency of energy resources to meet national energy demand at competitive and stable prices and the resilience of the energy supply; enabling development and deployment of technologies; building sufficient infrastructure to generate, store and transmit energy supplies and ensuring enforceable contracts of delivery.

Enhanced weathering

Enhancing the removal of *carbon dioxide (CO₂)* from the *atmosphere* through dissolution of silicate and carbonate rocks by grinding these minerals to small particles and actively applying them to soils, coasts or oceans.

(Model) Ensemble

A group of parallel model simulations characterising historical climate conditions, *climate* predictions, or *climate projections*. Variation of the results across the ensemble members may give an estimate of modelling-based *uncertainty*. Ensembles made with the same model but different initial conditions only characterise the uncertainty associated with internal *climate variability*, whereas multi-model ensembles including simulations by several models also include the impact of model differences. Perturbed parameter ensembles, in which model parameters are varied in a systematic manner, aim to assess the uncertainty resulting from internal model specifications within a single

model. Remaining sources of uncertainty unaddressed with model ensembles are related to systematic model errors or biases, which may be assessed from systematic comparisons of model simulations with observations wherever available.

See also *Climate projection*.

Equality

A principle that ascribes equal worth to all human beings, including equal opportunities, rights, and obligations, irrespective of origins.

Inequality

Uneven opportunities and social positions, and processes of discrimination within a group or society, based on gender, class, ethnicity, age, and (dis)ability, often produced by uneven development. Income inequality refers to gaps between highest and lowest income earners within a country and between countries.

See also *Equity and Fairness*.

Equilibrium climate sensitivity

See *Climate sensitivity*.

Equity

The principle of being fair and impartial, and a basis for understanding how the *impacts* and responses to *climate change*, including costs and benefits, are distributed in and by society in more or less equal ways. It is often aligned with ideas of *equality*, fairness and justice and applied with respect to *equity* in the responsibility for, and distribution of, climate impacts and policies across society, generations, and gender, and in the sense of who participates and controls the processes of decision making.

Distributive equity

Equity in the consequences, outcomes, costs and benefits of actions or policies. In the case of *climate change* or climate policies for different people, places and countries, including equity aspects of sharing burdens and benefits for *mitigation* and *adaptation*.

Gender equity

Equity between women and men with regard to their rights, resources and opportunities. In the case of *climate change*, gender equity recognises that women are often more vulnerable to the *impacts* of climate change and may be disadvantaged in the process and outcomes of climate policy.

Inter-generational equity

Equity between generations. In the context of *climate change*, inter-generational equity acknowledges that the effects of past and present emissions, *vulnerabilities* and policies impose costs and benefits for people in the future and of different age groups.

Procedural equity

Equity in the process of decision making including recognition and inclusiveness in participation, equal representation, bargaining power, voice and equitable access to knowledge and resources to participate.

See also *Equality and Fairness*.

Evaporation

The physical process by which a liquid (e.g., water) becomes a gas (e.g., water vapour).

Evapotranspiration

The combined processes through which water is transferred to the *atmosphere* from open water and ice surfaces, bare soil, and vegetation that make up the Earth's surface.

Potential Evapotranspiration

The potential rate of water loss without any limits imposed by the water supply.

See also *Evaporation*.

Evidence

Data and information used in the scientific process to establish findings. In this report, the degree of evidence reflects the amount, quality, and consistency of scientific/technical information on which the Lead Authors base their findings.

See also *Agreement, Confidence, Likelihood, and Uncertainty*.

Exposure

The presence of people; *livelihoods*; species or *ecosystems*; environmental functions, services, and resources; infrastructure; or economic, social, or cultural assets in places and settings that could be adversely affected.

See also *Hazard, Risk, and Vulnerability*.

Extratropical Cyclone

Any cyclonic-scale storm that is not a *tropical cyclone*. Usually refers to a middle- or high-latitude migratory storm system formed in regions of large horizontal temperature variations. Sometimes called extratropical storm or extratropical low.

See also *Tropical cyclone*.

Extreme weather or climate event

See *Climate extreme (extreme weather or climate event)*.

Extreme weather event

An event that is rare at a particular place and time of year. Definitions of 'rare' vary, but an extreme weather event would normally be as rare as or rarer than the 10th or 90th percentile of a probability density function estimated from observations. By definition, the characteristics of what is called extreme weather may vary from place to place in an absolute sense. When a pattern of extreme weather persists for some time, such as a season, it may be classed as an extreme climate event, especially if it yields an average or total that is itself extreme (e.g., *drought* or heavy rainfall over a season).

See also *Heat wave, and Climate extreme (extreme weather or climate event)*.

Fairness

Impartial and just treatment without favouritism or discrimination in which each person is considered of equal worth with equal opportunity.

See also *Equity*, and *Equality*.

Feasibility

The degree to which climate goals and response options are considered possible and/or desirable. Feasibility depends on geophysical, ecological, technological, economic, social and *institutional* conditions for change. Conditions underpinning feasibility are dynamic, spatially variable, and may vary between different groups.

See also *Enabling conditions*.

Feedback

See *Climate feedback*.

Flexible governance

See *Governance*.

Flood

The overflowing of the normal confines of a stream or other body of water, or the accumulation of water over areas that are not normally submerged. Floods include river (fluvial) floods, flash floods, urban floods, rain (pluvial) floods, sewer floods, coastal floods, and glacial lake outburst floods.

Flux

A movement (a flow) of matter (e.g., water vapor, particles), heat or energy from one place to another, or from one medium (e.g., land surface) to another (e.g., atmosphere).

Food loss and waste

‘The decrease in quantity or quality of food’. Food waste is part of food loss and refers to discarding or alternative (non-food) use of food that is safe and nutritious for human consumption along the entire food supply chain, from primary production to end household consumer level. Food waste is recognised as a distinct part of food loss because the drivers that generate it and the solutions to it are different from those of food losses (FAO, 2015b).

Food security

A situation that exists when all people, at all times, have physical, social and economic access to sufficient, safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life (FAO, 2001).

[Note: Whilst the term ‘food security’ explicitly includes nutrition within it ‘dietary needs ...for an active and healthy life’, in the past the term has sometimes privileged the supply of calories (energy), especially to the hungry. Thus, the term ‘food and nutrition security’ is often used (with the same definition as food security) to emphasise that the term food covers both energy and nutrition (FAO, 2009).]

Food system

All the elements (environment, people, inputs, processes, infrastructures, institutions, etc.) and activities that relate to the production, processing, distribution, preparation and consumption of food, and the output of these activities, including socio-economic and environmental outcomes (HLPE, 2017).

[Note: Whilst there is a global food system (encompassing the totality of global production and consumption), each location's food system is unique, being defined by that place's mix of food produced locally, nationally, regionally or globally.]

Forcing

See *Radiative forcing*.

Forest

A vegetation type dominated by trees. Many definitions of the term forest are in use throughout the world, reflecting wide differences in biogeophysical conditions, social structure and economics.

[Note: For a discussion of the term forest in the context of National GHG inventories, see the 2006 IPCC Guidelines for National GHG Inventories and information provided by the United Nations Framework Convention on Climate Change (UNFCCC, 2019).]

See also *Afforestation*, *Deforestation*, and *Reforestation*.

Fossil fuels

Carbon-based fuels from fossil hydrocarbon deposits, including coal, oil, and natural gas.

Framework Convention on Climate Change

See *United Nations Framework Convention on Climate Change (UNFCCC)*.

Gender equity

See *Equity*.

Glacier

A perennial mass of ice, and possibly firn and snow, originating on the *land* surface by the recrystallisation of snow and showing *evidence* of past or present flow. A glacier typically gains mass by accumulation of snow, and loses mass by melting and ice discharge into the sea or a lake if the glacier terminates in a body of water. Land ice masses of continental size (>50 000 km²) are referred to as *ice sheets*.

Global climate model (also referred to as general circulation model, both abbreviated as GCM)

See *Climate model*.

Global mean surface temperature (GMST)

Estimated global average of near-surface air temperatures over land and sea-ice, and *sea surface temperatures* over ice-free ocean regions, with changes normally expressed as departures from a value over a specified *reference period*. When estimating changes in GMST, near-surface air temperature over both land and oceans are also used.

See also *Global mean surface air temperature (GSAT)*, *Land surface air temperature*, and *Sea surface temperature (SST)*.

Global mean surface air temperature (GSAT)

Global average of near-surface air temperatures over land and oceans. Changes in GSAT are often used as a measure of global temperature change in *climate models* but are not observed directly.

See also *Global mean surface temperature (GMST)*, and *Land surface air temperature*.

Global warming

An increase in *global mean surface temperature (GMST)* averaged over a 30-year period, or the 30-year period centred on a particular year or decade, expressed relative to *pre-industrial* levels unless otherwise specified. For 30-year periods that span past and future years, the current multi-decadal warming trend is assumed to continue.

See also *Climate change*, and *Climate variability*.

Governance

A comprehensive and inclusive concept of the full range of means for deciding, managing, implementing and monitoring policies and measures. Whereas government is defined strictly in terms of the nation-state, the more inclusive concept of governance recognises the contributions of various levels of government (global, international, regional, sub-national and local) and the contributing roles of the private sector, of nongovernmental actors, and of civil society to addressing the many types of issues facing the global community, and the local context where the effectiveness of policies and measures are determined.

Adaptive governance

An emerging term in the literature for the evolution of formal and informal *institutions* of governance that prioritise planning, implementation and evaluation of policy through iterative *social learning*; in the context of *climate change*, governance facilitating social learning to steer the use and protection of natural resources, and *ecosystem services*, particularly in situations of complexity and *uncertainty*.

Climate governance

Purposeful mechanisms and measures aimed at steering social systems towards preventing, mitigating, or adapting to the risks posed by climate change (Jagers and Striiple, 2003).

Deliberative governance

Involves decision making through inclusive public conversation which allows opportunity for developing policy options through public discussion rather than collating individual preferences through voting or referenda (although the latter governance mechanisms can also be proceeded and legitimated by public deliberation processes).

Flexible governance

Strategies of governance at various levels, which prioritise the use of *social learning* and rapid feedback mechanisms in planning and policy making, often through incremental, experimental and iterative management processes.

Governance capacity

The ability of governance *institutions*, leaders, and non-state and civil society to plan, co-ordinate, fund, implement, evaluate and adjust policies and measures over the short, medium and long term, adjusting for *uncertainty*, rapid change and wide ranging impacts and multiple actors and demands.

Multi-level governance

Negotiated, non-hierarchical exchanges between *institutions* at the transnational, national, regional and local levels.

Participatory governance

A governance system that enables direct public engagement in decision-making using a variety of techniques for example, referenda, community deliberation, citizen juries or participatory budgeting. The approach can be applied in formal and informal *institutional* contexts from national to local, but is usually associated with devolved decision making (Fung and Wright, 2003; Sarmiento and Tilly, 2018).

Governance capacity

See *Governance*.

Grazing land

The sum of rangelands and *pastures* not considered as cropland, and subject to livestock grazing or hay production. It includes a wide range of *ecosystems*, e.g. systems with vegetation that fall below the threshold used in the *forest* land category, silvo-pastoral systems, as well as natural, managed grasslands and semideserts.

Green infrastructure

The interconnected set of natural and constructed ecological systems, green spaces and other landscape features. It includes planted and indigenous trees, wetlands, parks, green open spaces and original grassland and woodlands, as well as possible building and street level design interventions that incorporate vegetation. Green infrastructure provides services and functions in the same way as conventional infrastructure (Culwick and Bobbins, 2016).

Greenhouse gas (GHG)

Gaseous constituents of the *atmosphere*, both natural and *anthropogenic*, that absorb and emit radiation at specific wavelengths within the spectrum of terrestrial radiation emitted by the Earth's surface, the atmosphere itself, and by clouds. This property causes the greenhouse effect. Water vapour (H₂O), *carbon dioxide* (CO₂), *nitrous oxide* (N₂O), *methane* (CH₄) and *ozone* (O₃) are the primary GHGs in the Earth's atmosphere. Moreover, there are a number of entirely human-made GHGs in the atmosphere, such as the *halocarbons* and other chlorine- and bromine-containing substances, dealt with under the Montreal Protocol. Beside CO₂, N₂O and CH₄, the *Kyoto Protocol* deals with the GHGs sulphur hexafluoride (SF₆), hydrofluorocarbons (HFCs) and perfluorocarbons (PFCs).

Greenhouse gas removal (GGR)

Withdrawal of a *greenhouse gas* (GHG) and/or a *precursor* from the *atmosphere* by a *sink*.

See also *Carbon dioxide removal* (CDR), and *Negative emissions*.

Gross domestic product (GDP)

The sum of gross value added, at purchasers' prices, by all resident and non-resident producers in the economy, plus any taxes and minus any subsidies not included in the value of the products in a country or a geographic region for a given period, normally one year. GDP is calculated without deducting for depreciation of fabricated assets or depletion and degradation of natural resources.

Halocarbons

A collective term for the group of partially halogenated organic species, which includes the chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), halons, methyl chloride and methyl bromide. Many of the halocarbons have large Global Warming Potentials. The chlorine and bromine-containing halocarbons are also involved in the depletion of the ozone layer.

Hazard

The potential occurrence of a natural or human-induced physical event or trend that may cause loss of life, injury, or other health impacts, as well as damage and loss to property, infrastructure, *livelihoods*, service provision, *ecosystems* and environmental resources.

See also *Disaster*, *Exposure*, *Risk*, and *Vulnerability*.

Heatwave

A period of abnormally hot weather. Heatwaves and warm spells have various and in some cases overlapping definitions.

See also *Extreme weather event*.

Holocene

The current interglacial geological epoch, the second of two epochs within the Quaternary period, the preceding being the Pleistocene. The International Commission on Stratigraphy defines the start of the Holocene at 11,700 years before 2000 (ICS, 2019).

See also *Anthropocene*.

Human behaviour

The way in which a person acts in response to a particular situation or stimulus. Human actions are relevant at different levels, from international, national, and *sub-national actors*, to NGO, firm-level actors, and communities, households, and individual actions.

Adaptation behaviour

Human actions that directly or indirectly affect the risks of climate change *impacts*.

Mitigation behaviour

Human actions that directly or indirectly influence *mitigation*.

Human behavioural change

A transformation or modification of human actions. Behaviour change efforts can be planned in ways that mitigate *climate change* and/or reduce negative consequences of climate change *impacts*.

Human rights

Rights that are inherent to all human beings, universal, inalienable, and indivisible, typically expressed and guaranteed by law. They include the right to life, economic, social, and cultural rights, and the right to development and self-determination (based upon the definition by the UN Office of the High Commissioner).

Procedural rights

Rights to a legal procedure to enforce substantive rights.

Substantive rights

Basic human rights, including the right to the substance of being human such as life itself, liberty and happiness.

Human security

A condition that is met when the vital core of human lives is protected, and when people have the freedom and capacity to live with dignity. In the context of *climate change*, the vital core of human lives includes the universal and culturally specific, material and non-material elements necessary for people to act on behalf of their interests and to live with dignity.

Human system

Any system in which human organizations and *institutions* play a major role. Often, but not always, the term is synonymous with society or social system. Systems such as agricultural systems, urban systems, political systems, technological systems, and economic systems are all human systems in the sense applied in this report.

Hydrological cycle

The cycle in which water evaporates from the oceans and the land surface, is carried over the Earth in atmospheric circulation as water vapour, condenses to form clouds, precipitates as rain or snow, which on land can be intercepted by trees and vegetation, potentially accumulating as snow or ice, provides *runoff* on the land surface, infiltrates into soils, recharges groundwater, discharges into streams, and ultimately, flows out into the oceans as rivers, polar glaciers and *ice sheets*, from which it will eventually evaporate again. The various systems involved in the hydrological cycle are usually referred to as hydrological systems.

Ice sheet

An ice body originating on land that covers an area of continental size, generally defined as covering >50,000 km². An ice sheet flows outward from a high central ice plateau with a small average surface slope. The margins usually slope more steeply, and most ice is discharged through fast flowing ice streams or outlet *glaciers*, often into the sea or into ice shelves floating on the sea. There are only two ice sheets in the modern world, one on Greenland and one on Antarctica. The latter is divided into the East Antarctic Ice Sheet (EAIS), the West Antarctic Ice Sheet (WAIS) and the Antarctic Peninsula ice sheet. During glacial periods there were other ice sheets.

See also *Glacier*.

Impacts (consequences, outcomes)

The consequences of realised risks on natural and *human systems*, where risks result from the interactions of climate-related *hazards* (including *extreme weather and climate events*), *exposure*, and *vulnerability*. Impacts generally refer to effects on lives, *livelihoods*, health and *wellbeing*, *ecosystems* and species, economic, social and cultural assets, services (including *ecosystem services*), and infrastructure. Impacts may be referred to as consequences or outcomes, and can be adverse or beneficial.

See also *Adaptation, Exposure, Hazard, Loss and Damage, and loss and damages*, and *Vulnerability*.

(climate change) Impact assessment

The practice of identifying and evaluating, in monetary and/or non-monetary terms, the effects of climate change on natural and human systems.

Incremental adaptation

See *Adaptation*.

Indigenous knowledge

The understandings, skills and philosophies developed by societies with long histories of interaction with their natural surroundings. For many Indigenous peoples, Indigenous knowledge informs decision-making about fundamental aspects of life, from day-to-day activities to longer term actions. This knowledge is integral to cultural complexes, which also encompass language, systems of classification, resource use practices, social interactions, values, ritual and spirituality. These distinctive ways of knowing are important facets of the world's cultural diversity. (UNESCO, 2018)

See also *Local knowledge*.

Indirect land-use change

See *Land-use change*.

Industrial revolution

A period of rapid industrial growth with far-reaching social and economic consequences, beginning in Britain during the second half of the 18th century and spreading to Europe and later to other countries including the United States. The invention of the steam engine was an important trigger of this development. The industrial revolution marks the beginning of a strong increase in the use of *fossil fuels*, initially coal, and hence emission of *carbon dioxide (CO₂)*.

See also *Pre-industrial*.

Industrialised/developed/developing countries

There are a diversity of approaches for categorising countries on the basis of their level of economic development, and for defining terms such as industrialised, developed, or developing. Several categorisations are used in this report. (1) In the United Nations system, there is no established convention for designating of developed and developing countries or areas. (2) The United Nations Statistics Division specifies developed and developing regions based on common practice. In addition, specific countries are designated as Least Developed Countries (LDC), landlocked developing countries, *small island developing states*, and transition economies. Many countries appear in more than one of these categories. (3) The World Bank uses income as the main criterion for classifying countries as low, lower middle, upper middle, and high income. (4) The UNDP aggregates indicators for life expectancy, educational attainment, and income into a single composite Human Development Index (HDI) to classify countries as low, medium, high, or very high human development.

Inequality

See *Equality*.

Institution

Rules, norms and conventions held in common by social actors that guide, constrain and shape human interaction. Institutions can be formal, such as laws and policies, or informal, such as norms and conventions. Organizations - such as parliaments, regulatory agencies, private firms, and community bodies - develop and act in response to institutional frameworks and the incentives they frame. Institutions can guide, constrain and shape human interaction through direct control, through incentives, and through processes of socialisation.

See also *Institutional capacity*.

Institutional capacity

Building and strengthening individual organisations and providing technical and management training to support integrated planning and decision-making processes between organisations and people, as well as empowerment, social capital, and an enabling environment, including the culture, values and power relations (Willems and Baumert, 2003).

Integrated assessment

A method of analysis that combines results and models from the physical, biological, economic and social sciences and the interactions among these components in a consistent framework to evaluate the status and the consequences of environmental change and the policy responses to it.

See also *Integrated assessment model (IAM)*.

Integrated assessment model (IAM)

Models that integrate knowledge from two or more domains into a single framework. They are one of the main tools for undertaking *integrated assessments*.

One class of IAM used in respect of climate change *mitigation* may include representations of: multiple sectors of the economy, such as energy, *land use* and *land use change*; interactions between sectors; the economy as a whole; associated *greenhouse gas (GHG)* emissions and *sinks*; and reduced representations of the *climate system*. This class of model is used to assess linkages between economic, social and technological development and the evolution of the climate system.

Another class of IAM additionally includes representations of the costs associated with climate change *impacts*, but includes less detailed representations of economic systems. These can be used to assess impacts and mitigation in a *cost-benefit* framework and have been used to estimate the *social cost of carbon*.

Integrated response options

In this report, integrated response options are those options that simultaneously address more than one *land challenge*. These can be categorised into options that rely on a) *land management*, b) value chain management, and c) *risk management*. Integrated response options are not mutually exclusive.

See also *Land challenge*.

Integrated water resources management (IWRM)

A process which promotes the coordinated development and management of water, land and related resources in order to maximise economic and social welfare in an equitable manner without compromising the sustainability of vital *ecosystems*.

Inter-generational equity

See *Equity*.

Internal variability

See *Climate variability*.

Irreversibility

A perturbed state of a dynamical system is defined as irreversible on a given timescale if the recovery timescale from this state due to natural processes is substantially longer than the time it takes for the system to reach this perturbed state.

See also *Tipping point*.

Kyoto Protocol

The Kyoto Protocol to the *United Nations Framework Convention on Climate Change (UNFCCC)* is an international treaty adopted in December 1997 in Kyoto, Japan, at the Third Session of the *Conference of the Parties (COP3)* to the UNFCCC. It contains legally binding commitments, in addition to those included in the UNFCCC. Countries included in Annex B of the Protocol (mostly OECD countries and countries with economies in transition) agreed to reduce their anthropogenic greenhouse gas (GHG) emissions (*carbon dioxide (CO₂)*, *methane (CH₄)*, *nitrous oxide (N₂O)*, hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulphur hexafluoride (SF₆)) by at least 5% below 1990 levels in the first commitment period (2008-2012). The Kyoto Protocol entered into force on 16 February 2005 and as of May 2018 had 192 Parties (191 States and the European Union). A second commitment period was agreed in December 2012 at COP18, known as the Doha Amendment to the Kyoto Protocol, in which a new set of Parties committed to reduce GHG emissions by at least 18% below 1990 levels in the period from 2013 to 2020. However, as of May 2018, the Doha Amendment had not received sufficient ratifications to enter into force.

See also *Paris Agreement*.

Land

The terrestrial portion of the biosphere that comprises the natural resources (soil, near surface air, vegetation and other biota, and water), the ecological processes, topography, and human settlements and infrastructure that operate within that system (FAO, 2007; UNCCD, 1994).

Land challenges

In this report, land challenges refers to land-based *mitigation* and *adaptation*, *desertification*, *land degradation* and *food security*.

Land cover

The biophysical coverage of *land* (e.g., bare soil, rocks, forests, buildings and roads or lakes). Land cover is often categorised in broad land-cover classes (e.g., deciduous forest, coniferous forest, mixed forest, grassland, bare ground).

[Note: In some literature assessed in this report, land cover and *land use* are used interchangeably, but the two represent distinct classification systems. For example, the land cover class woodland can be under various land uses such as livestock grazing, recreation, conservation, or wood harvest.]

See also *Land-cover change*, and *Land-use change*.

Land cover change

Change from one *land cover* class to another, due to change in *land use* or change in natural conditions (Pongratz et al., 2018).

See also *Land-use change*, and *Land-management change*.

Land degradation

A negative trend in land condition, caused by direct or indirect human-induced processes including *anthropogenic* climate change, expressed as long-term reduction or loss of at least one of the following: biological productivity, ecological integrity or value to humans.

[Note: This definition applies to *forest* and non-forest land. Changes in land condition resulting solely from natural processes (such as volcanic eruptions) are not considered to be land degradation. Reduction of biological productivity or ecological integrity or value to humans *can* constitute degradation, but any one of these changes need not necessarily be considered degradation.]

Land degradation neutrality

A state whereby the amount and quality of land resources necessary to support *ecosystem* functions and services and enhance *food security* remain stable or increase within specified temporal and spatial scales and ecosystems (UNCCD, 2019).

Land management

Sum of *land-use* practices (e.g., sowing, fertilizing, weeding, harvesting, thinning, clear-cutting) that take place within broader land-use categories. (Pongratz et al., 2018)

Land management change

A change in land management that occurs within a *land-use* category.

See also *Land-use change*.

Land potential

The inherent, long-term potential of the *land* to sustainably generate *ecosystem services*, which reflects the capacity and *resilience* of the land-based natural capital, in the face of ongoing environmental change (UNEP, 2016).

Land rehabilitation

Direct or indirect actions undertaken with the aim of reinstating a level of *ecosystem* functionality, where the goal is provision of goods and services rather than ecological restoration (McDonald, et al., 2016).

Land restoration

The process of assisting the recovery of *land* from a degraded state (McDonald et al., 2016; IPBES, 2018).

Land surface air temperature (LSAT)

The near-surface air temperature over land, typically measured at 1.25-2 m above the ground using standard meteorological equipment.

Land use

The total of arrangements, activities and inputs applied to a parcel of *land*. The term land use is also used in the sense of the social and economic purposes for which land is managed (e.g., grazing, timber extraction, conservation and city dwelling). In national GHG inventories, land use is classified according to the IPCC land use categories of *forest* land, cropland, grassland, *wetlands*, settlements, other lands (see the 2006 IPCC Guidelines for National GHG Inventories for details).

See also *Land-use change* and *Land management*.

Land-use change (LUC)

The change from one *land use* category to another.

[Note: In some of the scientific literature assessed in this report, land-use change encompasses changes in land-use categories as well as changes in *land management*.]

Indirect land-use change (iLUC)

Land use change outside the area of focus, that occurs as a consequence of change in use or management of land within the area of focus, such as through market or policy drivers. For example, if agricultural land is diverted to *biofuel* production, *forest* clearance may occur elsewhere to replace the former agricultural production.

See also *Afforestation, Agriculture, Forestry and Other Land Use (AFOLU), Deforestation, Land use, land-use change and forestry (LULUCF), Reforestation, the IPCC Special Report on Land Use, Land-Use Change, and Forestry (IPCC, 2000,)*, and the *2006 IPCC Guidelines for National GHG Inventories (IPCC, 2006)*.

Land use, land-use change and forestry (LULUCF)

In the context of national *greenhouse gas (GHG)* inventories under the *United Nations Framework Convention on Climate Change (UNFCCC, 2019)*, LULUCF is a GHG inventory sector that covers *anthropogenic* emissions and removals of GHG in managed lands, excluding non-CO₂ agricultural emissions. Following the 2006 IPCC Guidelines for National GHG Inventories, ‘anthropogenic’ land-related GHG fluxes are defined as all those occurring on ‘managed land’, i.e., ‘where human interventions and practices have been applied to perform production, ecological or social functions’. Since managed land may include *carbon dioxide (CO₂)* removals not considered as ‘anthropogenic’ in some of the scientific literature assessed in this report (e.g., removals associated with CO₂ fertilisation and N deposition), the land-related net GHG emission estimates from global models included in this report are not necessarily directly comparable with LULUCF estimates in National GHG Inventories.

See also *Land use change (LUC)*.

Latent heat flux

The turbulent flux of heat from the Earth's surface to the atmosphere that is associated with *evaporation* or condensation of water vapour at the surface; a component of the surface energy budget.

See also *Atmosphere*, and *Flux*.

Leakage

The effects of policies that result in a displacement of the environmental impact, thereby counteracting the intended effects of the initial policies.

Lifecycle assessment (LCA)

Compilation and evaluation of the inputs, outputs and the potential environmental impacts of a product or service throughout its life cycle (ISO, 2018).

Likelihood

The chance of a specific outcome occurring, where this might be estimated probabilistically. Likelihood is expressed in this report using a standard terminology (Mastrandrea et al., 2010).

See also *Agreement, Evidence, Confidence, and Uncertainty*.

Livelihood

The resources used and the activities undertaken in order to live. Livelihoods are usually determined by the entitlements and assets to which people have access. Such assets can be categorised as human, social, natural, physical, or financial.

Local knowledge

The understandings and skills developed by individuals and populations, specific to the places where they live. Local knowledge informs decision-making about fundamental aspects of life, from day-to-day activities to longer term actions. This knowledge is a key element of the social and cultural systems which influence observations of, and responses to *climate change*; it also informs *governance* decisions (UNESCO, 2018).

See also *Indigenous knowledge*.

Lock-in

A situation in which the future development of a system, including infrastructure, technologies, investments, *institutions*, and behavioural norms, is determined or constrained ('locked in') by historic developments.

Long-lived climate forcers (LLCF)

A set of well-mixed *greenhouse gases* with long atmospheric lifetimes. This set of compounds includes *carbon dioxide (CO₂)* and *nitrous oxide (N₂O)*, together with some fluorinated gases. They have a warming effect on *climate*. These compounds accumulate in the atmosphere at decadal to centennial timescales, and their effect on climate hence persists for decades to centuries after their emission. On timescales of decades to a century already emitted emissions of long-lived climate forcers can only be abated by *greenhouse gas removal (GGR)*.

See also *Short-lived climate forcers (SLCF)*.

Loss and Damage, and losses and damages

Research has taken Loss and Damage (capitalised letters) to refer to political debate under the *United Nations Framework Convention on Climate Change (UNFCCC)* following the establishment of the Warsaw Mechanism on Loss and Damage in 2013, which is to 'address loss and damage associated with impacts of climate change, including extreme events and slow onset events, in developing

countries that are particularly vulnerable to the adverse effects of climate change.’ Lowercase letters (losses and damages) have been taken to refer broadly to harm from (observed) *impacts* and (projected) *risks* (Mechler et al., 2018).

Maladaptive actions (Maladaptation)

Actions that may lead to increased *risk* of adverse climate-related outcomes, including via increased *greenhouse gas (GHG)* emissions, increased *vulnerability to climate change*, or diminished welfare, now or in the future. Maladaptation is usually an unintended consequence.

Malnutrition

Deficiencies, excesses, or imbalances in a person’s intake of energy and/or nutrients. The term malnutrition addresses three broad groups of conditions: undernutrition, which includes wasting (low weight-for-height), stunting (low height-for-age) and underweight (low weight-for-age); micronutrient-related malnutrition, which includes micronutrient deficiencies (a lack of important vitamins and minerals) or micronutrient excess; and overweight, obesity and diet-related noncommunicable diseases (such as heart disease, stroke, diabetes and some cancers) (WHO, 2018).

Micronutrient deficiencies are sometimes termed ‘hidden hunger’ to emphasise that people can be malnourished in the sense of deficient without being deficient in calories. Hidden hunger can apply even where people are obese.

Managed forest

Forests subject to human interventions (notably silvicultural management such as planting, pruning, thinning), timber and fuelwood harvest, protection (fire suppression, insect suppression) and management for amenity values or conservation, with defined geographical boundaries (Ogle et al., 2018).

[Note: For a discussion of the term ‘forest’ in the context of National GHG inventories, see the 2006 IPCC Guidelines for National GHG Inventories.]

See also *Managed land*.

Managed grassland

Grasslands on which human interventions are carried out, such as grazing domestic livestock or hay removal.

Managed land

In the context of national *greenhouse gas (GHG)* inventories under the *United Nations Framework Convention on Climate Change (UNFCCC)*, the 2006 IPCC Guidelines for National GHG Inventories (IPCC, 2006) defines managed land ‘where human interventions and practices have been applied to perform production, ecological or social functions’. The IPCC (2006) defines *anthropogenic* GHG emissions and removals in the *LULUCF* sector as all those occurring on ‘managed land’. The key rationale for this approach is that the preponderance of anthropogenic effects occurs on managed lands.

[Note: More details can be found in IPCC 2006 Guidelines for National GHG Inventories, Volume 4, Chapter 1.]

Market failure

When private decisions are based on market prices that do not reflect the real scarcity of goods and services but rather reflect market distortions, they do not generate an efficient allocation of resources but cause welfare losses. A market distortion is any event in which a market reaches a market clearing price that is substantially different from the price that a market would achieve while operating under conditions of perfect competition and state enforcement of legal contracts and the ownership of private property. Examples of factors causing market prices to deviate from real economic scarcity are environmental externalities, public goods, monopoly power, information asymmetry, transaction costs, and non-rational behaviour.

Measurement, reporting and verification (MRV)

Measurement

‘The process of data collection over time, providing basic datasets, including associated accuracy and precision, for the range of relevant variables. Possible data sources are field measurements, field observations, detection through remote sensing and interviews’ (UN REDD, 2009).

Reporting

‘The process of formal reporting of assessment results to the UNFCCC, according to predetermined formats and according to established standards, especially the Intergovernmental Panel on Climate Change (IPCC) Guidelines and GPG (Good Practice Guidance)’ (UN REDD, 2009).

Verification

‘The process of formal verification of reports, for example, the established approach to verify national communications and national inventory reports to the UNFCCC’ (UN REDD, 2009).

Megadrought

See *Drought*.

Methane (CH₄)

One of the six *greenhouse gases (GHGs)* to be mitigated under the *Kyoto Protocol*. Methane is the major component of natural gas and associated with all hydrocarbon fuels. Significant *anthropogenic* emissions also occur as a result of animal husbandry and paddy rice production. Methane is also produced naturally where organic matter decays under anaerobic conditions, such as in *wetlands*.

Migrant

See *Migration*.

Migration

‘The movement of a person or a group of persons, either across an international border, or within a State. It is a population movement, encompassing any kind of movement of people, whatever its length, composition and causes; it includes migration of refugees, displaced persons, economic migrants, and persons moving for other purposes, including family reunification’ (IOM, 2018).

Migrant

‘Any person who is moving or has moved across an international border or within a State away from his/her habitual place of residence, regardless of (1) the person’s legal status; (2) whether the movement is voluntary or involuntary; (3) what the causes for the movement are; or (4) what the length of the stay is’ (IOM, 2018).

See also *(Internal) Displacement*.

Millennium Development Goals (MDGs)

A set of eight time-bound and measurable goals for combating *poverty*, hunger, disease, illiteracy, discrimination against women and environmental degradation. These goals were agreed at the UN Millennium Summit in 2000 together with an action plan to reach the goals by 2015.

Mitigation (of climate change)

A human intervention to reduce emissions or enhance the *sinks* of *greenhouse gases*.

Mitigation behaviour

See *Human behaviour*.

Mitigation measures

In climate policy, *mitigation* measures are technologies, processes or practices that contribute to mitigation, for example renewable energy technologies, waste minimization processes, public transport commuting practices.

Mitigation option

A technology or practice that reduces *greenhouse gas (GHG)* emissions or enhances *sinks*.

Mitigation pathways

See *Pathways*.

Mitigation scenario

A plausible description of the future that describes how the (studied) system responds to the implementation of *mitigation* policies and measures.

See also *Emission scenario*, *Pathways*, *Socio-economic scenarios*, and *Stabilisation (of GHG or CO₂-equivalent concentration)*.

Monitoring and evaluation (M&E)

Mechanisms put in place at national to local scales to respectively monitor and evaluate efforts to reduce *greenhouse gas* emissions and/or adapt to the *impacts* of *climate change* with the aim of systematically identifying, characterizing and assessing progress over time.

Motivation (of an individual)

An individual's reason or reasons for acting in a particular way; individuals may consider various consequences of actions, including financial, social, affective, and environmental consequences. Motivation can arise from factors external or internal to the individual.

Multi-level governance

See *Governance*.

Narratives (in the context of scenarios)

Qualitative descriptions of plausible future world evolutions, describing the characteristics, general logic and developments underlying a particular quantitative set of *scenarios*. Narratives are also referred to in the literature as ‘storylines’.

See also *Scenario*, *Scenario storyline*, and *Pathways*.

Nationally Determined Contributions (NDCs)

A term used under the *United Nations Framework Convention on Climate Change (UNFCCC)* whereby a country that has joined the *Paris Agreement* outlines its plans for reducing its emissions. Some countries NDCs also address how they will adapt to climate change impacts, and what support they need from, or will provide to, other countries to adopt low-carbon pathways and to build climate resilience. According to Article 4 paragraph 2 of the *Paris Agreement*, each Party shall prepare, communicate and maintain successive NDCs that it intends to achieve. In the lead up to 21st *Conference of the Parties* in Paris in 2015, countries submitted Intended Nationally Determined Contributions (INDCs). As countries join the Paris Agreement, unless they decide otherwise, this INDC becomes their first Nationally Determined Contribution (NDC).

Negative emissions

Removal of *greenhouse gases (GHGs)* from the *atmosphere* by deliberate human activities, i.e., in addition to the removal that would occur via natural *carbon cycle* processes.

See also *Net negative emissions*, *Net-zero emissions*, *Carbon dioxide removal (CDR)*, and *Greenhouse gas removal (GGR)*.

Negative emissions technologies

An activity or mechanism that results in *negative emissions*.

Net negative emissions

A situation of net negative emissions is achieved when, as result of human activities, more *greenhouse gases (GHG)* are removed from the *atmosphere* than are emitted into it. Where multiple greenhouse gases are involved, the quantification of *negative emissions* depends on the climate metric chosen to compare emissions of different gases (such as global warming potential, global temperature change potential, and others, as well as the chosen time horizon).

See also *Negative emissions*, *Net-zero emissions* and *Net-zero CO₂ emissions*.

Net-zero CO₂ emissions

Conditions in which any remaining *anthropogenic* carbon dioxide (CO₂) emissions are balanced by anthropogenic CO₂ removals over a specified period.

See also *Net-zero emissions*, and *Net negative emissions*.

Net-zero emissions

Net-zero emissions are achieved when emissions of *greenhouse gases (GHGs)* to the *atmosphere* are balanced by *anthropogenic removals*. Where multiple greenhouse gases are involved, the quantification of net-zero emissions depends on the climate metric chosen to compare emissions of different gases (such as global warming potential, global temperature change potential, and others, as well as the chosen time horizon).

See also *Net-zero CO₂ emissions*, *Negative emissions*, and *Net negative emission*.

Nitrous oxide (N₂O)

One of the six *greenhouse gases (GHGs)* to be mitigated under the *Kyoto Protocol*. The main *anthropogenic* source of N₂O is agriculture (soil and animal manure management), but important contributions also come from sewage treatment, *fossil fuel* combustion, and chemical industrial processes. N₂O is also produced naturally from a wide variety of biological sources in soil and water, particularly microbial action in wet tropical *forests*.

Non-overshoot pathways

See *Pathways*.

Nutrition transition

A predictable change in *dietary patterns* associated with a country's economic development whereby 'problems of under- and overnutrition often coexist, reflecting the trends in which an increasing proportion of people consume the types of diets associated with a number of chronic diseases' (Popkin, 1994).

Ocean acidification (OA)

A reduction in the *pH* of the ocean, accompanied by other chemical changes, over an extended period, typically decades or longer, which is caused primarily by uptake of *carbon dioxide (CO₂)* from the *atmosphere*, but can also be caused by other chemical additions or subtractions from the ocean. *Anthropogenic* ocean acidification refers to the component of pH reduction that is caused by human activity (IPCC, 2011, p. 37).

See also *Climate change*.

Ocean fertilisation

Deliberate increase of nutrient supply to the near-surface ocean in order to enhance biological production through which additional *carbon dioxide (CO₂)* from the *atmosphere* is sequestered. This can be achieved by the addition of micro-nutrients or macro-nutrients. Ocean fertilisation is regulated by the London Protocol.

Overshoot

See *Temperature overshoot*.

Overshoot pathways

See *Pathways*.

Ozone (O₃)

The triatomic form of oxygen (O₃). In the *troposphere*, it is created both naturally and by photochemical reactions involving gases resulting from human activities (smog). Tropospheric ozone acts as a *greenhouse gas (GHG)*. In the *stratosphere*, it is created by the interaction between solar ultraviolet radiation and molecular oxygen (O₂). Stratospheric ozone plays a dominant role in the stratospheric radiative balance. Its concentration is highest in the ozone layer.

Paris Agreement

The Paris Agreement under the *United Nations Framework Convention on Climate Change (UNFCCC)* was adopted on December 2015 in Paris, France, at the 21st session of the *Conference of the Parties (COP)* to the UNFCCC. The agreement, adopted by 196 Parties to the UNFCCC, entered into force on 4 November 2016 and as of May 2018 had 195 Signatories and was ratified by 177 Parties. One of the goals of the Paris Agreement is ‘Holding the increase in the global average temperature to well below 2°C above pre-industrial levels and pursuing efforts to limit the temperature increase to 1.5°C above pre-industrial levels’, recognising that this would significantly reduce the risks and impacts of climate change. Additionally, the Agreement aims to strengthen the ability of countries to deal with the impacts of climate change. The Paris Agreement is intended to become fully effective in 2020.

See also *Kyoto Protocol*, and *Nationally Determined Contributions (NDCs)*.

Participatory governance

See *Governance*.

Pasture

Area covered with grass or other plants used or suitable for grazing of livestock; grassland.

Pathways

The temporal evolution of natural and/or *human systems* towards a future state. Pathway concepts range from sets of quantitative and qualitative *scenarios* or *narratives* of potential futures to solution-oriented decision-making processes to achieve desirable societal goals. Pathway approaches typically focus on biophysical, techno-economic, and/or socio-behavioural trajectories and involve various dynamics, goals, and actors across different scales.

1.5°C pathway

A pathway of emissions of *greenhouse gases* and other climate forcers that provides an approximately one-in-two to two-in-three chance, given current knowledge of the climate response, of *global warming* either remaining below 1.5°C or returning to 1.5°C by around 2100 following an overshoot. See also *Temperature overshoot*.

Adaptation pathways

A series of *adaptation* choices involving trade-offs between short-term and long-term goals and values. These are processes of deliberation to identify solutions that are meaningful to people in the context of their daily lives and to avoid potential maladaptation.

Development pathways

Development pathways are trajectories based on an array of social, economic, cultural, technological, *institutional*, and biophysical features that characterise the interactions between human and natural systems and outline visions for the future, at a particular scale.

Mitigation pathways

A mitigation pathway is a temporal evolution of a set of *mitigation scenario* features, such as *greenhouse gas (GHG)* emissions and socio-economic development.

Overshoot pathways

Pathways that exceed the stabilization level (concentration, *forcing*, or temperature) before the end of a time horizon of interest (e.g., before 2100) and then decline towards that level by that time. Once the target level is exceeded, removal by *sinks* of *greenhouse gases (GHGs)* is required.

See also *Temperature overshoot*.

Non-overshoot pathways

Pathways that stay below the stabilization level (concentration, *forcing*, or temperature) during the time horizon of interest (e.g., until 2100).

Representative Concentration Pathways (RCPs)

Scenarios that include time series of emissions and concentrations of the full suite of *greenhouse gases (GHGs)* and *aerosols* and chemically active gases, as well as *land use/land cover* (Moss et al., 2008). The word representative signifies that each RCP provides only one of many possible scenarios that would lead to the specific *radiative forcing* characteristics. The term pathway emphasises the fact that not only the long-term concentration levels, but also the trajectory taken over time to reach that outcome are of interest (Moss et al., 2010). RCPs were used to develop *climate projections* in CMIP5.

- RCP2.6: One pathway where radiative forcing peaks at approximately 3 W m^{-2} and then declines to be limited at 2.6 W m^{-2} in 2100 (the corresponding Extended Concentration Pathway, or ECP, has constant emissions after 2100).
- RCP4.5 and RCP6.0: Two intermediate stabilisation pathways in which radiative forcing is limited at approximately 4.5 W m^{-2} and 6.0 W m^{-2} in 2100 (the corresponding ECPs have constant concentrations after 2150).
- RCP8.5: One high pathway which leads to $>8.5 \text{ W m}^{-2}$ in 2100 (the corresponding ECP has constant emissions after 2100 until 2150 and constant concentrations after 2250).

See also *Coupled Model Intercomparison Project (CMIP)*, and *Shared Socio-economic Pathways (SSPs)*.

Shared Socio-economic Pathways (SSPs)

Shared Socio-economic Pathways (SSPs) were developed to complement the Representative Concentration Pathways (RCPs) with varying socio-economic challenges to *adaptation* and *mitigation* (O'Neill et al., 2014). Based on five *narratives*, the SSPs describe alternative socio-economic futures in the absence of climate policy intervention, comprising sustainable development (SSP1), regional rivalry (SSP3), inequality (SSP4), fossil-fueled development (SSP5), and a middle-of-the-road development (SSP2) (O'Neill et al., 2017; Riahi et al., 2017). The combination of SSP-based socio-economic scenarios and RCP-based *climate projections* provides an integrative frame for climate *impact* and policy analysis.

Transformation pathways

Trajectories describing consistent sets of possible futures of *greenhouse gas (GHG)* emissions, atmospheric concentrations, or *global mean surface temperatures* implied from *mitigation* and *adaptation* actions associated with a set of broad and irreversible economic, technological, societal, and behavioural changes. This can encompass changes in the way energy and infrastructure are used and produced, natural resources are managed and *institutions* are set up and in the pace and direction of technological change (TC).

See also *Scenario*, *Scenario storyline*, *Emission scenario*, *Mitigation scenario*, *Baseline scenario*, *Stabilisation (of GHG or CO₂-equivalent concentration)*, and *Narratives*.

Peat

Soft, porous or compressed, sedentary deposit of which a substantial portion is partly decomposed plant material with high water content in the natural state (up to about 90 percent) (IPCC, 2013).

See also *Peatlands*.

Peatlands

Peatland is a land where soils are dominated by *peat*.

See also *Reservoir*, and *Sink*.

Peri-urban areas

Parts of a city that appear to be quite rural but are in reality strongly linked functionally to the city in its daily activities.

Permafrost

Ground (soil or rock and included ice and organic material) that remains at or below 0°C for at least two consecutive years.

pH

A dimensionless measure of the acidity of a solution given by its concentration of hydrogen ions ($[H^+]$). pH is measured on a logarithmic scale where $pH = -\log_{10}[H^+]$. Thus, a pH decrease of 1 unit corresponds to a 10-fold increase in the concentration of H^+ , or acidity.

See also *Ocean acidification*.

Phenology

The relationship between biological phenomena that recur periodically (e.g., development stages, migration) and *climate* and seasonal changes.

Planetary health

The Rockefeller-Lancet Commission defines planetary health as ‘the achievement of the highest attainable standard of health, wellbeing, and equity worldwide through judicious attention to the human systems — political, economic, and social — that shape the future of humanity *and* the Earth’s natural systems that define the safe environmental limits within which humanity can flourish. Put simply, planetary health is the health of human civilisation and the state of the natural systems on which it depends’ (Whitmee et al., 2015).

Political economy

The set of interlinked relationships between people, the state, society and markets as defined by law, politics, economics, customs and power that determine the outcome of trade and transactions and the distribution of wealth in a country or economy.

Poverty

A complex concept with several definitions stemming from different schools of thought. It can refer to material circumstances (such as need, pattern of deprivation or limited resources), economic conditions (such as standard of living, *inequality* or economic position) and/or social relationships (such as social class, dependency, exclusion, lack of basic security or lack of entitlement).

See also *Poverty eradication*.

Poverty eradication

A set of measures to end *poverty* in all its forms everywhere.

See also *Sustainable Development Goals (SDGs)*.

Pool, carbon and nitrogen

A *reservoir* in the earth system where elements, such as carbon and nitrogen, reside in various chemical forms for a period of time.

Precursors

Atmospheric compounds that are not *greenhouse gases* (GHGs) or *aerosols*, but that have an effect on GHG or aerosol concentrations by taking part in physical or chemical processes regulating their production or destruction rates.

See also *Aerosol*, and *Greenhouse gas (GHG)*.

Pre-industrial

The multi-century period prior to the onset of large-scale industrial activity around 1750. The *reference period* 1850-1900 is used to approximate pre-industrial *global mean surface temperature (GMST)*.

See also *Industrial revolution*.

Primary production

The synthesis of organic compounds by plants and microbes, on land or in the ocean, primarily by photosynthesis using light and *carbon dioxide (CO₂)* as sources of energy and carbon respectively. It can also occur through chemosynthesis, using chemical energy, e.g., in deep sea vents.

Gross Primary Production (GPP)

The total amount of carbon fixed by photosynthesis over a specific time period.

Net primary production (NPP)

The amount of carbon fixed by photosynthesis minus the amount lost by respiration over a specified time period.

Procedural equity

See *Equity*.

Procedural rights

See *Human rights*.

Projection

A potential future evolution of a quantity or set of quantities, often computed with the aid of a model. Unlike predictions, projections are conditional on assumptions concerning, for example, future socio-economic and technological developments that may or may not be realised.

See also *Climate projection*, *Scenario*, and *Pathways*.

Radiative forcing

The change in the net, downward minus upward, radiative flux (expressed in W m^{-2}) at the tropopause or top of *atmosphere* due to a change in an driver of *climate change*, such as a change in the concentration of *carbon dioxide (CO₂)*, the concentration of volcanic aerosols or the output of the

Sun. The traditional radiative forcing is computed with all tropospheric properties held fixed at their unperturbed values, and after allowing for stratospheric temperatures, if perturbed, to readjust to radiative-dynamical equilibrium. Radiative forcing is called instantaneous if no change in stratospheric temperature is accounted for. The radiative forcing once rapid adjustments are accounted for is termed the effective radiative forcing. Radiative forcing is not to be confused with cloud radiative forcing, which describes an unrelated measure of the impact of clouds on the radiative flux at the top of the atmosphere.

Reasons for concern (RFCs)

Elements of a classification framework, first developed in the IPCC Third Assessment Report, which aims to facilitate judgments about what level of *climate change* may be dangerous (in the language of Article 2 of the *UNFCCC*) by aggregating risks from various sectors, considering hazards, exposures, vulnerabilities, capacities to adapt, and the resulting impacts.

Reducing Emissions from Deforestation and Forest Degradation (REDD+)

REDD+ refers to reducing emissions from *deforestation*; reducing emissions from forest degradation; conservation of forest carbon stocks; sustainable management of forests; and enhancement of forest carbon stocks (see UNFCCC decision 1/CP.16, para. 70).

Reference period

The period relative to which *anomalies* are computed.

See also *Anomalies*.

Reference scenario

See *Baseline scenario*.

Reforestation

Conversion to *forest of land* that has previously contained forests but that has been converted to some other use.

[Note: For a discussion of the term forest and related terms such as *afforestation*, *reforestation* and *deforestation* in the context of reporting and accounting Article 3.3 and 3.4 activities under the *Kyoto Protocol*, see 2013 Revised Supplementary Methods and Good Practice Guidance Arising from the Kyoto Protocol.]

See also *Afforestation*, *Deforestation*, and *Reducing Emissions from Deforestation and Forest Degradation (REDD+)*.

Region

A relatively large-scale land or ocean area characterised by specific geographical and climatological features. The *climate* of a land-based region is affected by regional and local scale features like topography, *land use* characteristics and large water bodies, as well as remote influences from other regions, in addition to global climate conditions. The IPCC defines a set of standard regions for analyses of observed climate trends and climate model projections (see Fig. 3.2; AR5, SREX).

Remaining carbon budget

Cumulative global *carbon dioxide* (CO_2) emissions from the start of 2018 to the time that CO_2 emissions reach net-zero that would result, at some probability, in limiting *global warming* to a given level, accounting for the impact of other *anthropogenic emissions*.

See also *Carbon budget*.

Representative concentration pathways (RCPs)

See *Pathways*

Reservoir

A component or components of the climate system where a *greenhouse gas* (*GHG*) or a *precursor* of a greenhouse gas is stored (UNFCCC Article 1.7).

Resilience

The capacity of interconnected social, economic and ecological systems to cope with a hazardous event, trend or disturbance, responding or reorganizing in ways that maintain their essential function, identity and structure. Resilience is a positive attribute when it maintains capacity for *adaptation*, learning and/or *transformation* (adapted from the Arctic Council, 2013).

See also *Hazard*, *Risk*, and *Vulnerability*.

Respiration

The process whereby living organisms convert organic matter to *carbon dioxide* (CO_2), releasing energy and consuming molecular oxygen.

Rewetting

‘The deliberate action of changing a drained soil into a wet soil, e.g. by blocking *drainage* ditches, disabling pumping facilities or breaching obstructions’ (IPCC, 2013).

See also *Drainage*.

Risk

The potential for adverse consequences for human or ecological systems, recognizing the diversity of values and objectives associated with such systems. In the context of *climate change*, risks can arise from potential *impacts* of climate change as well as human responses to climate change. Relevant adverse consequences include those on lives, *livelihoods*, health and *wellbeing*, economic, social and cultural assets and investments, infrastructure, services (including *ecosystem services*), *ecosystems* and species.

In the context of climate change impacts, risks result from dynamic interactions between climate-related *hazards* with the *exposure* and *vulnerability* of the affected human or ecological system to the hazards. Hazards, exposure and vulnerability may each be subject to *uncertainty* in terms of magnitude and likelihood of occurrence, and each may change over time and space due to socio-economic changes and human decision-making (see also *risk management*, *adaptation*, and *mitigation*).

In the context of climate change responses, risks result from the potential for such responses not achieving the intended objective(s), or from potential trade-offs with, or negative side-effects on, other societal objectives, such as the *Sustainable Development Goals* (see also *risk trade-off*). Risks

can arise for example from uncertainty in implementation, effectiveness or outcomes of climate policy, climate-related investments, technology development or adoption, and system *transitions*.

Risk assessment

The qualitative and/or quantitative scientific estimation of *risks*.

See also *Risk management*, and *Risk perception*.

Risk management

Plans, actions, strategies or policies to reduce the *likelihood* and/or magnitude of adverse potential consequences, based on assessed or perceived *risks*.

See also *Risk assessment*, and *Risk perception*.

Risk perception

The subjective judgment that people make about the characteristics and severity of a *risk*.

See also *Risk assessment*, and *Risk management*.

Risk trade-off

The change in portfolio of *risks* that occurs when a countervailing risk is generated (knowingly or inadvertently) by an intervention to reduce the target risk (Wiener and Graham, 2009).

See also *Adverse side-effect*, and *Co-benefits*.

Runoff

The flow of water over the surface or through the subsurface, which typically originates from the part of liquid precipitation and/or snow/ice melt that does not evaporate or refreeze, and is not transpired.

See also *Hydrological cycle*.

Saline soils

Soils with levels of soluble salts (commonly sulphates and chlorides of calcium and magnesium) in the saturation extract high enough to negatively affect plant growth. Saline soils are usually flocculated and have good water permeability (Well and Brady, 2016).

See also *Soil salinity* and *Sodic soils*.

Scenario

A plausible description of how the future may develop based on a coherent and internally consistent set of assumptions about key driving forces (e.g., rate of technological change (TC), prices) and relationships. Note that scenarios are neither predictions nor forecasts, but are used to provide a view of the implications of developments and actions.

See also *Baseline scenario*, *Emission scenario*, *Mitigation scenario* and *Pathways*.

Scenario storyline

A *narrative* description of a *scenario* (or family of scenarios), highlighting the main scenario characteristics, relationships between key driving forces and the dynamics of their evolution. Also referred to as ‘narratives’ in the scenario literature.

Sea ice

Ice found at the sea surface that has originated from the freezing of seawater. Sea ice may be discontinuous pieces (ice floes) moved on the ocean surface by wind and currents (pack ice), or a motionless sheet attached to the coast (land-fast ice). Sea ice concentration is the fraction of the ocean covered by ice. Sea ice less than one year old is called first-year ice. Perennial ice is sea ice that survives at least one summer. It may be subdivided into second-year ice and multi-year ice, where multiyear ice has survived at least two summers.

Sea level change (sea level rise/sea level fall)

Change to the height of sea level, both globally and locally (relative sea level change) due to (1) a change in ocean volume as a result of a change in the mass of water in the ocean, (2) changes in ocean volume as a result of changes in ocean water density, (3) changes in the shape of the ocean basins and changes in the Earth’s gravitational and rotational fields, and (4) local subsidence or uplift of the land. Global mean sea level change resulting from change in the mass of the ocean is called barystatic. The amount of barystatic sea level change due to the addition or removal of a mass of water is called its sea level equivalent (SLE). Sea level changes, both globally and locally, resulting from changes in water density are called steric. Density changes induced by temperature changes only are called thermosteric, while density changes induced by salinity changes are called halosteric. Barystatic and steric sea level changes do not include the effect of changes in the shape of ocean basins induced by the change in the ocean mass and its distribution.

Sea surface temperature (SST)

The subsurface bulk temperature in the top few meters of the ocean, measured by ships, buoys, and drifters. From ships, measurements of water samples in buckets were mostly switched in the 1940s to samples from engine intake water. Satellite measurements of skin temperature (uppermost layer; a fraction of a millimetre thick) in the infrared or the top centimetre or so in the microwave are also used, but must be adjusted to be compatible with the bulk temperature.

Sendai Framework for Disaster Risk Reduction

The Sendai Framework for Disaster Risk Reduction 2015-2030 outlines seven clear targets and four priorities for action to prevent new, and to reduce existing disaster risks. The voluntary, non-binding agreement recognises that the State has the primary role to reduce disaster risk but that responsibility should be shared with other stakeholders including local government, the private sector and other stakeholders, with the aim for the substantial reduction of disaster risk and losses in lives, *livelihoods* and health and in the economic, physical, social, cultural and environmental assets of persons, businesses, communities and countries.

Sequestration

See *Uptake* and *Carbon sequestration*.

Shared socio-economic pathways (SSPs)

See *Pathways*.

Short-lived climate forcers (SLCF)

A set of compounds that are primarily composed of those with short lifetimes in the atmosphere compared to well-mixed *greenhouse gases (GHGs)*, and are also referred to as near-term climate forcers. This set of compounds includes *methane (CH₄)*, which is also a well-mixed greenhouse gas, as well as *ozone (O₃)* and *aerosols*, or their *precursors*, and some halogenated species that are not well-mixed greenhouse gases. These compounds do not accumulate in the atmosphere at decadal to centennial timescales, and so their effect on *climate* is predominantly in the first decade after their emission, although their changes can still induce long-term climate effects such as *sea level change*. Their effect can be cooling or warming. A subset of exclusively warming short-lived climate forcers is referred to as short-lived climate pollutants.

See also *Long-lived climate forcers (LLCF)*.

Short-lived climate pollutants (SLCP)

See *Short-lived climate forcers (SLCF)*.

Sink

Any process, activity or mechanism which removes a *greenhouse gas*, an *aerosol* or a *precursor* of a *greenhouse gas* from the *atmosphere* (UNFCCC Article 1.8).

See also *Sequestration*, *Source*, and *Uptake*.

Small Island Developing States (SIDS)

Small Island Developing States (SIDS), as recognised by the United Nations OHRLLS (Office of the High Representative for the Least Developed Countries, Landlocked Developing Countries and Small Island Developing States), are a distinct group of developing countries facing specific social, economic and environmental vulnerabilities (UN-OHRLLS, 2011). They were recognised as a special case both for their environment and development at the Rio Earth Summit in Brazil in 1992. Fifty eight countries and territories are presently classified as SIDS by the UN OHRLLS, with 38 being UN member states and 20 being Non-UN Members or Associate Members of the Regional Commissions (UN-OHRLLS, 2018).

Social costs

The full costs of an action in terms of social welfare losses, including external costs associated with the impacts of this action on the environment, the economy (GDP, employment) and on the society as a whole.

Social cost of carbon (SCC)

The net present value of aggregate climate damages (with overall harmful damages expressed as a number with positive sign) from one more tonne of carbon in the form of *carbon dioxide (CO₂)*, conditional on a global emissions trajectory over time.

Social-ecological system

An integrated system that includes human societies and *ecosystems*, in which humans are part of nature. The functions of such a system arise from the interactions and interdependence of the social and ecological subsystems. The system's structure is characterised by reciprocal feedbacks, emphasising that humans must be seen as a part of, not apart from, nature (Artic Council, 2016; Berkes and Folke, 1998).

Social inclusion

A process of improving the terms of participation in society, particularly for people who are disadvantaged, through enhancing opportunities, access to resources, and respect for rights (UN, DESA 2016).

Social learning

A process of social interaction through which people learn new behaviours, capacities, values, and attitudes.

Societal (social) transformation

See *Transformation*.

Socio-economic scenario

A *scenario* that describes a possible future in terms of population, *gross domestic product (GDP)*, and other socio-economic factors relevant to understanding the implications of *climate change*.

See also *Baseline scenario*, *Emission scenario*, *Mitigation scenario*, and *Pathways*.

Socio-technical transitions

Where technological change is associated with social systems and the two are inextricably linked.

Soil carbon sequestration (SCS)

Land management changes which increase the *soil organic carbon* content, resulting in a net removal of *carbon dioxide (CO₂)* from the *atmosphere*.

Soil conservation

The maintenance of soil fertility through controlling erosion, preserving soil organic matter, ensuring favourable soil physical properties, and retaining nutrients (Young, 1989).

Soil erosion

The displacement of the soil by the action of water or wind. Soil erosion is a major process of *land degradation*.

Soil organic carbon

Carbon contained in *soil organic matter*.

Soil organic matter

The organic component of soil, comprising plant and animal residue at various stages of decomposition, and soil organisms.

Soil moisture

Water stored in the soil in liquid or frozen form. Root-zone soil moisture is of most relevance for plant activity.

Soil salinity

The concentration of soluble salts in the water extracted from a saturated soil (saturation extract), comprising chlorides and sulphates of Sodium (Na^+), calcium (Ca^{2+}) and magnesium (Mg^{2+}) as well as carbonate salts (adapted from FAO, 1985).

See also *Saline soils*, and *Sodic soils*.

Sodic soils

Soils with disproportionately high concentration of sodium (Na^+) in relation to calcium (Ca^{2+}) and magnesium (Mg^{2+}) adsorbed at the cation exchange site on the surface of soil particles. Sodic soils are characterised by a poor soil structure and poor aeration (NDSU, 2014).

See also *Soil salinity*, and *Sodic soils*.

Source

Any process or activity which releases a *greenhouse gas*, an *aerosol* or a *precursor* of a *greenhouse gas* into the *atmosphere* (UNFCCC Article 1.9).

See also *Sink*.

Stabilisation (of GHG or CO₂-equivalent concentration)

A state in which the *atmospheric* concentrations of one *greenhouse gas* (*GHG*) (e.g., carbon dioxide) or of a CO₂-equivalent basket of GHGs (or a combination of GHGs and *aerosols*) remains constant over time.

Stranded assets

Assets exposed to devaluations or conversion to ‘liabilities’ because of unanticipated changes in their initially expected revenues due to innovations and/or evolutions of the business context, including changes in public regulations at the domestic and international levels.

Stratosphere

The highly stratified region of the *atmosphere* above the *troposphere* extending from about 10 km (ranging from 9 km at high latitudes to 16 km in the tropics on average) to about 50 km altitude.

See also *Atmosphere*, and *Troposphere*.

Subnational actors

State/provincial, regional, metropolitan and local/municipal governments as well as non-party stakeholders, such as civil society, the private sector, cities and other subnational authorities, local communities and indigenous peoples.

Substantive rights

See *Human rights*.

Supply-side measures

See *Demand and supply-side measures*.

Surface temperature

See *Global mean surface temperature (GMST)*, *Land surface air temperature*, and *Sea surface temperature (SST)*.

Sustainability

A dynamic process that guarantees the persistence of natural and *human systems* in an equitable manner.

Sustainable development (SD)

Development that meets the needs of the present without compromising the ability of future generations to meet their own needs (WCED, 1987) and balances social, economic and environmental concerns.

See also *Sustainable Development Goals (SDGs)*, and *Development pathways* (under *Pathways*).

Sustainable Development Goals (SDGs)

The 17 global goals for development for all countries established by the United Nations through a participatory process and elaborated in the *2030 Agenda for Sustainable Development*, including ending *poverty* and hunger; ensuring health and *wellbeing*, education, *gender equality*, clean water and energy, and decent work; building and ensuring *resilient* and sustainable infrastructure, cities and consumption; reducing *inequalities*; protecting land and water *ecosystems*; promoting peace, justice and partnerships; and taking urgent action on *climate change*.

See also *Sustainable development (SD)*.

Sustainable forest management

The stewardship and use of *forests* and forest lands in a way, and at a rate, that maintains their *biodiversity*, productivity, regeneration capacity, vitality and their potential to fulfil, now and in the future, relevant ecological, economic and social functions, at local, national, and global levels, and that does not cause damage to other *ecosystems* (Forest Europe, 1993).

Sustainable intensification (of agriculture)

Increasing yields from the same area of land while decreasing negative environmental impacts of agricultural production and increasing the provision of environmental services (CGIAR, 2019).

[Note: this definition is based on the concept of meeting demand from a finite land area, but it is scale-dependent. Sustainable intensification at a given scale (e.g., global or national) may require a decrease in production intensity at smaller scales and in particular places (often associated with previous, unsustainable, intensification) to achieve *sustainability* (Garnett et al., 2013).]

Sustainable land management

The stewardship and use of *land* resources, including soils, water, animals and plants, to meet changing human needs, while simultaneously ensuring the long-term productive potential of these resources and the maintenance of their environmental functions (Adapted from WOCAT, undated).

Technology transfer

The exchange of knowledge, hardware and associated software, money and goods among stakeholders, which leads to the spread of technology for *adaptation* or *mitigation*. The term encompasses both diffusion of technologies and technological cooperation across and within countries.

Teleconnections

A statistical association between climate variables at widely separated, geographically-fixed spatial locations. Teleconnections are caused by large spatial structures such as basin-wide coupled modes of ocean-atmosphere variability, Rossby wave-trains, mid-latitude jets and storm tracks, etc.

Temperature overshoot

The temporary exceedance of a specified level of *global warming*, such as 1.5°C. Overshoot implies a peak followed by a decline in global warming, achieved through *anthropogenic removal* of *carbon dioxide (CO₂)* exceeding remaining CO₂ emissions globally.

See also *Pathways (Subterms: Overshoot pathways, Non-overshoot Pathways)*.

Tier

In the context of the IPCC Guidelines for National Greenhouse Gas Inventories, a tier represents a level of methodological complexity. Usually three tiers are provided. Tier 1 is the basic method, Tier 2 intermediate and Tier 3 most demanding in terms of complexity and data requirements. Tiers 2 and 3 are sometimes referred to as higher tier methods and are generally considered to be more accurate (IPCC, 2019).

Tipping point

A level of change in system properties beyond which a system reorganises, often abruptly, and does not return to the initial state even if the drivers of the change are abated. For the *climate system*, it refers to a critical threshold beyond which global or regional climate changes from one stable state to another stable state. Tipping points are also used when referring to *impact*: the term can imply that an impact tipping point is (about to be) reached in a natural or *human system*.

See also *Irreversibility*.

Transformation

A change in the fundamental attributes of natural and human systems.

Societal (social) transformation

A profound and often deliberate shift initiated by communities toward sustainability, facilitated by changes in individual and collective values and behaviours, and a fairer balance of political, cultural, and *institutional* power in society.

Transformation pathways

See *Pathways*.

Transformational adaptation

See *Adaptation*.

Transformative change

A system wide change that alters the fundamental attributes of the system.

Transient climate response to cumulative CO₂ emissions (TCRE)

The transient global average surface temperature change per unit cumulative *carbon dioxide* (CO₂) emissions, usually 1000 GtC. TCRE combines both information on the airborne fraction of cumulative CO₂ emissions (the fraction of the total CO₂ emitted that remains in the *atmosphere*, which is determined by *carbon cycle* processes) and on the *transient climate response* (TCR).

See also *Transient climate response (TCR)* (under *Climate sensitivity*).

Transit-oriented development (TOD)

An approach urban development that maximises the amount of residential, business and leisure space within walking distance of efficient public transport, so as to enhance mobility of citizens, the viability of public transport and the value of urban land in mutually supporting ways.

Transition

The process of changing from one state or condition to another in a given period of time. Transition can occur in individuals, firms, cities, regions and nations, and can be based on incremental or transformative change.

Tropical cyclone

The general term for a strong, cyclonic-scale disturbance that originates over tropical oceans. Distinguished from weaker systems (often named tropical disturbances or depressions) by exceeding a threshold wind speed. A tropical storm is a tropical cyclone with one-minute average surface winds between 18 and 32 m s⁻¹. Beyond 32 m s⁻¹, a tropical cyclone is called a hurricane, typhoon, or cyclone, depending on geographic location.

See also *Extratropical cyclone*.

Troposphere

The lowest part of the *atmosphere*, from the surface to about 10 km in altitude at mid-latitudes (ranging from 9 km at high latitudes to 16 km in the tropics on average), where clouds and weather phenomena occur. In the troposphere, temperatures generally decrease with height.

See also *Atmosphere*, and *Stratosphere*.

Uncertainty

A state of incomplete knowledge that can result from a lack of information or from disagreement about what is known or even knowable. It may have many types of sources, from imprecision in the data to ambiguously defined concepts or terminology, incomplete understanding of critical processes, or uncertain *projections* of *human behaviour*. Uncertainty can therefore be represented by quantitative measures (e.g., a probability density function) or by qualitative statements (e.g., reflecting the judgment of a team of experts) (see IPCC, 2004; Mastrandrea et al., 2010; Moss and Schneider, 2000).

See also *Confidence*, and *Likelihood*.

United Nations Convention to Combat Desertification (UNCCD)

A legally binding international agreement linking environment and development to sustainable land management, established in 1994. The Convention's objective is 'to combat desertification and mitigate the effects of drought in countries experiencing drought and/or desertification'. The Convention specifically addresses the arid, semi-arid and dry sub-humid areas, known as the drylands, and has a particular focus on Africa. As of October 2018, the UNCCD had 197 Parties.

United Nations Framework Convention on Climate Change (UNFCCC)

The UNFCCC was adopted in May 1992 and opened for signature at the 1992 Earth Summit in Rio de Janeiro. It entered into force in March 1994 and as of May 2018 had 197 Parties (196 States and the European Union). The Convention's ultimate objective is the 'stabilisation of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system'. The provisions of the Convention are pursued and implemented by two treaties: the *Kyoto Protocol* and the *Paris Agreement*.

Urban green infrastructure

Public and private green spaces, including remnant native vegetation, parks, private gardens, golf courses, street trees, urban farming and engineered options such as green roofs, green walls, biofilters and raingardens (Norton et al., 2015).

Urban and Peri-urban agriculture

'The cultivation of crops and rearing of animals for food and other uses within and surrounding the boundaries of cities, including fisheries and forestry' (EPRS, 2014).

Uptake

The addition of a substance of concern to a *reservoir*.

See also *Carbon sequestration*, and *Sink*.

Vulnerability

The propensity or predisposition to be adversely affected. Vulnerability encompasses a variety of concepts and elements including sensitivity or susceptibility to harm and lack of capacity to cope and adapt.

See also *Exposure*, *Hazard*, and *Risk*.

Water cycle

See *Hydrological cycle*.

Wellbeing

A state of existence that fulfils various human needs, including material living conditions and quality of life, as well as the ability to pursue one's goals, to thrive, and feel satisfied with one's life. Ecosystem well-being refers to the ability of *ecosystems* to maintain their diversity and quality.

Wetland

Land that is covered or saturated by water for all or part of the year (e.g., *peatland*).

1	Table of Contents	
2		
3	Chapter 1: Framing and Context.....	1-1
4	Executive summary.....	1-1
5	1.1 Introduction and scope of the report	1-3
6	1.1.1 Objectives and scope of the assessment.....	1-3
7	1.1.2 Status and dynamics of the (global) land system	1-7
8	1.2 Key challenges related to land use change.....	1-13
9	1.2.1 Land system change, land degradation, desertification and food security	1-13
10	1.2.2 Progress in dealing with uncertainties in assessing land processes in the climate system... 1-	
11	18	
12	Cross-Chapter Box 1: Scenarios and other methods to characterise the future of land	1-22
13	1.3 Response options to the key challenges	1-26
14	1.3.1 Targeted decarbonisation relying on large land-area need.....	1-27
15	Cross-Chapter Box 2: Implications of large-scale conversion from non-forest to forest land.....	1-29
16	1.3.2 Land Management.....	1-32
17	1.3.3 Value chain management	1-32
18	1.3.4 Risk management	1-35
19	1.3.5 Economics of land-based mitigation pathways: Costs versus benefits of early action under	
20	uncertainty.....	1-35
21	1.3.6 Adaptation measures and scope for co-benefits with mitigation	1-36
22	1.4 Enabling the response	1-37
23	1.4.1 Governance to enable the response.....	1-37
24	1.4.2 Gender agency as a critical factor in climate and land sustainability outcomes	1-39
25	1.4.3 Policy Instruments.....	1-40
26	1.5 The interdisciplinary nature of the SRCCL	1-42
27	Frequently Asked Questions	1-42
28	References.....	1-44
29	Supplementary Material.....	1-90

1 Executive summary

2 **Land, including its water bodies, provides the basis for human livelihoods and well-being through**
3 **primary productivity, the supply of food, freshwater, and multiple other ecosystem services (*high***
4 ***confidence*)**. Neither our individual or societal identities, nor the World's economy would exist without
5 the multiple resources, services and livelihood systems provided by land ecosystems and biodiversity.
6 The annual value of the World's total terrestrial ecosystem services has been estimated at 75–85 trillion
7 USD in 2011 (based on USD 2007 values) (*low confidence*). This substantially exceeds the annual World
8 GDP (*high confidence*). Land and its biodiversity also represent essential, intangible benefits to humans,
9 such as cognitive and spiritual enrichment, sense of belonging and aesthetic and recreational values.
10 Valuing ecosystem services with monetary methods often overlooks these intangible services that shape
11 societies, cultures and quality of life and the intrinsic value of biodiversity. The Earth's land area is finite.
12 Using land resources sustainably is fundamental for human well-being (*high confidence*). {1.1.1}

13 **The current geographic spread of the use of land, the large appropriation of multiple ecosystem**
14 **services and the loss of biodiversity are unprecedented in human history (*high confidence*)**. By 2015,
15 about three-quarters of the global ice-free land surface was affected by human use. Humans appropriate
16 one quarter to one third of global terrestrial potential net primary production (*high confidence*). Croplands
17 cover 12–14% of the global ice-free surface. Since 1961, the supply of global per capita food calories
18 increased by about one third, with the consumption of vegetable oils and meat more than doubling. At the
19 same time, the use of inorganic nitrogen fertiliser increased by nearly 9-fold, and the use of irrigation
20 water roughly doubled (*high confidence*). Human use, at varying intensities, affects about 60–85% of
21 forests and 70–90% of other natural ecosystems (e.g., savannahs, natural grasslands) (*high confidence*).
22 Land use caused global biodiversity to decrease by around 11–14% (*medium confidence*). {1.1.2}

23 **Warming over land has occurred at a faster rate than the global mean and this has had observable**
24 **impacts on the land system (*high confidence*)**. The average temperature over land for the period 1999–
25 2018 was 1.41°C higher than for the period 1881–1900, and 0.54°C larger than the equivalent global
26 mean temperature change. These warmer temperatures (with changing precipitation patterns) have altered
27 the start and end of growing seasons, contributed to regional crop yield reductions, reduced freshwater
28 availability, and put biodiversity under further stress and increased tree mortality (*high confidence*).
29 Increasing levels of atmospheric CO₂, have contributed to observed increases in plant growth as well as to
30 increases in woody plant cover in grasslands and savannahs (*medium confidence*). {1.1.2}

31 **Urgent action to stop and reverse the over-exploitation of land resources would buffer the negative**
32 **impacts of multiple pressures, including climate change, on ecosystems and society (*high***
33 ***confidence*)**. Socio-economic drivers of land use change such as technological development, population
34 growth and increasing per capita demand for multiple ecosystem services are projected to continue into
35 the future (*high confidence*). These and other drivers can amplify existing environmental and societal
36 challenges, such as the conversion of natural ecosystems into managed land, rapid urbanisation, pollution
37 from the intensification of land management and equitable access to land resources (*high confidence*).
38 Climate change will add to these challenges through direct, negative impacts on ecosystems and the
39 services they provide (*high confidence*). Acting immediately and simultaneously on these multiple drivers
40 would enhance food, fibre and water security, alleviate desertification, and reverse land degradation,
41 without compromising the non-material or regulating benefits from land (*high confidence*). {1.1.2, 1.2.1,
42 1.3.2-1.3.6, Cross-Chapter Box 1, Chapter 1}

1 **Rapid reductions in anthropogenic greenhouse gas emissions that restrict warming to “well-below”**
2 **2°C would greatly reduce the negative impacts of climate change on land ecosystems (*high***
3 ***confidence*).** In the absence of rapid emissions reductions, reliance on large-scale, land-based,
4 **climate change mitigation is projected to increase, which would aggravate existing pressures on**
5 **land (*high confidence*).** Climate change mitigation efforts that require large land areas (e.g., bioenergy
6 and afforestation/reforestation) are projected to compete with existing uses of land (*high confidence*). The
7 competition for land could increase food prices and lead to further intensification (e.g., fertiliser and water
8 use) with implications for water and air pollution, and the further loss of biodiversity (*medium*
9 *confidence*). Such consequences would jeopardise societies’ capacity to achieve many sustainable
10 development goals that depend on land (*high confidence*). {1.3.1, Cross-Chapter Box 2 in Chapter 1}

11 **Nonetheless, there are many land-related climate change mitigation options that do not increase the**
12 **competition for land (*high confidence*).** Many of these options have co-benefits for climate change
13 **adaptation (*medium confidence*).** Land use contributes about one quarter of global greenhouse gas
14 emissions, notably CO₂ emissions from deforestation, CH₄ emissions from rice and ruminant livestock
15 and N₂O emissions from fertiliser use (*high confidence*). Land ecosystems also take up large amounts of
16 carbon (*high confidence*). Many land management options exist to both reduce the magnitude of
17 emissions and enhance carbon uptake. These options enhance crop productivity, soil nutrient status,
18 microclimate or biodiversity, and thus, support adaptation to climate change (*high confidence*). In
19 addition, changes in consumer behaviour, such as reducing the over-consumption of food and energy
20 would benefit the reduction of GHG emissions from land (*high confidence*). The barriers to the
21 implementation of mitigation and adaptation options include skills deficit, financial and institutional
22 barriers, absence of incentives, access to relevant technologies, consumer awareness and the limited
23 spatial scale at which the success of these practices and methods have been demonstrated. {1.2.1, 1.3.2,
24 1.3.3, 1.3.4, 1.3.5, 1.3.6}

25 **Sustainable food supply and food consumption, based on nutritionally balanced and diverse diets,**
26 **would enhance food security under climate and socio-economic changes (*high confidence*).**
27 Improving food access, utilisation, quality and safety to enhance nutrition, and promoting globally
28 equitable diets compatible with lower emissions have demonstrable positive impacts on land use and food
29 security (*high confidence*). Food security is also negatively affected by food loss and waste (estimated as
30 more than 30% of harvested materials) (*high confidence*). Barriers to improved food security include
31 economic drivers (prices, availability and stability of supply) and traditional, social and cultural norms
32 around food eating practices. Climate change is expected to increase variability in food production and
33 prices globally (*high confidence*), but the trade in food commodities can buffer these effects. Trade can
34 provide embodied flows of water, land and nutrients (*medium confidence*). Food trade can also have
35 negative environmental impacts by displacing the effects of overconsumption (*medium confidence*).
36 Future food systems and trade patterns will be shaped as much by policies as by economics (*medium*
37 *confidence*). {1.2.1, 1.3.3}

38 **A gender inclusive approach offers opportunities to enhance the sustainable management of land**
39 **(*medium confidence*).** Women play a significant role in agriculture and rural economies globally. In
40 many World regions, laws, cultural restrictions, patriarchy and social structures such as discriminatory
41 customary laws and norms reduce women’s capacity in supporting the sustainable use of land resources
42 (*medium confidence*). Therefore, acknowledging women’s land rights and bringing women’s land
43 management knowledge into land-related decision-making would support the alleviation of land
44 degradation, and facilitate the take-up of integrated adaptation and mitigation measures (*medium*
45 *confidence*). {1.4.1, 1.4.2}

1 **Regional and country specific contexts affect the capacity to respond to climate change and its**
2 **impacts, through adaptation and mitigation (*high confidence*).** There is large variability in the
3 availability and use of land resources between regions, countries and land-management systems. In
4 addition, differences in socio-economic conditions, such as wealth, degree of industrialisation, institutions
5 and governance, affect the capacity to respond to climate change, food insecurity, land degradation and
6 desertification. The capacity to respond is also strongly affected by local land ownership. Hence, climate
7 change will affect regions and communities differently (*high confidence*). {1.3, 1.4}

8 **Cross-scale, cross-sectoral and inclusive governance can enable coordinated policy that supports**
9 **effective adaptation and mitigation (*high confidence*).** There is a lack of coordination across
10 governance levels, for example, local, national, transboundary and international, in addressing climate
11 change and sustainable land management challenges. Policy design and formulation is often strongly
12 sectoral, which poses further barriers when integrating international decisions into relevant (sub)national
13 policies. A portfolio of policy instruments that are inclusive of the diversity of governance actors would
14 enable responses to complex land and climate challenges (*high confidence*). Inclusive governance that
15 considers women's and indigenous people's rights to access and use land enhances the equitable sharing
16 of land resources, fosters food security and increases the existing knowledge about land use, which can
17 increase opportunities for adaptation and mitigation (*medium confidence*). {1.3.5, 1.4.1, 1.4.2, 1.4.3}

18 **Scenarios and models are important tools to explore the trade-offs and co-benefits of land**
19 **management decisions under uncertain futures (*high confidence*).** Participatory, co-creation processes
20 with stakeholders can facilitate the use of scenarios in designing future sustainable development strategies
21 (*medium confidence*). In addition to qualitative approaches, models are critical in quantifying scenarios,
22 but uncertainties in models arise from, for example, differences in baseline datasets, land cover classes
23 and modelling paradigms (*medium confidence*). Current scenario approaches are limited in quantifying
24 time-dependent, policy and management decisions that can lead from today to desirable futures or visions.
25 Advances in scenario analysis and modelling are needed to better account for full environmental costs and
26 non-monetary values as part of human decision-making processes. {1.2.2, Cross Chapter Box 1 in
27 Chapter 1}

28 **1.1 Introduction and scope of the report**

29 **1.1.1 Objectives and scope of the assessment**

30 Land, including its water bodies, provides the basis for our livelihoods through basic processes such as
31 net primary production that fundamentally sustain the supply of food, bioenergy and freshwater, and the
32 delivery of multiple other ecosystem services and biodiversity (Hoekstra and Wiedmann 2014; Mace et
33 al. 2012; Newbold et al. 2015; Runting et al. 2017; Isbell et al. 2017)(see Cross-Chapter Box 8:
34 Ecosystem Services, Chapter 6). The annual value of the world's total terrestrial ecosystem services has
35 been estimated to be about USD 75–85 trillion (in 2011 based on USD 2007 values)(Costanza et al.
36 2014). This equates approximately to the world's average GDP over the last 5 years (IMF 2018). Land
37 also supports non-material ecosystem services such as cognitive and spiritual enrichment and aesthetic
38 values (Hernández-Morcillo et al. 2013; Fish et al. 2016), intangible services that shape societies, cultures
39 and human well-being. Exposure of people living in cities to (semi-)natural environments has been found
40 to decrease mortality, cardiovascular disease and depression (Rook 2013; Terraube et al. 2017). Non-
41 material and regulating ecosystem services have been found to decline globally and rapidly, often at the
42 expense of increasing material services (Fischer et al. 2018; IPBES 2018a). Climate change will
43 exacerbate diminishing land and freshwater resources, increase biodiversity loss, and will intensify

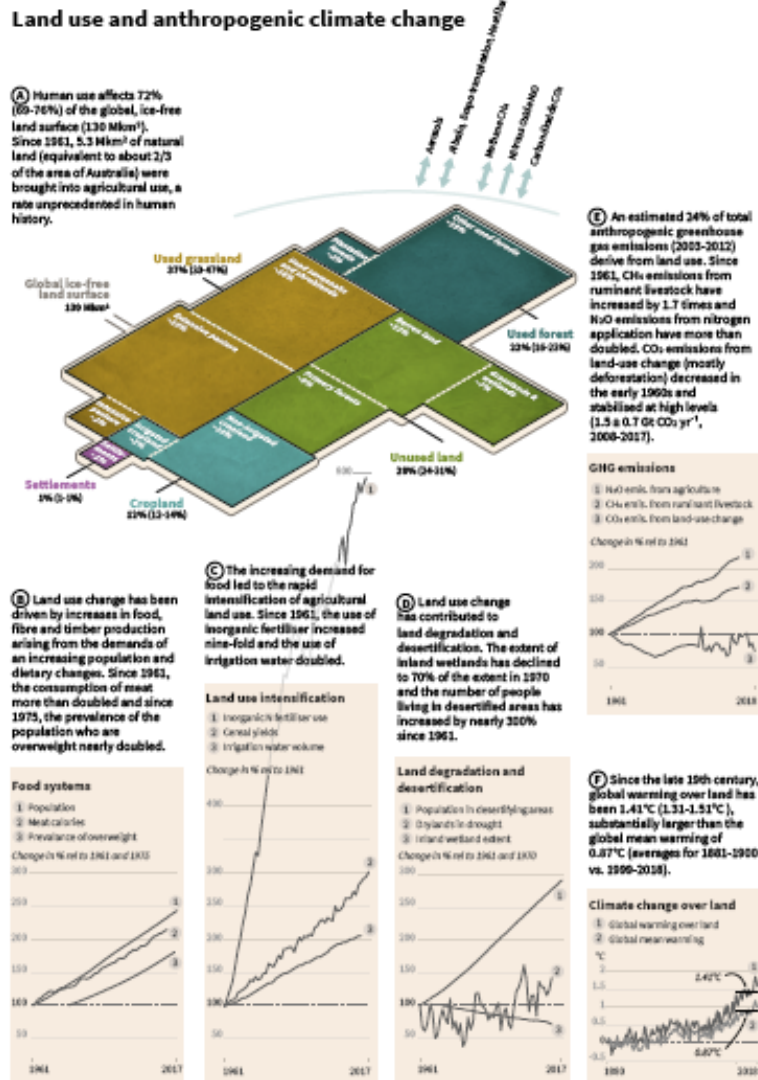

1 societal vulnerabilities, especially in regions where economies are highly dependent on natural resources.
2 Enhancing food security and reducing malnutrition, whilst also halting and reversing desertification and
3 land degradation, are fundamental societal challenges that are increasingly aggravated by the need to both
4 adapt to and mitigate climate change impacts without compromising the non-material benefits of land
5 (Kongsager et al. 2016; FAO et al. 2018).

6 Annual emissions of greenhouse gases (GHGs) and other climate forcers continue to increase unabatedly.
7 *Confidence is very high* that the window of opportunity, the period when significant change can be made,
8 for limiting climate change within tolerable boundaries is rapidly narrowing (Schaeffer et al. 2015;
9 Bertram et al. 2015; Riahi et al. 2015; Millar et al. 2017; Rogelj et al. 2018a). The Paris Agreement
10 formulates the goal of limiting global warming this century well below 2°C above pre-industrial levels,
11 for which rapid actions are required across the energy, transport, infrastructure and agricultural sectors,
12 while factoring in the need for these sectors to accommodate a growing human population (Wynes and
13 Nicholas 2017; Le Quere et al. 2018). Conversion of natural land, and land management, are significant
14 net contributors to GHG emissions and climate change, but land ecosystems are also a GHG sink (Smith
15 et al. 2014; Tubiello et al. 2015; Le Quere et al. 2018; Ciais et al. 2013a). It is not surprising, therefore,
16 that land plays a prominent role in many of the Nationally Determined Contributions (NDCs) of the
17 parties to the Paris Agreement (Rogelj et al. 2018a,b; Grassi et al. 2017; Forsell et al. 2016), and land-
18 measures will be part of the NDC review by 2023.

19 A range of different climate change mitigation and adaptation options on land exist, which differ in terms
20 of their environmental and societal implications (Meyfroidt 2018; Bonsch et al. 2016; Crist et al. 2017;
21 Humpenoder et al. 2014; Harvey and Pilgrim 2011; Mouratiadou et al. 2016; Zhang et al. 2015; Sanz-
22 Sanchez et al. 2017; Pereira et al. 2010; Griscom et al. 2017; Rogelj et al. 2018a)(see Chapters 4-6). The
23 Special Report on climate change, desertification, land degradation, sustainable land management, food
24 security, and GHG fluxes in terrestrial ecosystems (SRCCL) synthesises the current state of scientific
25 knowledge on the issues specified in the report's title (see Figure 1.1, Figure 1.2). This knowledge is
26 assessed in the context of the Paris Agreement, but many of the SRCCL issues concern other international
27 conventions such as the United Nations Convention on Biodiversity (UNCBD), the UN Convention to
28 Combat Desertification (UNCCD), the UN Sendai Framework for Disaster Risk Reduction (UNISDR)
29 and the UN Agenda 2030 and its Sustainable Development Goals (SDGs). The SRCCL is the first report
30 in which land is the central focus since the IPCC Special Report on land use, land-use change and forestry
31 (Watson et al. 2000)(see Box 1.1). The main objectives of the SRCCL are to:

- 32 1) Assess the current state of the scientific knowledge on the impacts of socio-economic drivers and their
33 interactions with climate change on land, including degradation, desertification and food security;
- 34 2) Evaluate the feasibility of different land-based response options to GHG mitigation, and assess the
35 potential synergies and trade-offs with ecosystem services and sustainable development;
- 36 3) Examine adaptation options under a changing climate to tackle land degradation and desertification
37 and to build resilient food systems, as well as evaluating the synergies and trade-offs between
38 mitigation and adaptation; and
- 39 4) Delineate the policy, governance and other enabling conditions to support climate mitigation, land
40 ecosystem resilience and food security in the context of risks, uncertainties and remaining knowledge
41 gaps.

42

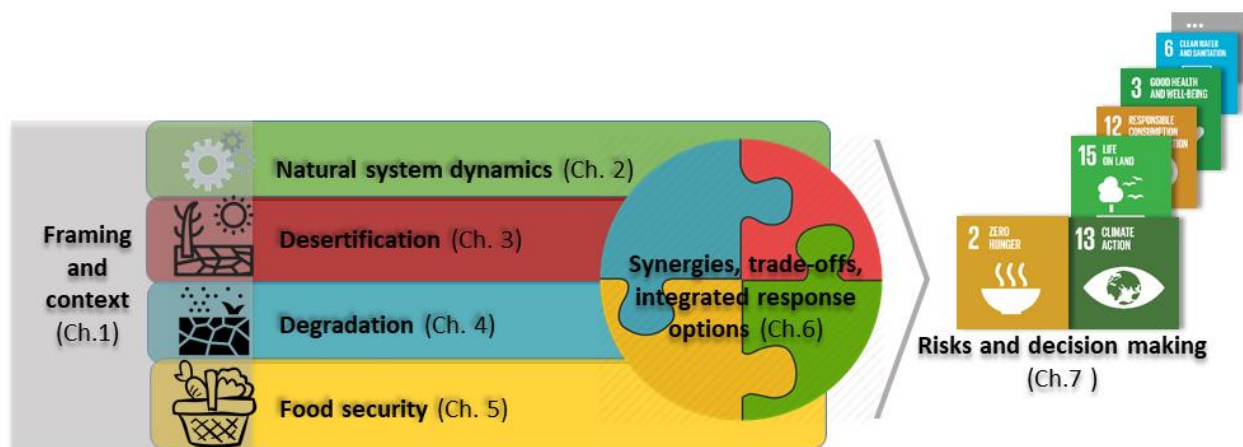

1

2 **Figure 1.1 A representation of the principal land challenges and land-climate system processes covered in this**
 3 **assessment report.** A. The tiles show the current extent (in about 2015) of the human use of the land surface,
 4 aggregated into five broad land use and land cover categories with uncertainty ranges. Colour shading indicates
 5 different intensities of human use (Table 1.1). B. Agricultural areas have increased to supply the increasing demand
 6 for food arising from population growth, income growth and increasing consumption of animal-sourced products.
 7 The proportion of the global population that is overweight (body mass index > 25 kg/m²) has increased markedly
 8 (section 5.1.2). Population density (*Source: United Nations, Department of Economic and Social Affairs 2017*).
 9 Meat calories supplied (*Source: FAOSTAT 2018*) Prevalence of people overweight (*Source: Abarca-Gómez et al.*
 10 *2017*)(5.1.2). C. Increasing food production has led to rapid land use intensification, including increases in the use of
 11 nitrogen fertiliser and irrigation water that have supported the growth in cereal yields (section 1.1). Change in cereal
 12 yield and irrigation water use (*Source: FAOSTAT 2018*); Change in total inorganic nitrogen fertiliser consumption
 13 (*Source: International Fertiliser Industry Association, <https://www.ifastat.org/databases>*). Note that the very large
 14 percentage change in fertiliser use reflects the very low use in 1961. The increase relates to both increasing fertiliser
 15 input per area as well as the expansion of fertilised cropland and grassland. D. Land use change has led to
 16 substantial losses in the extent of inland wetlands (section 4.2.1, 4.6.1). Dryland areas are under increasing pressures
 17 both from the increasing number of people living in these areas and from the increase in droughts (section 3.1.1).
 18 The inland wetland extent trends (WET) index was developed by aggregating data from 2130 time series that report
 19 changes in local wetland area over time (Dixon et al. 2016; Darrah et al. 2019). Dryland areas were defined using
 20 TerraClimate precipitation and potential evapotranspiration (1980-2015) (Abatzoglou et al. 2018) to identify areas

1 where the Aridity Index is below 0.65. Areas undergoing human caused desertification, after accounting for
 2 precipitation variability and CO₂ fertilisation, are identified in (Le et al. 2016). Population data for these areas were
 3 extracted from the gridded historical population database HYDE3.2 (Goldewijk et al. 2017). The 12-month
 4 accumulation Global Precipitation Climatology Centre Drought Index (Ziese et al. 2014) was extracted for drylands.
 5 The area in drought was calculated for each month (Drought Index below -1), and the mean over the year was used
 6 to calculate the percentage of drylands in drought that year. E. Land use change and intensification have contributed
 7 to CH₄ emissions from ruminant livestock, agricultural N₂O emissions and CO₂ emissions from net deforestation
 8 {2.3}. Sources: N₂O from agricultural activities and CH₄ from enteric fermentation: Edgar database
 9 (<http://edgar.jrc.ec.europa.eu/overview.php?v=42FT2012>) from 1970. From 1970 back to 1961, CH₄ and N₂O were
 10 extrapolated using a regression with time, taken for the years 1970-1979 from Edgar. Net-land use change emissions
 11 of CO₂ are from the annual Global Carbon Budget, using the mean of two bookkeeping models (Le Quéré et al.
 12 2018). Chapter 2 (Section 2.2, 2.3) and Chapter 5 (Section 5.4) provides a discussion of uncertainties and other
 13 emissions estimates. The various exchanges between the land surface and the atmosphere, including the emission
 14 and uptake of greenhouse gases, exchanges related to the land-surface energy balance and aerosols are indicated by
 15 arrows (section 2.1, 2.3, 2.4). Warming over land is more rapid than the global mean temperature change (section
 16 2.2). Future climate change will exacerbate the already considerable challenges faced by land systems. The warming
 17 curves are averages of four historical estimates, and described in Section 2.1.

18 The SRCCCL identifies and assesses land-related challenges and response-options in an integrative way,
 19 aiming to be policy relevant across sectors. Chapter 1 provides a synopsis of the main issues addressed in
 20 this report, which are explored in more detail in Chapters 2–7. Chapter 1 also introduces important
 21 concepts and definitions and highlights discrepancies with previous reports that arise from different
 22 objectives (a full set of definitions is provided in the Glossary). Chapter 2 focuses on the natural system
 23 dynamics, assessing recent progress towards understanding the impacts of climate change on land, and the
 24 feedbacks arising from altered biogeochemical and biophysical exchange fluxes (Figure 1.2).

25

26

Figure 1.2 Overview over the SRCCCL

27 Chapter 3 examines how the world's dryland populations are uniquely vulnerable to desertification and
 28 climate change, but also have significant knowledge in adapting to climate variability and addressing
 29 desertification. Chapter 4 assesses the urgency of tackling land degradation across all land ecosystems.
 30 Despite accelerating trends of land degradation, reversing these trends is attainable through restoration
 31 efforts and proper implementation of sustainable land management (SLM), which is expected to improve
 32 resilience to climate change, mitigate climate change, and ensure food security for generations to come.
 33 Food security is the focus of Chapter 5, with an assessment of the risks and opportunities that climate
 34 change presents to food systems, considering how mitigation and adaptation can contribute to both human
 35 and planetary health.

1 Chapters 6 focuses on the response options within the land system that deal with trade-offs and increase
2 benefits in an integrated way in support of the SDGs. Chapter 7 highlights these aspects further, by
3 assessing the opportunities, decision making and policy responses to risks in the climate-land-human
4 system.

5

6 **Box 1.1 Land in previous IPCC and other relevant reports**

7 Previous IPCC reports have made reference to land and its role in the climate system. Threats to
8 agriculture forestry and other ecosystems, but also the role of land and forest management in climate
9 change, have been documented since the IPCC Second Assessment Report, especially so in the Special
10 report on land use, land-use change and forestry (Watson et al. 2000). The IPCC Special Report on
11 Extreme events (SREX) discussed sustainable land management, including land use planning, and
12 ecosystem management and restoration among the potential low-regret measures that provide benefits
13 under current climate and a range of future, climate change scenarios. Low-regret measures are defined in
14 the report as those with the potential to offer benefits now and lay the foundation for tackling future,
15 projected change. Compared to previous IPCC reports, the SRCCL offers a more integrated analysis of
16 the land system as it embraces multiple direct and indirect drivers of natural resource management
17 (related to food, water and energy securities), which have not previously been addressed to a similar depth
18 (Field et al. 2014a; Edenhofer et al. 2014).

19 The recent IPCC Special Report on Global Warming of 1.5°C (SR15) targeted specifically the Paris
20 Agreement, without exploring the possibility of future global warming trajectories above 2°C (IPCC
21 2018). Limiting global warming to 1.5°C compared to 2°C is projected to lower the impacts on terrestrial,
22 freshwater and coastal ecosystems and to retain more of their services for people. In many scenarios
23 proposed in this report, large-scale land use features as a mitigation measure. In the reports of the Food
24 and Agriculture Organisation (FAO), land degradation is discussed in relation to ecosystem goods and
25 services, principally from a food security perspective (FAO and ITPS 2015). The UNCCD report (2014)
26 discusses land degradation through the prism of desertification. It devotes due attention to how land
27 management can contribute to reversing the negative impacts of desertification and land degradation. The
28 IPBES assessments (2018a,b,c,d,e) focuses on biodiversity drivers, including a focus on land degradation
29 and desertification, with poverty as a limiting factor. The reports draw attention to a world in peril in
30 which resource scarcity conspires with drivers of biophysical and social vulnerability to derail the
31 attainment of sustainable development goals. As discussed in chapter 4 of the SRCCL, different
32 definitions of degradation have been applied in the IPBES degradation assessment (IPBES 2018b), which
33 potentially can lead to different conclusions for restoration and ecosystem management.

34 The SRCCL complements and adds to previous assessments, whilst keeping the IPCC-specific “climate
35 perspective”. It includes a focussed assessment of risks arising from maladaptation and land-based
36 mitigation (i.e. not only restricted to direct risks from climate change impacts) and the co-benefits and
37 trade-offs with sustainable development objectives. As the SRCCL cuts across different policy sectors it
38 provides the opportunity to address a number of challenges in an integrative way at the same time, and it
39 progresses beyond other IPCC reports in having a much more comprehensive perspective on land.

40 **1.1.2 Status and dynamics of the (global) land system**

41 **1.1.2.1 Land ecosystems and climate change**

42 Land ecosystems play a key role in the climate system, due to their large carbon pools and carbon
43 exchange fluxes with the atmosphere (Ciais et al. 2013b). Land use, the total of arrangements, activities

1 and inputs applied to a parcel of land (such as agriculture, grazing, timber extraction, conservation or city
2 dwelling; see glossary), and land management (sum of land-use practices that take place within broader
3 land-use categories, see glossary) considerably alter terrestrial ecosystems and play a key role in the
4 global climate system. An estimated one quarter of total anthropogenic GHG emissions arise mainly from
5 deforestation, ruminant livestock and fertiliser application (Smith et al. 2014; Tubiello et al. 2015; Le
6 Quere et al. 2018; Ciais et al. 2013a), and especially methane and nitrous oxide emissions from
7 agriculture have been rapidly increasing over the last decades (Hoesly et al. 2018; Tian et al. 2019)(see
8 Figure 1.1, see Section 2.3.2, 2.3.3).

9 Globally, land also serves as a large carbon dioxide sink, which was estimated for the period 2008–2017
10 to be nearly 30% of total anthropogenic emissions (Le Quere et al. 2015; Canadell and Schulze 2014;
11 Ciais et al. 2013a; Zhu et al. 2016)(see Section 2.3.1). This sink has been attributed to increasing
12 atmospheric CO₂ concentration, a prolonged growing season in cool environments, or forest regrowth (Le
13 Quéré et al. 2013; Pugh et al. 2019; Le Quéré et al. 2018; Ciais et al. 2013a; Zhu et al. 2016). Whether or
14 not this sink will persist into the future is one of the largest uncertainties in carbon cycle and climate
15 modelling (Ciais et al. 2013a; Bloom et al. 2016; Friend et al. 2014; Le Quere et al. 2018). In addition,
16 changes in vegetation cover caused by land use (such as conversion of forest to cropland or grassland, and
17 vice versa) can result in regional cooling or warming through altered energy and momentum transfer
18 between ecosystems and the atmosphere. Regional impacts can be substantial, but whether the effect leads
19 to warming or cooling depends on the local context (Lee et al. 2011; Zhang et al. 2014; Alkama and
20 Cescatti 2016; see Section 2.6). Due to the current magnitude of GHG emissions and carbon dioxide
21 removal in land ecosystems, there is *high confidence* that greenhouse-gas reduction measures in
22 agriculture, livestock management and forestry would have substantial climate change mitigation
23 potential with co-benefits for biodiversity and ecosystem services (Smith and Gregory 2013; Smith et al.
24 2014; Griscom et al. 2017; see Section 2.6, Section 6.3).

25 The mean temperature increase over land has been substantially larger than the global mean (land and
26 ocean), averaging 1.41°C vs. 0.87°C for the years 1999–2018 compared with 1881–1900 (see Section
27 2.2). Climate change affects land ecosystems in various ways (see Section 7.2). Growing seasons and
28 natural biome boundaries shift in response to warming or changes in precipitation (Gonzalez et al. 2010;
29 Wärlind et al. 2014; Davies-Barnard et al. 2015; Nakamura et al. 2017). Atmospheric CO₂ increases have
30 been attributed to underlie, at least partially, observed woody plant cover increase in grasslands and
31 savannahs (Donohue et al. 2013). Climate change-induced shifts in habitats, together with warmer
32 temperatures, causes pressure on plants and animals (Pimm et al. 2014; Urban et al. 2016). National
33 cereal crop losses of nearly 10% have been estimated for the period 1964–2007 as a consequence of heat
34 and drought weather extremes (Deryng et al. 2014; Lesk et al. 2016). Climate change is expected to
35 reduce yields in areas that are already under heat and water stress (Schlenker and Lobell 2010; Lobell et
36 al. 2011,2012; Challinor et al. 2014; see Section 5.2.2). At the same time, warmer temperatures can
37 increase productivity in cooler regions (Moore and Lobell 2015) and might open opportunities for crop
38 area expansion, but any overall benefits might be counterbalanced by reduced suitability in warmer
39 regions (Pugh et al. 2016; Di Paola et al. 2018). Increasing atmospheric CO₂ is expected to increase
40 productivity and water use efficiency in crops and in forests (Muller et al. 2015; Nakamura et al. 2017;
41 Kimball 2016). The increasing number of extreme weather events linked to climate change is also
42 expected to result in forest losses; heat waves and droughts foster wildfires (Seidl et al. 2017; Fasullo et
43 al. 2018; see Cross-Chapter Box 3: Fire and Climate Change, Chapter 2). Episodes of observed enhanced
44 tree mortality across many world regions have been attributed to heat and drought stress (Allen et al.
45 2010; Anderegg et al. 2012), whilst weather extremes also impact local infrastructure and hence

1 transportation and trade in land-related goods (Schweikert et al. 2014; Chappin and van der Lei 2014).
2 Thus, adaptation is a key challenge to reduce adverse impacts on land systems (see Section 1.3.6).

3 *1.1.2.2 Current patterns of land use and land cover*

4 Around three quarters of the global ice-free land, and most of the highly-productive land area, are by now
5 under some form of land use (Erb et al. 2016a; Luyssaert et al. 2014; Venter et al. 2016; see Table 1.1).
6 One third of used land is associated with changed land cover. Grazing land is the single largest land-use
7 category, followed by used forestland and cropland. The total land area used to raise livestock is notable:
8 it includes all grazing land and an estimated additional one fifth of cropland for feed production (Foley et
9 al. 2011). Globally, 60–85% of the total forested area is used, at different levels of intensity, but
10 information on management practices globally are scarce (Erb et al. 2016a). Large areas of unused
11 (primary) forests remain only in the tropics and northern boreal zones (Luyssaert et al. 2014; Birdsey and
12 Pan 2015; Morales-Hidalgo et al. 2015; Potapov et al. 2017; Erb et al. 2017), while 73–89% of other,
13 non-forested natural ecosystems (natural grasslands, savannas, etc.) are used. Large uncertainties relate to
14 the extent of forest (32.0–42.5 million km²) and grazing land (39–62 million km²), due to discrepancies in
15 definitions and observation methods (Luyssaert et al. 2014; Erb et al. 2017; Putz and Redford 2010;
16 Schepaschenko et al. 2015; Birdsey and Pan 2015; FAO 2015a; Chazdon et al. 2016a; FAO 2018a).
17 Infrastructure areas (including settlements, transportation and mining), while being almost negligible in
18 terms of extent, represent particularly pervasive land-use activities, with far-reaching ecological, social
19 and economic implications (Cherlet et al. 2018; Laurance et al. 2014).

20 The large imprint of humans on the land surface has led to the definition of anthromes, i.e. large-scale
21 ecological patterns created by the sustained interactions between social and ecological drivers. The
22 dynamics of these ‘anthropogenic biomes’ are key for land-use impacts as well as for the design of
23 integrated response options (Ellis and Ramankutty 2008; Ellis et al. 2010; Cherlet et al. 2018; Ellis et al.
24 2010, see Chapter 6).

25 The intensity of land use varies hugely within and among different land use types and regions. Averaged
26 globally, around 10% of the ice-free land surface was estimated to be intensively managed (such as tree
27 plantations, high livestock density grazing, large agricultural inputs), two thirds moderately and the
28 remainder at low intensities (Erb et al. 2016a). Practically all cropland is fertilised, with large regional
29 variations. Irrigation is responsible for 70% of ground- or surface-water withdrawals by humans (Wisser
30 et al. 2008; Chaturvedi et al. 2015; Siebert et al. 2015; FAOSTAT 2018). Humans appropriate one quarter
31 to one third of the total potential net primary production, i.e. the NPP that would prevail in the absence of
32 land use (estimated at about 60 GtC yr⁻¹; Bajželj et al. 2014; Haberl et al. 2014), about equally through
33 biomass harvest and changes in NPP due to land management. The current total of agricultural (cropland
34 and grazing) biomass harvest is estimated at about 6 GtC yr⁻¹, around 50–60% of this is consumed by
35 livestock. Forestry harvest for timber and wood fuel amounts to about 1 GtC yr⁻¹ (Alexander et al. 2017;
36 Bodirsky and Müller 2014; Lassaletta et al. 2014, 2016; Mottet et al. 2017; Haberl et al. 2014; Smith et al.
37 2014; Bais et al. 2015; Bajželj et al. 2014)(see Cross-Chapter Box 7: Bioenergy and BECCS, Chapter 6).

38 **Table 1.1 Extent of global land use and management around the year 2015**

	Best guess	Range	Range	Type	Ref.
	[million km ²]		[% of total]		
Total	130.4		100%		
USED LAND	92.6	90.0-99.3	71%	69-76%	
Infrastructure (Settlements, mining, etc.)	1.4	1.2-1.9	1%	LCC	1,2,3,4,5,6

Cropland	15.9	15.9-18.8	12%	12-14%		1,7
irrigated cropland	3.1		2%		LCC	8
non-irrigated cropland	12.8	12.8-15.7	10%		LCC	8
Grazing land	48.0	38.8-61.9	37%	30-47%		
Permanent pastures	27.1	22.8-32.8	21%	17-25%		5,7,8
Intensive permanent pastures*	2.6		2%		LCC	8,9
Extensive perm. pastures, on potential forest sites**	8.7		7%		LCC	9
Extensive perm. pastures, on natural grasslands**	15.8	11.5-21.56	12%	9-16%	LM	
Non-forested, used land, multiple uses[§]	20.1	6.1-39.1	16%	5-30%	LM	
Used forests[#]	28.1	20.3-30.5	22%	16-23%		10,11,12
Planted forests	2.9		2%		LCC	12
Managed for timber and other uses	25.2	17.4-27.6	19%	13-21%	LM	12
UNUSED LAND	37.0	31.1-40.4	28%	24-31%		5,11,13
Unused, unforested ecosystems, including grasslands and wetlands	9.4	5.9-10.4	7%	5-8%		1,13
Unused forests (intact or primary forests)	12.0	11.7-12.0	9%			11,12
Other land (barren wilderness, rocks, etc.)	15.6	13.5-18.0	12%	10-14%		4,5,13,14
Land-cover conversions (sum of LCC)	31.5	31.3-34.9	24%	24-27%		
Land-use occurring within natural land-cover types (sum of LM)	61.1	55.1-68.0	47%	42-52%		

1 *>100 animals/km²

2 **<100 animals/km², residual category within permanent pastures

3 § Calculated as residual category. Contains land not classified as forests or cropland, such as savanna and tundra
4 used as rangelands, with extensive uses like seasonal, rough grazing, hunting, fuelwood collection outside forests,
5 wild products harvesting, etc.

6 # used forest calculated as total forest minus unused forests

7 **Note:** This table is based on data and approaches described in Lambin and Meyfroidt (2011,2014); Luyssaert et al.
8 (2014); Erb et al. (2016a), and references below. The target year for data is 2015, but proportions of some
9 subcategories are from 2000 (the year with still most reconciled datasets available) and their relative extent was
10 applied to some broad land use categories for 2015. Sources: Settlements (1): (Luyssaert et al. 2014); (2) (Lambin
11 and Meyfroidt 2014); (3) Global Human Settlements dataset, <https://ghsl.jrc.ec.europa.eu/>. Total infrastructure
12 including transportation (4) (Erb et al. 2007); (5) (Stadler et al. 2018); mining (6) (Cherlet et al. 2018); (7)
13 (FAOSTAT 2018); (8) proportions from (Erb et al. 2016a); (9) (Ramankutty et al. 2008) extrapolated from 2000 to
14 2010 trend for permanent pastures from (7); (9) (Erb et al. 2017); (10) (Schepaschenko et al. 2015); (11) (Potapov et
15 al. 2017); (12) (FAO 2015a); (13) (Venter et al. 2016); (14) (Ellis et al. 2010)

16 1.1.2.3 Past and ongoing trends

17 Globally, cropland area changed by +15% and the area of permanent pastures by +8% since the early
18 1960s (FAOSTAT 2018), with strong regional differences (Figure 1.3). In contrast, cropland production
19 since 1961 increased by about 3.5 times, the production of animal products by 2.5 times, and forestry by
20 1.5 times; in parallel with strong yield (production per unit area) increases (FAOSTAT 2018; Figure 1.3).
21 Per capita calorie supply increased by 17% (since 1970; Kastner et al. 2012), and diet composition
22 changed markedly, tightly associated with economic development and lifestyle: Since the early 1960s, per
23 capita dairy product consumption increased by a factor 1.2, and meat and vegetable oil consumption more
24 than doubled (FAO 2017, 2018b; Tilman and Clark 2014; Marques et al. 2019). Population and livestock
25 production represent key drivers of the global expansion of cropland for food production, only partly

1 compensated by yield increases at the global level (Alexander et al. 2015). A number of studies have
2 reported reduced growth rates or stagnation in yields in some regions in the last decades (*medium*
3 *evidence, high agreement*; Lin and Huybers 2012; Ray et al. 2012; Elbehri, Aziz, Joshua Elliott 2015; see
4 Section 5.2.2).

5 The past increases in agricultural production have been associated with strong increases in agricultural
6 inputs (Foley et al. 2011; Siebert et al. 2015; Lassaletta et al. 2016; Figure 1.1, Figure 1.3). Irrigation area
7 doubled, total nitrogen fertiliser use increased 9 times (FAOSTAT 2018; IFASTAT 2018) since the early
8 1960s. Biomass trade volumes grew by a factor of nine (in tons dry matter yr⁻¹) in this period, which is
9 much stronger than production (FAOSTAT 2018), resulting in a growing spatial disconnect between
10 regions of production and consumption (Friis et al. 2016; Friis and Nielsen 2017; Schröter et al. 2018; Liu
11 et al. 2013; Krausmann and Langthaler 2019). Urban and other infrastructure areas expanded by a factor 2
12 since 1960 (Krausmann et al. 2013), resulting in disproportionately large losses of highly-fertile cropland
13 (Seto and Reenberg 2014; Martellozzo et al. 2015; Bren d'Amour et al. 2016; Seto and Ramankutty 2016;
14 van Vliet et al. 2017). World regions show distinct patterns of change (Figure 1.3).

15 While most pastureland expansion replaced natural grasslands, cropland expansion replaced mainly
16 forests (Ramankutty et al. 2018; Ordway et al. 2017; Richards and Friess 2016). Noteworthy large
17 conversions occurred in tropical dry woodlands and savannahs, for example, in the Brazilian Cerrado
18 (Lehmann and Parr 2016; Strassburg et al. 2017), the South-American Caatinga and Chaco regions (Parr
19 et al. 2014; Lehmann and Parr 2016) or African savannahs (Ryan et al. 2016). More than half of the
20 original 4.3–12.6 million km² global wetlands (Erb et al. 2016a; Davidson 2014; Dixon et al. 2016) have
21 been drained; since 1970 the wetland extend index, developed by aggregating data field-site time series
22 that report changes in local wetland area indicate a decline by > 30% (Figure 1.1, see Section 4.2.1,
23 Darrah et al. 2019). Likewise, one third of the estimated global area that in a non-used state would be
24 covered in forests (Erb et al. 2017) has been converted to agriculture.

25 Global forest area declined by 3% since 1990 (about -5% since 1960) and continues to do so (FAO 2015a;
26 Keenan et al. 2015; MacDicken et al. 2015; FAO 1963; Figure 1.1), but uncertainties are large. *Low*
27 *agreement* relates to the concomitant trend of global tree-cover. Some remote-sensing based assessments
28 show global net-losses of forest or tree cover (Li et al. 2016; Nowosad et al. 2018; Hansen et al. 2013),
29 others indicate a net gain (Song et al. 2018). Tree-cover gains would be in line with observed and
30 modelled increases in photosynthetic active tissues (“greening”; Chen et al. 2019; Zhu et al. 2016; Zhao et
31 al. 2018; de Jong et al. 2013; Pugh et al. 2019; De Kauwe et al. 2016; Kolby Smith et al. 2015; see Box
32 2.3 in Chapter 2), but *confidence* remains *low* whether gross forest or tree cover gains are as large, or
33 larger, than losses. This uncertainty, together with poor information on forest management, affects
34 estimates and attribution of the land carbon sink (see Section 2.3, 4.3, 4.6). Discrepancies are caused by
35 different classification schemes and applied thresholds (e.g., minimum tree height and tree cover
36 thresholds used to define a forest), the divergence of forest and tree cover, and differences in methods and
37 spatiotemporal resolution (Keenan et al. 2015; Schepaschenko et al. 2015; Bastin et al. 2017; Sloan and
38 Sayer 2015; Chazdon et al. 2016a; Achard et al. 2014). However, there is *robust evidence and high*
39 *agreement* that a net loss of forest and tree cover prevails in the tropics and a net-gain, mainly of
40 secondary, semi-natural and planted, forests, in the temperate and boreal zones.

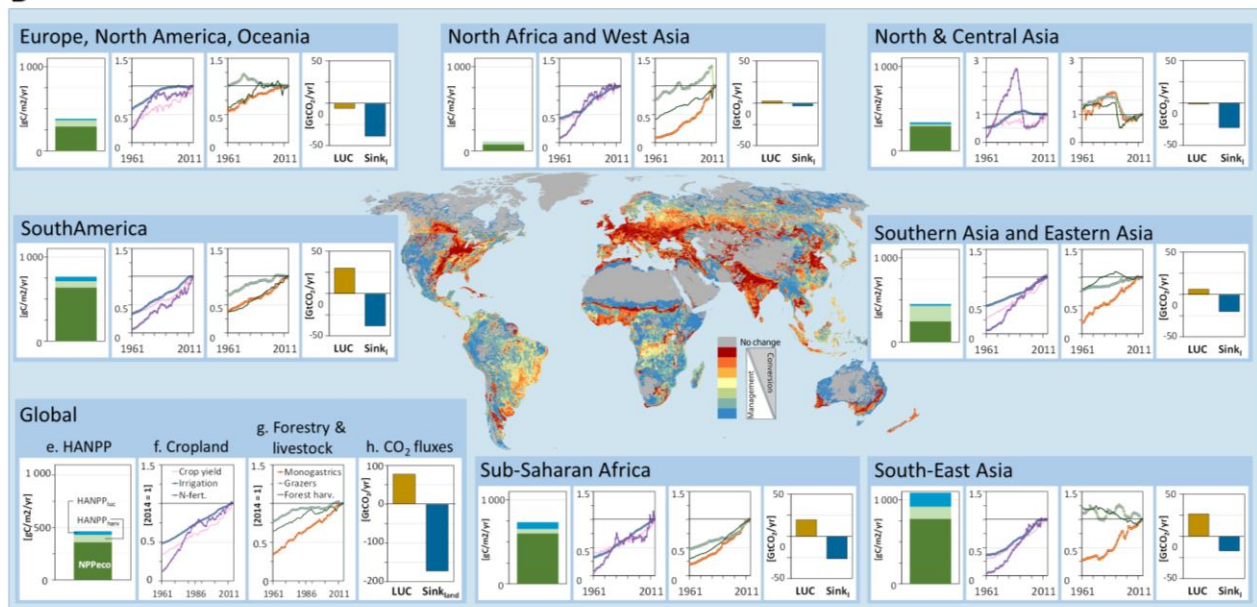

41 The observed regional and global historical land-use trends result in regionally distinct patterns of C
42 fluxes between land and the atmosphere (Figure 1.3B). They are also associated with declines in
43 biodiversity, far above background rates (Ceballos et al. 2015; De Vos et al. 2015; Pimm et al. 2014;
44 Newbold et al. 2015; Maxwell et al. 2016; Marques et al. 2019). Biodiversity losses from past global

1 land-use change have been estimated to be about 8–14%, depending on the biodiversity indicator applied
 2 (Newbold et al. 2015; Wilting et al. 2017; Gossner et al. 2016; Newbold et al. 2018; Paillet et al. 2010).
 3 In future, climate warming has been projected to accelerate losses of species diversity rapidly (Settele et
 4 al. 2014; Urban et al. 2016; Scholes et al. 2018; Fischer et al. 2018; Hoegh-Guldberg et al. 2018). The
 5 concomitance of land-use and climate-change pressures render ecosystem restoration a key challenge
 6 (Anderson-Teixeira 2018; Yang et al. 2019; see Section 4.8, 4.9).

7
 8 **Figure 1.3 Status and trends in the global land system. A. Trends in area, production and trade, and drivers**
 9 **of change. The map shows the global pattern of land systems (combination of maps Nachtergaele (2008); Ellis**
 10 **et al. (2010); Potapov et al. (2017); FAO’s Animal Production and Health Division (2018); livestock low/high**
 11 **relates to low or high livestock density, respectively). The inlay figures show, for the globe and 7 world**
 12 **regions, from left to right: (a) Cropland, permanent pastures and forest (used and unused) areas,**

1 standardised to total land area, (b) production in dry matter per year per total land area, (c) trade in dry
2 matter in percent of total domestic production, all for 1961 to 2014 (data from FAOSTAT (2018) and FAO
3 (1963) for forest area 1961). (d) drivers of cropland for food production between 1994 and 2011 (Alexander et
4 al. 2015). See panel “global” for legend. “Plant Produc., Animal P.”: changes in consumption of plant-based
5 products and animal-products, respectively. B. Selected land-use pressures and impacts. The map shows the
6 ratio between impacts on biomass stocks of land cover conversions and of land management (changes that
7 occur with land cover types; only changes larger than 30 gCm⁻² displayed; Erb et al. 2017), compared to the
8 biomass stocks of the potential vegetation (vegetation that would prevail in the absence of land use, but with
9 current climate). The inlay figures show, from left to right (e) the global Human Appropriation of Net
10 Primary production (HANPP) in the year 2005, in gCm⁻²yr⁻¹ (Krausmann et al. 2013). The sum of the three
11 components represents the NPP of the potential vegetation and consist of: (i) NPP_{eco}, i.e. the amount of NPP
12 remaining in ecosystem after harvest, (ii) HANPP_{harv}, i.e. NPP harvested or killed during harvest, and (iii)
13 HANPP_{luc}, i.e. NPP foregone due to land-use change. The sum of NPP_{eco} and HANPP_{harv} is the NPP of the
14 actual vegetation (Haberl et al. 2014; Krausmann et al. 2013). The two central inlay figures show changes in
15 land-use intensity, standardised to 2014, related to (f) cropland (yields, fertilisation, irrigated area) and (g)
16 forestry harvest per forest area, and grazers and monogastric livestock density per agricultural area
17 (FAOSTAT 2018). (h) Cumulative CO₂ fluxes between land and the atmosphere between 2000 and 2014.
18 LUC: annual CO₂ land use flux due to changes in land cover and forest management; Sink_{land}: the annual
19 CO₂ land sink caused mainly by the indirect anthropogenic effects of environmental change (e.g. climate
20 change and the fertilising effects of rising CO₂ and N concentrations), excluding impacts of land-use change
21 (Le Quéré et al. 2018; see Section 2.3).

22 1.2 Key challenges related to land use change

23 1.2.1 Land system change, land degradation, desertification and food security

24 1.2.1.1 Future trends in the global land system

25 Human population is projected to increase to nearly 9.8 (± 1) billion people by 2050 and 11.2 billion by
26 2100 (United Nations 2018). More people, a growing global middle class (Crist et al. 2017), economic
27 growth, and continued urbanisation (Jiang and O’Neill 2017) increase the pressures on expanding crop
28 and pasture area and intensifying land management. Changes in diets, efficiency and technology could
29 reduce these pressures (Billen et al. 2015; Popp et al. 2016; Muller et al. 2017; Alexander et al. 2015;
30 Springmann et al. 2018; Myers et al. 2017; Erb et al. 2016c; FAO 2018b; see Section 5.3, Section 6.2.2).

31 Given the large uncertainties underlying the many drivers of land use, as well as their complex relation to
32 climate change and other biophysical constraints, future trends in the global land system are explored in
33 scenarios and models that seek to span across these uncertainties (see Cross-Chapter Box 1: Scenarios, in
34 this Chapter). Generally, these scenarios indicate a continued increase in global food demand, owing to
35 population growth and increasing wealth. The associated land area needs are a key uncertainty, a function
36 of the interplay between production, consumption, yields, and production efficiency (in particular for
37 livestock and waste)(FAO 2018b; van Vuuren et al. 2017; Springmann et al. 2018; Riahi et al. 2017;
38 Prestele et al. 2016; Ramankutty et al. 2018; Erb et al. 2016b; Popp et al. 2016; see 1.3 and Cross-Chapter
39 Box 1: Scenarios, in this Chapter). Many factors, such as climate change, local contexts, education,
40 human and social capital, policy-making, economic framework conditions, energy availability,
41 degradation, and many more, affect this interplay, as discussed in all chapters of this report.

42 Global telecouplings in the land system, the distal connections and multidirectional flows between
43 regions and land systems, are expected to increase, due to urbanisation (Seto et al. 2012; van Vliet et al.
44 2017; Jiang and O’Neill 2017; Friis et al. 2016), and international trade (Konar et al. 2016; Erb et al.
45 2016b; Billen et al. 2015; Lassaletta et al. 2016). Telecoupling can support efficiency gains in production,
46 but can also lead to complex cause-effect chains and indirect effects such as land competition or leakage
47 (displacement of the environmental impacts, see glossary), with governance challenges (Baldos and

1 Hertel 2015; Kastner et al. 2014; Liu et al. 2013; Wood et al. 2018; Schröter et al. 2018; Lapola et al.
2 2010; Jadin et al. 2016; Erb et al. 2016b; Billen et al. 2015; Chaudhary and Kastner 2016; Marques et al.
3 2019; Seto and Ramankutty 2016; see Section 1.2.1.5). Furthermore, urban growth is anticipated to occur
4 at the expense of fertile (crop)land, posing a food security challenge, in particular in regions of high
5 population density and agrarian-dominated economies, with limited capacity to compensate for these
6 losses (Seto et al. 2012; Güneralp et al. 2013; Aronson et al. 2014; Martellozzo et al. 2015; Bren d'Amour
7 et al. 2016; Seto and Ramankutty 2016; van Vliet et al. 2017).

8 Future climate change and increasing atmospheric CO₂ concentration are expected to accentuate existing
9 challenges by, for example, shifting biomes or affecting crop yields (Baldos and Hertel 2015; Schlenker
10 and Lobell 2010; Lipper et al. 2014; Challinor et al. 2014; Myers et al. 2017; see Section 5.2.2), as well
11 as through land-based, climate change mitigation. There is *high confidence* that large-scale
12 implementation of bioenergy or afforestation can further exacerbate existing challenges (Smith et al. 2016;
13 see also Section 1.3.1 and Cross-chapter box 7 on bioenergy in Chapter 6).

14 **1.2.1.2 Land Degradation**

15 As discussed in Chapter 4, the concept of land degradation, including its definition, has been used in
16 different ways in different communities and in previous assessments (such as the IPBES Land
17 degradation and restoration assessment). In the SRCCL, land degradation is defined as a *negative trend in*
18 *land condition, caused by direct or indirect human-induced processes including anthropogenic climate*
19 *change, expressed as long-term reduction or loss of at least one of the following: biological productivity,*
20 *ecological integrity or value to humans.* This definition applies to forest and non-forest land (see Chapter
21 4 and Glossary).

22 Land degradation is a critical issue for ecosystems around the world due to the loss of actual or potential
23 productivity or utility (Ravi et al. 2010; Mirzabaev et al. 2015; FAO and ITPS 2015; Cerretelli et al.
24 2018). Land degradation is driven to a large degree by unsustainable agriculture and forestry,
25 socioeconomic pressures, such as rapid urbanisation and population growth, and unsustainable production
26 practices in combination with climatic factors (Field et al. 2014b; Lal 2009; Beinroth, F. H., Eswaran, H.,
27 Reich, P. F. and Van Den Berg 1994; Abu Hammad and Tumeizi 2012; Ferreira et al. 2018; Franco and
28 Giannini 2005; Abahussain et al. 2002).

29 Global estimates of the total degraded area (excluding deserted area) vary from less than 10 million km²
30 to over 60 million km², with additionally large disagreement regarding the spatial distribution (Gibbs and
31 Salmon 2015; see Section 4.3). The annual increase in the degraded land area has been estimated as
32 50,000–10,000 million km² yr⁻¹ (Stavi and Lal 2015), and the loss of total ecosystem services equivalent
33 to about 10% of the world's GDP in the year 2010 (Sutton et al. 2016). Although land degradation is a
34 common risk across the globe, poor countries remain most vulnerable to its impacts. Soil degradation is
35 of particular concern, due to the long period necessary to restore soils (Lal 2009; Stockmann et al. 2013;
36 Lal 2015), as well as the rapid degradation of primary forests through fragmentation (Haddad et al. 2015).
37 Among the most vulnerable ecosystems to degradation are high carbon stock wetlands (including
38 peatlands). Drainage of natural wetlands for use in agriculture leads to high CO₂ emissions and
39 degradation (*high confidence*) (Strack 2008; Limpens et al. 2008; Aich et al. 2014; Murdiyarso et al.
40 2015; Kauffman et al. 2016; Dohong et al. 2017; Arifanti et al. 2018; Evans et al. 2019). Land
41 degradation is an important factor contributing to uncertainties in the mitigation potential of land-based
42 ecosystems (Smith et al. 2014). Furthermore, degradation that reduces forest (and agricultural) biomass
43 and soil organic carbon leads to higher rates of runoff (*high confidence*) (Molina et al. 2007; Valentin et

1 al. 2008; Mateos et al. 2017; Noordwijk et al. 2017) and hence to increasing flood risk (*low confidence*)
2 (Bradshaw et al. 2007; Laurance 2007; van Dijk et al. 2009).

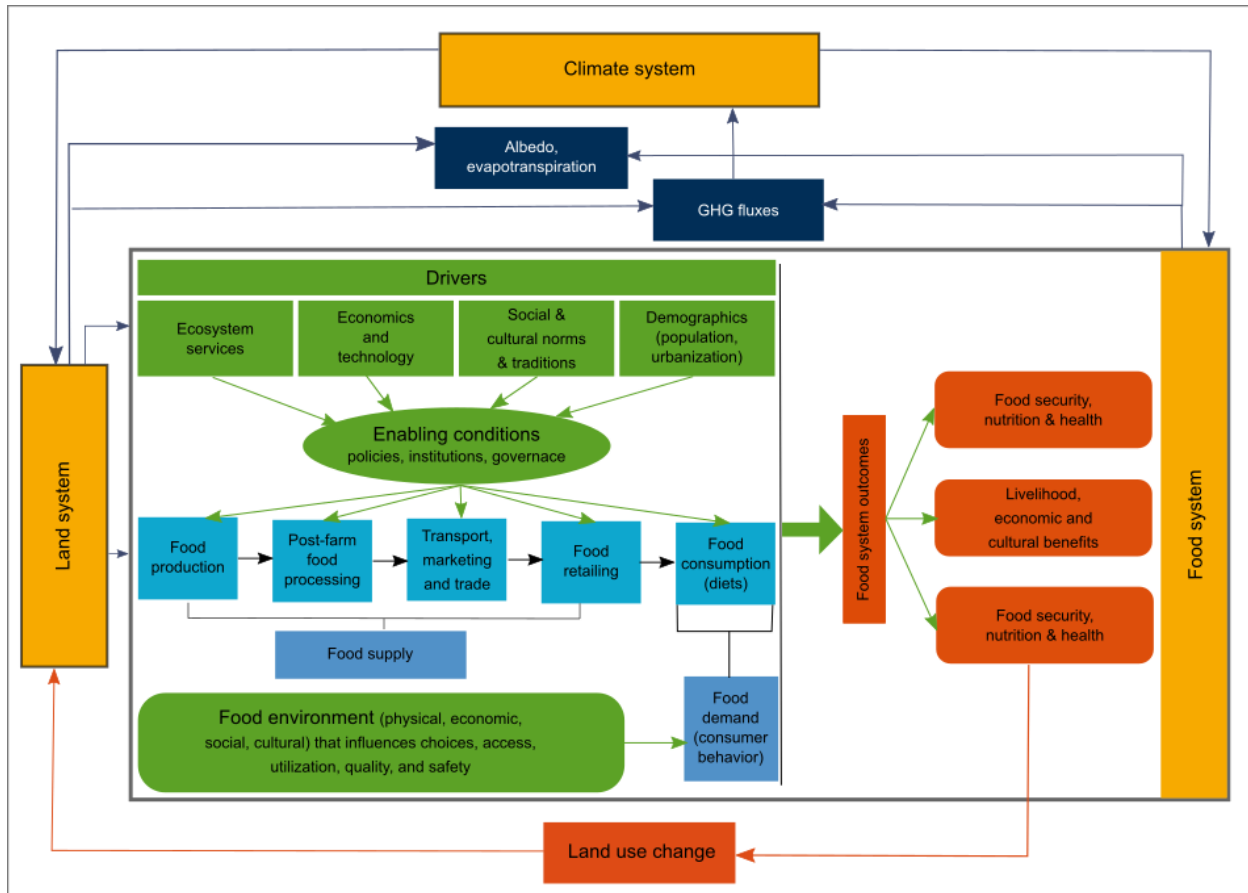

3 **1.2.1.3 Desertification**

4 The SRCCL adopts the definition of the UNCCD of desertification being land degradation in arid, semi-
5 arid and dry sub-humid areas (drylands) (see glossary, and Section 3.1.1). Desertification results from
6 various factors, including climate variations and human activities, and is not limited to irreversible forms
7 of land degradation (Tal 2010)(Bai et al. 2008). A critical challenge in the assessment of desertification is
8 to identify a “non-desertified” reference state (Bestelmeyer et al. 2015). While climatic trends and
9 variability can change the intensity of desertification processes, some authors exclude climate effects,
10 arguing that desertification is a purely human-induced process of land degradation with different levels of
11 severity and consequences (Sivakumar 2007).

12 As a consequence of varying definitions and different methodologies, the area of desertification varies
13 widely (see (D’Odorico et al. 2013; Bestelmeyer et al. 2015), and references therein). Arid regions of the
14 world cover up to about 46% of the total terrestrial surface (about 60 million km²; Pravalie 2016;
15 Koutroulis 2019). Around 3 billion people reside in dryland regions (D’Odorico et al. 2013; Maestre et al.
16 2016; see Section 3.1.1), and the number of people living in areas affected by desertification has been
17 estimated as > 630 million, compared to 211 million in the early 1960s (see Fig. 1.1, see Section 3.1.1).
18 The combination of low rainfall with frequently infertile soils renders these regions, and the people who
19 rely on them, vulnerable to both climate change, and unsustainable land management (*high confidence*).
20 In spite of the national, regional and international efforts to combat desertification, it remains one of the
21 major environmental problems (Abahussain et al. 2002; Cherlet et al. 2018).

22 **1.2.1.4 Food security, food systems and linkages to land-based ecosystems**

23 The High Level Panel of Experts of the Committee on Food Security define the food system as to “gather
24 all the elements (environment, people, inputs, processes, infrastructures, institutions, etc.) and activities
25 that relate to the production, processing, distribution, preparation and consumption of food, and the
26 output of these activities, including socio-economic and environmental outcomes” (HLPE 2017).
27 Likewise, food security has been defined as “a situation that exists when all people, at all times, have
28 physical, social and economic access to sufficient, safe and nutritious food that meets their dietary needs
29 and food preferences for an active and healthy life “ (FAO 2017). By this definition, food security is
30 characterised by food availability, economic and physical access to food, food utilisation and food
31 stability over time. Food and nutrition security is one of the key outcomes of the food system (FAO
32 2018b; Figure 1.4).

1
 2 **Figure 1.4 Food system (and its relations to land and climate):** The food system is conceptualised through
 3 **supply (production, processing, marketing and retailing) and demand (consumption and diets) that are**
 4 **shaped by physical, economic, social and cultural determinants influencing choices, access, utilisation,**
 5 **quality, safety and waste. Food system drivers (ecosystem services, economics and technology, social and**
 6 **cultural norms and traditions, and demographics) combine with the enabling conditions (policies, institutions**
 7 **and governance) to affect food system outcomes including food security, nutrition and health, livelihoods,**
 8 **economic and cultural benefits as well as environmental outcomes or side-effects (nutrient and soil loss, water**
 9 **use and quality, GHG emissions and other pollutants). Climate and climate change has direct impact on the**
 10 **food system (productivity, variability, nutritional quality) while the latter contribute to local climate (albedo,**
 11 **evapotranspiration) and global warming (GHGs). The land system (function, structures, and processes) affect**
 12 **the food system directly (food production) and indirectly (ecosystem services) while food demand and supply**
 13 **processes affect land (land use change) and land-related processes (e.g., land degradation, desertification) (see**
 14 **chapter 5).**

15 After a prolonged decline, world hunger appears to be on the rise again with the number of
 16 undernourished people having increased to an estimated 821 million in 2017, up from 804 million in 2016
 17 and 784 million in 2015, although still below the 900 million reported in 2000 (FAO et al. 2018; see
 18 Section 5.1.2). Of the total undernourished in 2018, lived, for example, 256.5 million in Africa, and 515.1
 19 million in Asia (excluding Japan). The same report also states that child undernourishment continues to
 20 decline, but levels of overweight populations and obesity are increasing. The total number of overweight
 21 children in 2017 was 38-40 million worldwide, and globally up to around two billion adults are by now
 22 overweight (see Section 5.1.2). FAO also estimated that close to 2000 million people suffer from
 23 micronutrient malnutrition (FAO 2018b).

1 Food insecurity most notably occurs in situations of conflict and conflict combined with droughts or
2 floods (Cafiero et al. 2018; Smith et al. 2017). The close parallel between food insecurity prevalence and
3 poverty means that tackling development priorities would enhance sustainable land use options for
4 climate mitigation.

5 Climate change affects the food system as changes in trends and variability in rainfall and temperature
6 variability impact crop and livestock productivity and total production (Osborne and Wheeler 2013;
7 Tigchelaar et al. 2018; Iizumi and Ramankutty 2015), the nutritional quality of food (Loladze 2014;
8 Myers et al., 2014; Ziska et al. 2016; Medek et al., 2017), water supply (Nkhonjera 2017), and incidence
9 of pests and diseases (Curtis et al. 2018). These factors also impact on human health and increase
10 morbidity and affect human ability to process ingested food (Franchini and Mannucci 2015; Wu et al.
11 2016; Raiten and Aimone 2017). At the same time, the food system generates negative externalities (the
12 environmental effects of production and consumption) in the form of GHG emissions (Section 1.1.2,
13 Section 2.3), pollution (van Noordwijk and Brussaard 2014; Thyberg and Tonjes 2016; Borsato et al.
14 2018; Kibler et al. 2018), water quality (Malone et al. 2014; Norse and Ju 2015), and ecosystem services
15 loss (Schipper et al. 2014; Eraerts et al. 2017) with direct and indirect impacts on climate change and
16 reduced resilience to climate variability. As food systems are assessed in relation to their contribution to
17 global warming and/or to land degradation (e.g., livestock systems) it is critical to evaluate their
18 contribution to food security and livelihoods and to consider alternatives, especially for developing
19 countries where food insecurity is prevalent (Röös et al. 2017; Salmon et al. 2018).

20 **1.2.1.5 Challenges arising from land governance**

21 Land use change has both positive and negative effects: it can lead to economic growth, but it can become
22 a source of tension and social unrest leading to elite capture, and competition (Haberl 2015). Competition
23 for land plays out continuously among different use types (cropland, pastureland, forests, urban spaces,
24 and conservation and protected lands) and between different users within the same land use category
25 (subsistence vs. commercial farmers)(Dell'Angelo et al. 2017b). Competition is mediated through
26 economic and market forces (expressed through land rental and purchases, as well as trade and
27 investments). In the context of such transactions, power relations often disfavour disadvantaged groups
28 such as small scale farmers, indigenous communities or women (Doss et al. 2015; Ravnborg et al. 2016).
29 These drivers are influenced to a large degree by policies, institutions and governance structures. Land
30 governance determines not only who can access the land, but also the role of land ownership (legal,
31 formal, customary or collective) which influences land use, land use change and the resulting land
32 competition (Moroni 2018).

33 Globally, there is competition for land because it is a finite resource and because most of the highly-
34 productive land is already exploited by humans (Lambin and Meyfroidt 2011; Lambin 2012; Venter et al.
35 2016). Driven by growing population, urbanisation, demand for food and energy, as well as land
36 degradation, competition for land is expected to accentuate land scarcity in the future(Tilman et al. 2011;
37 Foley et al. 2011; Lambin 2012; Popp et al. 2016)(*robust evidence, high agreement*). Climate change
38 influences land use both directly and indirectly, as climate policies can also play a role in increasing
39 land competition via forest conservation policies, afforestation, or energy crop production (see Section
40 1.3.1), with the potential for implications for food security (Hussein et al. 2013) and local land-ownership.

41 An example of large-scale change in land ownership is the much-debated large-scale land acquisition
42 (LSLA) by investors which peaked in 2008 during the food price crisis, the financial crisis, and has also
43 been linked to the search for biofuel investments (Dell'Angelo et al. 2017a). Since 2000, almost 50
44 million hectares of land, have been acquired, and there are no signs of stagnation in the foreseeable future

1 (Land Matrix 2018). The LSLA phenomenon, which largely targets agriculture, is widespread, including
 2 Sub-Saharan Africa, Southeast Asia, Eastern Europe and Latin America (Rulli et al. 2012; Nolte et al.
 3 2016; Constantin et al. 2017). LSLAs are promoted by investors and host governments on economic
 4 grounds (infrastructure, employment, market development)(Deininger et al. 2011), but their social and
 5 environmental impacts can be negative and significant (Dell'Angelo et al. 2017a).

6 Much of the criticism of LSLA focuses on their social impacts, especially the threat to local communities'
 7 land rights (especially indigenous people and women) (Anseeuw et al. 2011) and displaced communities
 8 creating secondary land expansion (Messerli et al. 2014; Davis et al. 2015). The promises that LSLAs
 9 would develop efficient agriculture on non-forested, unused land (Deininger et al. 2011) has so far not
 10 been fulfilled. However, LSLAs is not the only outcome of weak land governance structures (Wang et al.
 11 2016), other forms of inequitable or irregular land acquisition can also be home-grown pitting one
 12 community against a more vulnerable group (Xu 2018) or land capture by urban elites (McDonnell 2017).
 13 As demands on land are increasing, building governance capacity and securing land tenure becomes
 14 essential to attain sustainable land use, which has the potential to mitigate climate change, promote food
 15 security, and potentially reduce risks of climate-induced migration and associated risks of conflicts (see
 16 Section 7.6).

17 **1.2.2 Progress in dealing with uncertainties in assessing land processes in the climate** 18 **system**

19 **1.2.2.1 Concepts related to risk, uncertainty and confidence**

20 In context of the SRCCL, risk refers to the potential for the adverse consequences for human or (land-
 21 based) ecological systems, arising from climate change or responses to climate change. Risk related to
 22 climate change impacts integrates across the hazard itself, the time of exposure and the vulnerability of
 23 the system; the assessment of all three of these components, their interactions, and outcomes are uncertain
 24 (see glossary for expanded definition and Section 7.1.2). For instance, a risk to human society is the
 25 continued loss of productive land which might arise from climate change, mismanagement, or a
 26 combination of both factors. However, risk can also arise from the potential for adverse consequences
 27 from responses to climate change, such as widespread deployment of bioenergy which is intended to
 28 reduce greenhouse gas emissions and thus limit climate change, but can present its own risks to food
 29 security (see chapters 5, 6 and 7).

30 Demonstrating with some statistical certainty that the climate or the land system affected by climate or
 31 land use has changed (detection), and evaluating the relative contributions of multiple causal factors to
 32 that change (with a formal assessment of confidence; attribution. See glossary) remain challenging
 33 aspects in both observations and models (Rosenzweig and Neofotis 2013; Gillett et al. 2016; Lean 2018).
 34 Uncertainties arising for example, from missing or imprecise data, ambiguous terminology, incomplete
 35 process representation in models, or human decision making contribute to these challenges, and some
 36 examples are provided in this subsection. In order to reflect various sources of uncertainties in the state of
 37 scientific understanding, IPCC assessment reports provide estimates of confidence (Mastrandrea et al.
 38 2011). This confidence language is also used in the SRCCL (Figure 1.5):

Agreement ↑	High agreement Limited evidence	High agreement Medium evidence	High agreement Robust evidence	Confidence low high
	Medium agreement Limited evidence	Medium agreement Medium evidence	Medium agreement Robust evidence	
	Low agreement Limited evidence	Low agreement Medium evidence	Low agreement Robust evidence	
	Evidence (type, amount, quality, consistency) →			

Figure 1.5 Use of confidence language

1.2.2.2 Nature and scope of uncertainties related to land use

Identification and communication of uncertainties is crucial to support decision making towards sustainable land management. Providing a robust, and comprehensive understanding of uncertainties in observations, models and scenarios is a fundamental first step in the IPCC confidence framework (see above). This will remain a challenge in future, but some important progress has been made over recent years.

Uncertainties in observations

The detection of changes in vegetation cover and structural properties underpins the assessment of land-use change, degradation and desertification. It is continuously improving by enhanced Earth observation capacity (Hansen et al. 2013; He et al. 2018; Ardö et al. 2018; Spennemann et al. 2018) (see also Table SM. 1.1 in Supplementary Materials). Likewise, the picture of how soil organic carbon, and GHG and water fluxes respond to land-use change and land management continues to improve through advances in methodologies and sensors (Kostyanovsky et al. 2018; Brümmer et al. 2017; Iwata et al. 2017; Valayamkunnath et al. 2018). In both cases, the relative shortness of the record, data gaps, data treatment algorithms and –for remote sensing- differences in the definitions of major vegetation cover classes limits the detection of trends (Alexander et al. 2016a; Chen et al. 2014; Yu et al. 2014; Lacaze et al. 2015; Song 2018; Peterson et al. 2017). In many developing countries, the cost of satellite remote sensing remains a challenge, although technological advances are starting to overcome this problem (Santilli et al. 2018), while ground-based observations networks are often not available.

Integration of multiple data sources in model and data assimilation schemes reduces uncertainties (Li et al. 2017; Clark et al. 2017; Lees et al. 2018), which might be important for the advancement of early warning systems. Early warning systems are a key feature of short-term (i.e. seasonal) decision support systems and are becoming increasingly important for sustainable land management and food security (Shtienberg 2013; Jarroudi et al. 2015; see Section 6.2.3, 7.4.3). Early warning systems can help to optimise fertiliser and water use, aid disease suppression, and/or increase the economic benefit by enabling strategic farming decisions on when and what to plant (Caffi et al. 2012; Watmuff et al. 2013; Jarroudi et al. 2015; Chipanshi et al. 2015). Their suitability depends on the capability of the methods to accurately predict crop or pest developments, which in turn depends on expert agricultural knowledge, and the accuracy of the weather data used to run phenological models (Caffi et al. 2012; Shtienberg 2013).

Uncertainties in models

Model intercomparison is a widely used approach to quantify some sources of uncertainty in climate change, land-use change and ecosystem modelling, often associated with the calculation of model-ensemble medians or means (see e.g., Section 2.2; Section 5.2). Even models of broadly similar structure differ in their projected outcome for the same input, as seen for instance in the spread in climate change

1 projections from Earth System Models (ESMs) to similar future anthropogenic GHG emissions (Parker
2 2013; Stocker et al. 2013a). These uncertainties arise, for instance, from different parameter values,
3 different processes represented in models, or how these processes are mathematically described. If the
4 output of ESM simulations are used as input to impact models, these uncertainties can propagate to
5 projected impacts (Ahlstrom et al. 2013).

6 Thus, the increased quantification of model performance in benchmarking exercises (the repeated
7 confrontation of models with observations to establish a track-record of model developments and
8 performance) is an important development to support the design and the interpretation of the outcomes of
9 model ensemble studies (Randerson et al. 2009; Luo et al. 2012; Kelley et al. 2013). Since observational
10 data sets in themselves are uncertain, benchmarking benefits from transparent information on the
11 observations that are used, and the inclusion of multiple, regularly updated data sources (Luo et al. 2012;
12 Kelley et al. 2013). Improved benchmarking approaches and the associated scoring of models may
13 support weighted model means contingent on model performance. This could be an important step
14 forward when calculating ensemble means across a range of models (Buisson et al. 2009; Parker 2013;
15 Prestele et al. 2016).

16 *Uncertainties arising from unknown futures*

17 Large differences exist in projections of future land cover change, both between and within scenario
18 projections (Fuchs et al. 2015; Eitelberg et al. 2016; Popp et al. 2016; Krause et al. 2017; Alexander et al.
19 2016a). These differences reflect the uncertainties associated with baseline data, thematic classifications,
20 different model structures and model parameter estimation (Alexander et al. 2017a; Prestele et al. 2016;
21 Cross-Chapter Box 1: Scenarios, in this Chapter). Likewise, projections of future land-use change are also
22 highly uncertain, reflecting –among other factors- the absence of important crop, pasture and management
23 processes in Integrated Assessment Models (Cross-Chapter Box 1: Scenarios, in this Chapter; Rose 2014)
24 and in models of the terrestrial carbon cycle (Arneth et al. 2017). These processes have been shown to
25 have large impacts on carbon stock changes (Arneth et al. 2017). Common scenario frameworks are used
26 to capture the range of future uncertainties in scenarios. The most commonly used recent framework in
27 climate change studies is based on the Representative Concentration Pathways (RCPs) and the Shared
28 Socio-economic Pathways (SSPs)(Popp et al. 2016; Riahi et al. 2017). The RCPs prescribe levels of
29 radiative forcing (Wm^{-2}) arising from different atmospheric concentrations of GHGs that lead to different
30 levels of climate change. For example, RCP2.6 (2.6 Wm^{-2}) is projected to lead to global mean
31 temperature changes of about 0.9°C – 2.3°C , and RCP8.5 (8.5 Wm^{-2}) to global mean temperature changes
32 of about 3.2°C – 5.4°C (van Vuuren et al 2014).

33 The SSPs describe alternative trajectories of future socio-economic development with a focus on
34 challenges to climate mitigation and challenges to climate adaptation (O'Neill et al. 2014). SSP1
35 represents a sustainable and co-operative society with a low carbon economy and high capacity to adapt
36 to climate change. SSP3 has social inequality that entrenches reliance on fossil fuels and limits adaptive
37 capacity. SSP4 has large differences in income within and across world regions that facilitates low carbon
38 economies in places, but limits adaptive capacity everywhere. SSP5 is a technologically advanced world
39 with a strong economy that is heavily dependent on fossil fuels, but with high adaptive capacity. SSP2 is
40 an intermediate case between SSP1 and SSP3 (O'Neill et al. 2014). The SSPs are commonly used with
41 models to project future land use change (Cross-Chapter Box 1: Scenarios, in this Chapter).

42 The SSPs map onto the RCPs through shared assumptions. For example, a higher level of climate change
43 (RCP8.5) is associated with higher challenges for climate change mitigation (SSP5). Not all SSPs are,
44 however, associated with all RCPs. For example, an SSP5 world is committed to high fossil fuel use,

1 associated GHG emissions, and this is not commensurate with lower levels of climate change (e.g.,
2 RCP2.6). (Engstrom et al. 2016) took this approach further by ascribing levels of probability that
3 associate an SSP with an RCP, contingent on the SSP scenario assumptions (see Cross-Chapter Box 1:
4 Scenarios, in this Chapter).

Cross-Chapter Box 1: Scenarios and other methods to characterise the future of land

Mark Rounsevell (United Kingdom/Germany), Almut Arneth (Germany), Katherine Calvin (The United States of America), Edouard Davin (France/Switzerland), Jan Fuglestad (Norway), Joanna House (United Kingdom), Alexander Popp (Germany), Joana Portugal Pereira (United Kingdom), Prajal Pradhan (Nepal/Germany), Jim Skea (United Kingdom), David Viner (United Kingdom).

About this box

The land-climate system is complex and future changes are uncertain, but methods exist (collectively known as *futures analysis*) to help decision makers in navigating through this uncertainty. Futures analysis comprises a number of different and widely used methods, such as scenario analysis (Rounsevell and Metzger 2010), envisioning or target setting (Kok et al. 2018), pathways analysis¹ (IPBES 2016; IPCC 2018), and conditional probabilistic futures (Vuuren et al. 2018; Engstrom et al. 2016; Henry et al. 2018)(see Cross-Chapter Box 1, Table 1). Scenarios and other methods to characterise the future can support a discourse with decision makers about the sustainable development options that are available to them. All chapters of this assessment draw conclusions from futures analysis and so, the purpose of this box is to outline the principal methods used, their application domains, their uncertainties and their limitations.

Exploratory scenario analysis

Many exploratory scenarios are reported in climate and land system studies on climate change (Dokken 2014), land-based, climate-change mitigation for example, reforestation/afforestation, avoided deforestation and bioenergy (Kraxner et al. 2013; Humpenoder et al. 2014; Krause et al. 2017) and climate change impacts and adaptation (Warszawski et al. 2014). There are global-scale scenarios of food security (Foley et al. 2011; Pradhan et al. 2013, 2014), but fewer scenarios of desertification, land degradation and restoration (Wolff et al. 2018). Exploratory scenarios combine qualitative ‘storylines’ or descriptive narratives of the underlying causes (or drivers) of change (Nakicenovic and Swart 2000; Rounsevell and Metzger 2010; O’Neill et al. 2014) with quantitative projections from computer models. Different types of models are used for this purpose based on very different modelling paradigms, baseline data and underlying assumptions (Alexander et al. 2016a; Prestele et al. 2016). Cross-Chapter Box 1, Figure 1 outlines how a combination of models can quantify these components as well as the interactions between them.

Exploratory scenarios often show that socio-economic drivers have a larger effect on land use change than climate drivers (Harrison et al. 2014, 2016). Of these, technological development is critical in affecting the production potential (yields) of food and bioenergy and the feed conversion efficiency of livestock (Rounsevell et al. 2006; Wise et al. 2014; Kreidenweis et al. 2018), as well as the area of land needed for food production (Foley et al. 2011; Weindl et al. 2017; Kreidenweis et al. 2018). Trends in consumption, for example, diets, waste reduction, are also fundamental in affecting land use change (Pradhan et al. 2013; Alexander et al. 2016b; Weindl et al. 2017; Alexander et al. 2017; Vuuren et al.

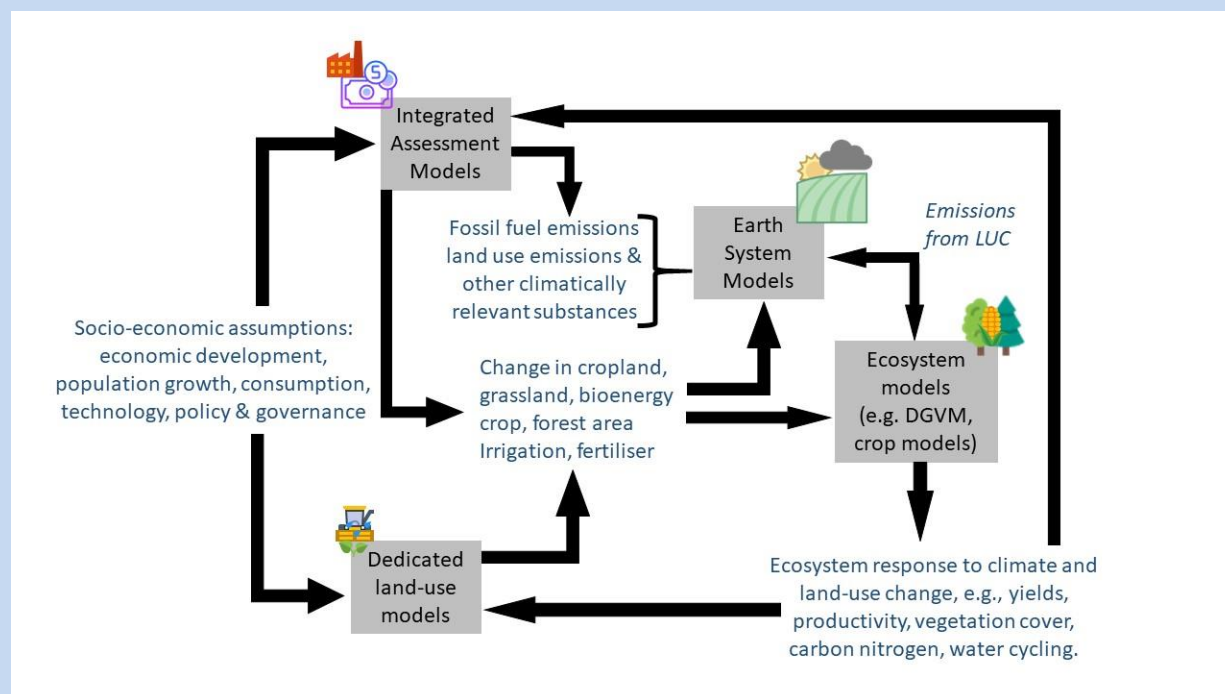

¹ FOOTNOTE: Different communities have a different understanding of the concept of pathways, as noted in the Cross-Chapter Box 1 on scenarios in (IPCC 2018). Here, we refer to pathways as a description of the time-dependent actions required to move from today’s world to a set of future visions (IPCC 2018). However, the term pathways is commonly used in the climate change literature as a synonym for projections or trajectories (e.g. Shared socio-economic pathways).

2018; Bajželj et al. 2014). Scenarios of land-based mitigation through large-scale bioenergy production and afforestation often lead to negative trade-offs with food security (food prices), water resources and biodiversity (cross chapter box on bioenergy, Ch6).

Cross-Chapter Box 1, Table 1 Description of the principal methods used in land and climate futures analysis

Futures method	Description and subtypes	Application domain	Time horizon	Examples in this assessment
<i>Exploratory scenarios.</i> Trajectories of change in system components from the present to contrasting, alternative futures based on plausible and internally consistent assumptions about the underlying drivers of change	<i>Long-term projections</i> quantified with models	Climate system, land system and other components of the environment (e.g., biodiversity, ecosystem functioning, water resources and quality), for example the SSPs	10-100 years	2.3, 2.6.2, 5.2.3, 6.1.4, 6.4.4, 7.2
	<i>Business-as-usual scenarios</i> (including 'outlooks')	A continuation into the future of current trends in key drivers to explore the consequences of these in the near-term	5-10 years, 20-30 years for outlooks	1.2.1, 2.6.2, 5.3.4, 6.1.4
	<i>Policy & planning scenarios</i> (including business planning)	Ex Ante analysis of the consequences of alternative policies or decisions based on known policy options or already implemented policy and planning measures	5-30 years	2.6.3, 5.5.2, 5.6.2, 6.4.4
	<i>Stylised scenarios</i> (with single and multiple options)	Afforestation/reforestation areas, bioenergy areas, protected areas for conservation, consumption patterns (e.g., diets, food waste)	10-100 years	2.6.1, 5.5.1, 5.5.2, 5.6.1, 5.6.2, 6.4.4, 7.2
	<i>Shock scenarios</i> (high impact single events)	Food supply chain collapses, cyberattacks, pandemic diseases (humans, crops and livestock)	Near-term events (up to 10 years) leading to long-term impacts (10-100 years)	5.8.1
	<i>Conditional probabilistic futures</i> ascribe probabilities to uncertain drivers that are conditional on scenario assumptions	Where some knowledge is known about driver uncertainties, for example, population, economic growth, land use change	10-100 years	1.2
<i>Normative scenarios.</i> Desired futures or outcomes that are aspirational and how to achieve them	<i>Visions, goal-seeking or target-seeking scenarios</i>	Environmental quality, societal development, human well-being, the Representative Concentration Pathways (RCPs,) 1.5 °C scenarios	5-10 years to 10-100 years	2.6.2, 6.4.4, 7.2, 5.5.2

	<i>Pathways</i> as alternative sets of choices, actions or behaviours that lead to a future vision (goal or target)	Socio-economic systems, governance and policy actions	5-10 years to 10-100 years	5.5.2, 6.4.4, 7.2
--	---	---	----------------------------	-------------------

Cross-Chapter Box 1, Figure 1 Interactions between land and climate system components and models in scenario analysis. The blue text describes selected model inputs and outputs.

Many exploratory scenarios are based on common frameworks such as the Shared Socio-economic Pathways (SSPs) (Popp et al. 2016; Riahi et al. 2017; Doelman et al. 2018) (see section 1.2). However, other methods are used. *Stylised scenarios* prescribe assumptions about climate and land use change solutions for example, dietary change, food waste reduction, afforestation areas (Pradhan et al. 2013, 2014; Kreidenweis et al. 2016; Rogelj et al. 2018b; Seneviratne et al. 2018; Vuuren et al. 2018). These scenarios provide useful thought experiments, but the feasibility of achieving the stylised assumptions is often unknown. *Shock scenarios* explore the consequences of low probability, high impact events such as pandemic diseases, cyberattacks and failures in food supply chains (Challinor et al. 2018) often in food security studies. Because of the diversity of exploratory scenarios, attempts have been made to categorise them into ‘archetypes’ based on the similarity between their assumptions in order to facilitate communication (IPBES 2018a).

Conditional probabilistic futures explore the consequences of model parameter uncertainty in which these uncertainties are conditional on scenario assumptions (Neill 2004). Only a few studies have applied the conditional probabilistic approach to land use futures (Brown et al. 2014; Engstrom et al. 2016; Henry et al. 2018). By accounting for uncertainties in key drivers these studies show large ranges in land use change, for example, global cropland areas of 893–2380 Mha by the end of the 21st Century (Engstrom et al. 2016). They also find that land-use targets may not be achieved, even across a wide

range of scenario parameter settings, because of trade-offs arising from the competition for land (Henry et al. 2018; Heck et al. 2018). Accounting for uncertainties across scenario assumptions can lead to convergent outcomes for land use change, which implies that certain outcomes are more robust across a wide range of uncertain scenario assumptions (Brown et al. 2014).

In addition to global scale scenario studies, sub-national studies demonstrate that regional climate change impacts on the land system are highly variable geographically because of differences in the spatial patterns of both climate and socio-economic change (Harrison et al. 2014). Moreover, the capacity to adapt to these impacts is strongly dependent on the regional, socio-economic context and coping capacity (Dunford et al. 2014); processes that are difficult to capture in global scale scenarios. Regional scenarios are often co-created with stakeholders through participatory approaches (Kok et al. 2014), which is powerful in reflecting diverse worldviews and stakeholder values. Stakeholder participatory methods provide additional richness and context to storylines, as well as providing saliency and legitimacy for local stakeholders (Kok et al. 2014).

Normative scenarios: visions and pathways analysis

Normative scenarios reflect a desired or target-seeking future. Pathways analysis is important in moving beyond the ‘*what if?*’ perspective of exploratory scenarios to evaluate how normative futures might be achieved in practice, recognising that multiple pathways may achieve the same future vision. Pathways analysis focuses on consumption and behavioural changes through transitions and transformative solutions (IPBES 2018a). Pathways analysis is highly relevant in support of policy, since it outlines sets of time-dependent actions and decisions to achieve future targets, especially with respect to sustainable development goals, as well as highlighting trade-offs and co-benefits (IPBES 2018a). Multiple, alternative pathways have been shown to exist that mitigate trade-offs whilst achieving the priorities for future sustainable development outlined by governments and societal actors. Of these alternatives, the most promising focus on long-term societal transformations through education, awareness raising, knowledge sharing and participatory decision-making (IPBES 2018a).

What are the limitations of land use scenarios?

Applying a common scenario framework (e.g., RCPs/SSPs) supports the comparison and integration of climate and land system scenarios, but a ‘climate-centric’ perspective can limit the capacity of these scenarios to account for a wider range of land-relevant drivers (Rosa et al. 2017). For example, in climate mitigation scenarios it is important to assess the impact of mitigation actions on the broader environment for example, biodiversity, ecosystem functioning, air quality, food security, desertification/degradation and water cycles (Rosa et al. 2017). This implies the need for a more encompassing and flexible approach to creating scenarios that considers other environmental aspects, not only as a part of impact assessment, but also during the process of creating the scenarios themselves.

A limited number of models can quantify global scale, land use change scenarios, and there is large variance in the outcomes of these models (Alexander et al. 2016a; Prestele et al. 2016). In some cases, there is greater variability between the models themselves than between the scenarios that they are quantifying, and these differences vary geographically (Prestele et al. 2016). These differences arise from variations in baseline datasets, thematic classes and modelling paradigms (Alexander et al. 2016a; Popp et al. 2016; Prestele et al. 2016). Model evaluation is critical in establishing confidence in the outcomes of modelled futures (Ahlstrom et al. 2012; Kelley et al. 2013). Some, but not all, land use models are evaluated against observational data and model evaluation is rarely reported. Hence, there is a need for more transparency in land use modelling, especially in evaluation and testing, as well as making model code available with complete sets of scenario outputs (e.g., Dietrich et al. 2018).

There is a small, but growing literature on quantitative pathways to achieve normative visions and their associated trade-offs (IPBES 2018a). Whilst the visions themselves may be clearly articulated, the societal choices, behaviours and transitions needed to attain them, are not. Better accounting for human behaviour and decision-making processes in global scale, land-use models would improve the capacity to quantify pathways to sustainable futures (Rounsevell et al. 2014; Arneth et al. 2014; Calvin and Bond-Lamberty 2018). It is, however, difficult to understand and represent human behaviour and social interaction processes at global scales. Decision-making in global models is commonly represented through economic processes (Arneth et al. 2014). Other important human processes for land systems including equity, fairness, land tenure and the role of institutions and governance, receive less attention, and this limits the use of global models to quantify transformative pathways, adaptation and mitigation (Arneth et al. 2014; Rounsevell et al. 2014; Wang et al. 2016). No model exists at present to represent complex human behaviours at the global scale, although the need has been highlighted (Rounsevell et al. 2014; Arneth et al. 2014; Robinson et al. 2017; Brown et al. 2017; Calvin and Bond-Lamberty 2018).

1

2 **1.2.2.3 Uncertainties in decision making**

3 Decision makers develop and implement policy in the face of many uncertainties (Rosenzweig and
4 Neofotis 2013; Anav et al. 2013; Ciais et al. 2013a; Stocker et al. 2013b; see Section 7.5). In context of
5 climate change, the term *deep uncertainty* is frequently used to denote situations in which either the
6 analysis of a situation is inconclusive, or parties to a decision cannot agree on a number of criteria that
7 would help to rank model results in terms of likelihood (e.g., Hallegatte and Mach 2016; Maier et al.
8 2016) (see Section 7.1, 7.5, and Supplementary Material Table SM. 1.2). However, existing uncertainty
9 does not support societal and political inaction.

10 The many ways of dealing with uncertainty in decision making can be summarised by two decision
11 approaches: (economic) cost-benefit analyses, and the precautionary approach. A typical variant of cost
12 benefit analysis is the minimisation of negative consequences. This approach needs reliable probability
13 estimates (Gleckler et al. 2016; Parker 2013) and tends to focus on the short-term. The precautionary
14 approach does not take account of probability estimates (cf. Raffensperger and Tickner 1999), but instead
15 focuses on avoiding the worst outcome (Gardiner 2006).

16 Between these two extremes, various decision approaches seek to address uncertainties in a more
17 reflective manner that avoids the limitations of cost-benefit analysis and the precautionary approach.
18 Climate-informed decision analysis combines various approaches to explore options and the
19 vulnerabilities and sensitivities of certain decisions. Such an approach includes stakeholder involvement
20 (e.g., elicitation methods), and can be combined with, for example, analysis of climate or land-use change
21 modelling (Hallegatte and Rentschler 2015; Luedeling and Shepherd 2016).

22 Flexibility is facilitated by political decisions that are not set in stone and can change over time (Walker et
23 al. 2013; Hallegatte and Rentschler 2015). Generally, within the research community that investigates
24 deep uncertainty a paradigm is emerging that requires to develop a strategic vision of the long- or mid-
25 term future, while committing to short-term actions and establishing a framework to guide future actions
26 including revisions and flexible adjustment of decisions (Haasnoot 2013; see Section 7.5).

27 **1.3 Response options to the key challenges**

28 A number of response options underpin solutions to the challenges arising from GHG emissions from
29 land, and the loss of productivity arising from degradation and desertification. These options are

1 discussed in Sections 2.5, 6.2 and rely on a) land management, b) value chain management and c) risk
 2 management (see Table 1.2). None of these response options are mutually exclusive, and it is their
 3 combination in a regionally, context-specific manner that is most likely to achieve co-benefits between
 4 climate change mitigation, adaptation and other environmental challenges in a cost- effective way
 5 (Griscom et al. 2017; Kok et al. 2018). Sustainable solutions affecting both demand and supply are
 6 expected to yield most co-benefits if these rely not only on the carbon footprint, but are extended to other
 7 vital ecosystems such as water, nutrients and biodiversity footprints (van Noordwijk and Brussaard 2014;
 8 Cremasch 2016). As an entry-point to the discussion in Chapter 6, we introduce here a selected number of
 9 examples that cut across climate change mitigation, food security, desertification, and degradation issues,
 10 including potential trade-offs and co-benefits.

11 **Table 1.2 Broad categorisation of response options into three main classes and eight sub-classes.** For
 12 illustration, the table includes examples of individual response options. A complete list and description is provided
 13 in Chapter 6.

Response options based on land management	
<i>in agriculture</i>	Improved management of: cropland, grazing land, livestock; Agro-forestry; Avoidance of conversion of grassland to cropland; Integrated water management
<i>in forests</i>	Improved management of forests and forest restoration; Reduced deforestation and degradation; Afforestation
<i>of soils</i>	Increased soil organic carbon content; Reduced soil erosion; Reduced soil salinisation
<i>across all/other ecosystems</i>	Reduced landslides and natural hazards; Reduced pollution including acidification; Biodiversity conservation; Restoration and reduced conversion of peatlands
<i>specifically for carbon dioxide removal</i>	Enhanced weathering of minerals; Bioenergy and BECCS
Response options based on value chain management	
<i>through demand management</i>	Dietary change; Reduced post-harvest losses; Reduced food waste
<i>through supply management</i>	Sustainable sourcing; Improved energy use in food systems; Improved food processing and retailing
Response options based on risk management	
<i>risk management</i>	Risk sharing instruments; Use of local seeds; Disaster risk management

14

15 1.3.1 Targeted decarbonisation relying on large land-area need

16 Most global future scenarios that aim to achieve global warming of 2°C or well below rely on bioenergy
 17 (BE; with or without carbon capture and storage, BECCS; see Cross-Chapter Box 7 in Chapter 6) or
 18 afforestation and reforestation (Cross-Chapter Box 2 in this Chapter)(de Coninck et al. 2018; Rogelj et al.
 19 2018b,a; Anderson and Peters 2016; Popp et al. 2016; Smith et al. 2016). In addition to the very large
 20 area requirements projected for 2050 or 2100, several other aspects of these scenarios have also been
 21 criticised. For instance, they simulate very rapid technological and societal uptake rates for the land-
 22 related mitigation measures, when compared with historical observations (Turner et al. 2018; Brown et al.
 23 2019; Vaughan and Gough 2016). Furthermore, confidence in the projected bioenergy or BECCS net
 24 carbon uptake potential is *low*, because of many diverging assumptions. This includes assumptions about
 25 bioenergy crop yields, the possibly large energy demand for CCS, which diminishes the net-GHG-saving

1 of bioenergy systems, or the incomplete accounting for ecosystem processes and of the cumulative
2 carbon-loss arising from natural vegetation clearance for bioenergy crops or bioenergy forests and
3 subsequent harvest regimes (Anderson and Peters 2016; Bentsen 2017; Searchinger et al. 2017; Bayer et
4 al. 2017; Fuchs et al. 2017; Pingoud et al. 2018; Schlesinger 2018). Bioenergy provision under politically
5 unstable conditions may also be a problem (Erb et al. 2012; Searle and Malins 2015).

6 Large-scale bioenergy plantations and forests may compete for the same land area (Harper et al. 2018).
7 Both potentially have adverse side effects on biodiversity and ecosystem services, as well as socio-
8 economic trade-offs such as higher food prices due to land area competition (Shi et al. 2013; Bárcena et al.
9 2014; Fernandez-Martinez et al. 2014; Searchinger et al. 2015; Bonsch et al. 2016; Creutzig et al. 2015;
10 Kreidenweis et al. 2016; Santangeli et al. 2016; Williamson 2016; Graham et al. 2017; Krause et al. 2017;
11 Hasegawa et al. 2018; Humpenoeder et al. 2018). Although forest-based mitigation could have co-
12 benefits for biodiversity and many ecosystem services, this depends on the type of forest planted and the
13 vegetation cover it replaces (Popp et al. 2014; Searchinger et al. 2015) (see also Cross-Chapter Box 2 in
14 this Chapter).

15 There is *high confidence* that scenarios with large land requirements for climate change mitigation may
16 not achieve sustainable development goals, such as no poverty, zero hunger and life on land, if
17 competition for land and the need for agricultural intensification are greatly enhanced (Creutzig et al.
18 2016; Dooley and Kartha 2018; Hasegawa et al. 2015; Hof et al. 2018; Roy et al. 2018; Santangeli et al.
19 2016; Boysen et al. 2017; Henry et al. 2018; Kreidenweis et al. 2016; UN 2015). This does not mean that
20 smaller-scale land-based climate mitigation can have positive outcomes for then achieving these goals
21 (see e.g., Sections 6.2, 4.5, cross chapter box 7 in Chapter 6).

Cross-Chapter Box 2: Implications of large-scale conversion from non-forest to forest land

Baldur Janz (Germany), Almut Arneth (Germany), Francesco Cherubini (Norway/Italy), Edouard Davin (Switzerland/France), Aziz Elbehri (Morocco), Kaoru Kitajima (Japan), Werner Kurz (Canada)

Efforts to increase forest area

While deforestation continues in many world regions, especially in the tropics, large expansion of mostly managed forest area has taken place in some countries. In the IPCC context, reforestation (conversion to forest of land that previously contained forests but has been converted to some other use) is distinguished from afforestation (conversion to forest of land that historically has not contained forests (see glossary)). Past expansion of managed forest area occurred in many world-regions for a variety of reasons, from meeting needs for wood fuel or timber (Vadell et al. 2016; Joshi et al. 2011; Zaloumis and Bond 2015; Payn et al. 2015; Shoyama 2008; Miyamoto et al. 2011) to restoration-driven efforts, with the aim of enhancing ecological function (Filoso et al. 2017; Salvati and Carlucci 2014; Ogle et al. 2018; Crouzeilles et al. 2016; FAO 2016)(see Section 3.7, 4.9).

In many regions, net forest area increase includes deforestation (often of native forests) alongside increasing forest area (often managed forest, but also more natural forest restoration efforts; (Heilmayr et al. 2016; Scheidel and Work 2018; Hua et al. 2018; Crouzeilles et al. 2016; Chazdon et al. 2016b). China and India have seen the largest net forest area increase, aiming to alleviate soil erosion, desertification and overgrazing (Ahrends et al. 2017; Cao et al. 2016; Deng et al. 2015; Chen et al. 2019)(see Section 3.7, 4.9) but uncertainties in exact forest area changes remain large, mostly due to differences in methodology and forest classification (FAO 2015a; Song et al. 2018; Hansen et al. 2013; MacDicken et al. 2015)(Section 1.1.2).

What are the implications for ecosystems?

1) Implications for biogeochemical and biophysical processes

There is *robust evidence* and *medium agreement* that whilst forest area expansion increases ecosystem carbon storage, the magnitude of the increased stock depends on the type and length of former land-use, forest type planted, and climatic regions (Bárcena et al. 2014; Poeplau et al. 2011; Shi et al. 2013; Li et al. 2012)(see Section 4.3). While, reforestation of former croplands increases net ecosystem carbon storage (Bernal et al. 2018; Lamb 2018), afforestation on native grassland results in reduction of soil carbon stocks, which can reduce or negate the net carbon benefits which are dominated by increases in biomass, dead wood and litter carbon pools (Veldman et al. 2015, 2017).

Forest vs. non-forest lands differ in land surface reflectiveness of short-wave radiation and evapotranspiration (Anderson et al. 2011; Perugini et al. 2017)(see Section 2.4). Evapotranspiration from forests during the growing season regionally cools the land surface and enhances cloud cover that reduces short wave radiation reaching the land, an impact that is especially pronounced in the tropics. However, dark evergreen conifer-dominated forests have low surface reflectance, and tend to cause warming of the near surface atmosphere compared to non-forest land, especially when snow cover is present such as in boreal regions (Duveiller et al. 2018; Alkama and Cescatti 2016; Perugini et al. 2017)(*medium evidence, high agreement*).

2) Implications for water balance

Evapotranspiration by forests reduces surface runoff and erosion of soil and nutrients (Salvati et al.

2014). Planting of fast-growing species in semi-arid regions or replacing natural grasslands with forest plantations can divert soil water resources to evapotranspiration from groundwater recharge (Silveira et al. 2016; Zheng et al. 2016; Cao et al. 2016). Multiple cases are reported from China where afforestation programs, some with irrigation, without having tailored to local precipitation conditions, resulted in water shortages and tree mortality (Cao et al. 2016; Yang et al. 2014; Li et al. 2014; Feng et al. 2016). Water shortages may create long-term water conflicts (Zheng et al. 2016). However, reforestation (in particular for restoration) is also associated with improved water filtration, groundwater recharge (Ellison et al. 2017) and can reduce risk of soil erosion, flooding, and associated disasters (Lee et al. 2018; see Section 4.9).

3) Implications for biodiversity

Impacts of forest area expansion on biodiversity depend mostly on the vegetation cover that is replaced: afforestation on natural non-tree dominated ecosystems can have negative impacts on biodiversity (Abreu et al. 2017; Griffith et al. 2017; Veldman et al. 2015; Parr et al. 2014; Wilson et al. 2017; Hua et al. 2016)(see also IPCC 1.5° report (2018). Reforestation with monocultures of fast growing, non-native trees has little benefit to biodiversity (Shimamoto et al. 2018; Hua et al. 2016). There are also concerns regarding the impacts of some commonly used plantation species (e.g., *Acacia* and *Pinus* species) to become invasive (Padmanaba and Corlett 2014; Cunningham et al. 2015b).

Reforestation with mixes of native species, especially in areas that retain fragments of native forest, can support ecosystem-services and biodiversity recovery, with positive social and environmental co-benefits (Cunningham et al. 2015a; Dendy et al. 2015; Chaudhary and Kastner 2016; Huang et al. 2018; Locatelli et al. 2015b)(see Section 4.5). Even though species diversity in re-growing forests is typically lower than in primary forests, planting native or mixed species can have positive effects on biodiversity (Brockerhoff et al. 2013; Pawson et al. 2013; Thompson et al. 2014). Reforestation has been shown to improve links among existing remnant forest patches, increasing species movement, and fostering gene flow between otherwise isolated populations (Gilbert-Norton et al. 2010; Barlow et al. 2007; Lindenmayer and Hobbs 2004).

4) Implications for other ecosystem services and societies

Forest area expansion could benefit recreation and health, preservation of cultural heritage and local values and knowledge, livelihood support (via reduced resource conflicts, restoration of local resources). These social benefits could be most successfully achieved if local communities' concerns are considered (Le et al. 2012). However, these co-benefits have rarely been assessed due to a lack of suitable frameworks and evaluation tools (Baral et al. 2016).

Industrial forest management can be in conflict with needs of forest-dependent people and community-based forest management over access to natural resources (Gerber 2011; Baral et al. 2016) and/or loss of customary rights over land use (Malkamäki et al. 2018; Cotula et al. 2014). A common result is out-migration from rural areas and diminishing local uses of ecosystems (Gerber 2011). Policies promoting large-scale tree plantations gain if these are reappraised in view of potential co-benefits with several ecosystem services and local societies (Bull et al. 2006; Le et al. 2012).

Scenarios of forest-area expansion for land-based climate change mitigation

Conversion of non-forest to forest land has been discussed as a relatively cost-effective climate change mitigation option when compared to options in the energy and transport sectors (*medium evidence, medium agreement*) (de Coninck et al. 2018; Griscom et al. 2017; Fuss et al. 2018), and can have co-

benefits with adaptation.

Sequestration of CO₂ from the atmosphere through forest area expansion has become a fundamental part of stringent climate change mitigation scenarios (Rogelj et al. 2018a; Fuss et al. 2018)(see e.g., Sections 2.5, 4.5, 6.2). The estimated mitigation potential ranges from about 0.5 to 10 Gt CO₂yr⁻¹ (*robust evidence, medium agreement*), and depends on assumptions regarding available land and forest carbon uptake potential (Houghton 2013; Houghton and Nassikas 2017; Griscom et al. 2017; Lenton 2014; Fuss et al. 2018; Smith 2016) (see Section 2.5.1). In climate change mitigation scenarios, typically, no differentiation is made between reforestation and afforestation despite different overall environmental impacts between these two measures. Likewise, biodiversity conservation, impacts on water balances, other ecosystem services, or land-ownership as constraints when simulating forest area expansion (see Cross-Chapter Box 1 in this Chapter) tend not to be included as constraints when simulating forest area expansion.

Projected forest area increases, relative to today's forest area, range from approximately 25% in 2050 and increase to nearly 50% by 2100 (Rogelj et al. 2018a; Kreidenweis et al. 2016; Humpenoder et al. 2014). Potential adverse side-effects of such large-scale measures, especially for low-income countries, could be increasing food prices from the increased competition for land (Kreidenweis et al. 2016; Hasegawa et al. 2015, 2018; Boysen et al. 2017)(see Section 5.5). Forests also emit large amounts of biogenic volatile compounds that under some conditions contribute to the formation of atmospherically short-lived climate forcing compounds, which are also detrimental to health (Ashworth et al. 2013; Harrison et al. 2013). Recent analyses argued for an upper limit of about 5 million km² of land globally available for climate change mitigation through reforestation, mostly in the tropics (Houghton 2013) – with potential regional co-benefits.

Since forest growth competes for land with bioenergy crops (Harper et al. 2018)(Cross-Chapter Box 7: Bioenergy and BECCS, Chapter 6), global area estimates need to be assessed in light of alternative mitigation measures at a given location. In all forest-based mitigation efforts, the sequestration potential will eventually saturate unless the area keeps expanding, or harvested wood is either used for long-term storage products or for carbon capture and storage (Fuss et al. 2018; Houghton et al. 2015)(see Section 2.5.1). Considerable uncertainty in forest carbon uptake estimates is further introduced by potential forest losses from fire or pest outbreaks (Allen et al. 2010; Anderegg et al. 2015)(Cross-Chapter Box 3: Fire and climate change, Chapter 2). And like all land-based mitigation measures, benefits may be diminished by land-use displacement, through trade of land-based products, especially in poor countries that experience forest loss (e.g., Africa) (Bhojvaid et al. 2016; Jadin et al. 2016).

Conclusion

Reforestation is a mitigation measure with potential co-benefits for conservation and adaptation, including biodiversity habitat, air and water filtration, flood control, enhanced soil fertility and reversal of land degradation. Potential adverse side-effects of forest area expansion depend largely on the state of the land it displaces as well as tree species selections. Active governance and planning contribute to maximising co-benefits while minimising adverse side-effects (Laestadius et al. 2011; Dinerstein et al. 2015; Veldman et al. 2017)(see Section 4.8 and Chapter 7). At large spatial scales, forest expansion is expected to lead to increased competition for land, with potentially undesirable impacts on food prices, biodiversity, non-forest ecosystems and water availability (Bryan and Crossman 2013; Boysen et al. 2017; Kreidenweis et al. 2016; Egginton et al. 2014; Cao et al. 2016; Locatelli et al. 2015a; Smith et al.

2013)

1

2 **1.3.2 Land Management**

3 ***1.3.2.1 Agricultural, forest and soil management***

4 Sustainable land management (SLM) describes “*the stewardship and use of land resources, including*
5 *soils, water, animals and plants, to meet changing human needs while simultaneously assuring the long-*
6 *term productive potential of these resources and the maintenance of their environmental functions*”
7 (Alemu 2016, Altieri and Nicholls 2017)(see e.g., Section 4.1.5), and includes ecological, technological
8 and governance aspects.

9 The choice of SLM strategy is a function of regional context and land use types, with *high agreement* on
10 (a combination of) choices such as agroecology (including agroforestry), conservation agriculture and
11 forestry practices, crop and forest species diversity, appropriate crop and forest rotations, organic farming,
12 integrated pest management, the preservation and protection of pollination services, rain water harvesting,
13 range and pasture management, and precision agriculture systems (Stockmann et al. 2013; Ebert, 2014;
14 Schulte et al. 2014; Zhang et al. 2015; Sunil and Pandravada 2015; Poepflau and Don 2015; Agus et al.
15 2015; Keenan 2015; MacDicken et al. 2015; Abberton et al. 2016). Conservation agriculture and forestry
16 uses management practises with minimal soil disturbance such as no tillage or minimum tillage,
17 permanent soil cover with mulch combined with rotations to ensure a permanent soil surface, or rapid
18 regeneration of forest following harvest (Hobbs et al. 2008; Friedrich et al. 2012). Vegetation and soils in
19 forests and woodland ecosystems play a crucial role in regulating critical ecosystem processes, therefore
20 reduced deforestation together with sustainable forest management are integral to SLM (FAO 2015b; see
21 Section 4.8). In some circumstances, increased demand for forest products can also lead to increased
22 management of carbon storage in forests (Favero and Mendelsohn 2014). Precision agriculture is
23 characterised by a “management system that is information and technology based, is site specific and uses
24 one or more of the following sources of data: soils, crops, nutrients, pests, moisture, or yield, for optimum
25 profitability, sustainability, and protection of the environment” (USDA 2007)(see also Cross-Chapter Box
26 6: Agricultural intensification, Chapter 5). The management of protected areas that reduce deforestation
27 also plays an important role in climate change mitigation and adaptation while delivering numerous
28 ecosystem services and sustainable development benefits (Bebber and Butt 2017). Similarly, when
29 managed in an integrated and sustainable way, peatlands are also known to provide numerous ecosystem
30 services, as well as socio-economic and mitigation and adaptation benefits (Ziadat et al. 2018).

31 Biochar is an organic compound used as soil amendment and is believed to be potentially an important
32 global resource for mitigation. Enhancing the carbon content of soil and/or use of biochar (see Chapter 4)
33 have become increasingly important as a climate change mitigation option with possibly large co-benefits
34 for other ecosystem services. Enhancing soil carbon storage and the addition of biochar can be practised
35 with limited competition for land, provided no productivity/yield loss and abundant unused biomass, but
36 evidence is limited and impacts of large scale application of biochar on the full GHG balance of soils, or
37 human health are yet to be explored (Gurwick et al. 2013; Lorenz and Lal 2014; Smith 2016).

38 **1.3.3 Value chain management**

39 ***1.3.3.1 Supply management***

40 **Food losses from harvest to retailer.** Approximately one third of losses and waste in the food system
41 occurs between crop production and food consumption, increasing substantially if losses in livestock

1 production and overeating are included (Gustavsson et al. 2011; Alexander et al. 2017). This includes on-
2 farm losses, farm to retailer losses, as well retailer and consumer losses (see Section 1.3.3.2).

3 Post-harvest food loss on farm and from farm to retailer is a widespread problem, especially in
4 developing countries (Xue et al. 2017), but are challenging to quantify. For instance, averaged for eastern
5 and southern Africa an estimated 10–17% of annual grain production is lost (Zorya et al. 2011). Across
6 84 countries and different time periods, annual median losses in the supply chain before retailing were
7 estimated at about 28 kg per capita for cereals or about 12 kg per capita for eggs and dairy products (Xue
8 et al. 2017). For the year 2013, losses prior to the reaching retailers were estimated at 20% (dry weight) of
9 the production amount (22% wet weight) (Gustavsson et al. 2011; Alexander et al. 2017). While losses of
10 food cannot be realistically reduced to zero, advancing harvesting technologies (Bradford et al. 2018;
11 Affognon et al. 2015), storage capacity (Chegere 2018) and efficient transportation could all contribute to
12 reducing these losses with co-benefits for food availability, the land area needed for food production and
13 related GHG emissions.

14 **Stability of food supply, transport and distribution.** Increased climate variability enhances fluctuations
15 in world food supply and price variability (Warren 2014; Challinor et al. 2015; Elbehri et al. 2017). “Food
16 price shocks” need to be understood regarding their transmission across sectors and borders and impacts
17 on poor and food insecure populations, including urban poor subject to food deserts and inadequate food
18 accessibility (Widener et al. 2017; Lehmann et al. 2013; LE 2016; FAO 2015b). Trade can play an
19 important stabilising role in food supply, especially for regions with agro-ecological limits to production,
20 including water scarce regions, as well as regions that experience short term production variability due to
21 climate, conflicts or other economic shocks (Gilmont 2015; Marchand et al. 2016). Food trade can either
22 increase or reduce the overall environmental impacts of agriculture (Kastner et al. 2014). Embedded in
23 trade are virtual transfers of water, land area, productivity, ecosystem services, biodiversity, or nutrients
24 (Marques et al. 2019; Wiedmann and Lenzen 2018; Chaudhary and Kastner 2016) with either positive or
25 negative implications (Chen et al. 2018; Yu et al. 2013). Detrimental consequences in countries in which
26 trade dependency may accentuate the risk of food shortages from foreign production shocks could be
27 reduced by increasing domestic reserves or importing food from a diversity of suppliers (Gilmont 2015;
28 Marchand et al. 2016).

29 Climate mitigation policies could create new trade opportunities (e.g., biomass) (Favero and Massetti
30 2014) or alter existing trade patterns. The transportation GHG-footprints of supply chains may be causing
31 a differentiation between short and long supply chains (Schmidt et al. 2017) that may be influenced by
32 both economics and policy measures (see Section 5.4). In the absence of sustainable practices and when
33 the ecological footprint is not valued through the market system, trade can also exacerbate resource
34 exploitation and environmental leakages, thus weakening trade mitigation contributions (Dalin and
35 Rodríguez-Iturbe 2016; Mosnier et al. 2014; Elbehri et al. 2017). Ensuring stable food supply while
36 pursuing climate mitigation and adaptation will benefit from evolving trade rules and policies that allow
37 internalisation of the cost of carbon (and costs of other vital resources such as water, nutrients). Likewise,
38 future climate change mitigation policies would gain from measures designed to internalise the
39 environmental costs of resources and the benefits of ecosystem services (Elbehri et al. 2017; Brown et
40 al., 2007).

41 **1.3.3.2 Demand management**

42 **Dietary change.** Demand-side solutions to climate mitigation are an essential complement to supply-side,
43 technology and productivity driven solutions (Creutzig et al. 2016; Bajželj et al. 2014; Erb et al. 2016b;
44 Creutzig et al. 2018)(see Sections 5.5.1, 5.5.2)(*high confidence*). The environmental impacts of the

1 animal-rich “western diets” are being examined critically in the scientific literature (Hallström et al. 2015;
2 Alexander et al. 2016b; Alexander et al. 2015; Tilman and Clark 2014; Aleksandrowicz et al. 2016; Poore
3 and Nemecek 2018)(see Section 5.4.6). For example, if the average diet of each country were consumed
4 globally, the agricultural land area needed to supply these diets would vary 14-fold, due to country
5 differences in ruminant protein and calorific intake (-55% to +178% compared to existing cropland
6 areas). Given the important role enteric fermentation plays in methane (CH₄) emissions, a number of
7 studies have examined the implications of lower animal diets (Swain et al. 2018; Rööös et al. 2017; Rao et
8 al. 2018). Reduction of animal protein intake has been estimated to reduce global green water (from
9 precipitation) use by 11% and blue water (from rivers, lakes, groundwater) use by 6% (Jalava et al. 2014).
10 By avoiding meat from producers with above-median GHG emissions and halving animal-product intake,
11 consumption change could free-up 21 million km² of agricultural land and reduce GHG emissions by
12 nearly 5 Gt CO₂-eq yr⁻¹ or up to 10.4 Gt CO₂-eq yr⁻¹ when vegetation carbon uptake is considered on the
13 previously agricultural land (Poore and Nemecek 2018, 2019).

14 Diets can be location and community specific, are rooted in culture and traditions while responding to
15 changing lifestyles driven for instance by urbanisation and changing income. Changing dietary and
16 consumption habits would require a combination of non-price (government procurement, regulations,
17 education and awareness raising) and price (Juhl and Jensen 2014) incentives to induce consumer
18 behavioural change with potential synergies between climate, health and equity (addressing growing
19 global nutrition imbalances that emerge as undernutrition, malnutrition, and obesity) (FAO 2018b).

20 **Reduced waste and losses in the food demand system.** Global averaged per capita food waste and loss
21 (FWL) have increased by 44% between 1961 and 2011 (Porter et al. 2016) and are now around 25–30%
22 of global food produced (Kummu et al. 2012)(Alexander et al. 2017). Food waste occurs at all stages of
23 the food supply chain from the household to the marketplace (Parfitt et al. 2010) and is found to be larger
24 at household than at supply chain levels. A meta-analysis of 55 studies showed that the highest share of
25 food waste was at the consumer stage (43.9% of total) with waste increasing with per capita GDP for high
26 income countries until a plateau at about 100 kg cap⁻¹ yr⁻¹ (around 16% of food consumption) above
27 about 70 000 USD cap⁻¹ (van der Werf and Gilliland 2017; Xue et al. 2017). Food loss from supply chains
28 tends to be more prevalent in less developed countries where inadequate technologies, limited
29 infrastructure, and imperfect markets combine to raise the share of the food production lost before use.

30 There are several causes behind food waste including economics (cheap food), food policies (subsidies)
31 as well as individual behaviour (Schanes et al. 2018). Household level food waste arises from overeating
32 or overbuying (Thyberg and Tonjes 2016). Globally, overconsumption was found to waste 9–10% of
33 food bought (Alexander et al. 2017).

34 Solutions to FWL thus need to address technical and economic aspects. Such solutions would benefit
35 from more accurate data on the loss-source, -magnitude and -causes along the food supply chain. In the
36 long run, internalising the cost of food waste into the product price would more likely induce a shift in
37 consumer behaviour towards less waste and more nutritious, or alternative, food intake (FAO 2018b).
38 Reducing FWL would bring a range of benefits for health, reducing pressures on land, water and
39 nutrients, lowering emissions and safeguarding food security. Reducing food waste by 50% would
40 generate net emissions reductions in the range of 20 to 30% of total food-sourced GHGs (Bajželj et al.
41 2014). The SDG 12 (“Ensure sustainable consumption and production patterns”) calls for per capita
42 global food waste to be reduced by one half at the retail and consumer level, and reducing food losses
43 along production and supply chains by 2030.

1 **1.3.4 Risk management**

2 Risk management refers to plans, actions, strategies or policies to reduce the likelihood and/or magnitude
3 of adverse potential consequences, based on assessed or perceived risks' Insurance and early warning
4 systems are examples of risk management, but risk can also be reduced (or resilience enhanced) through a
5 broad set of options ranging from seed sovereignty, livelihood diversification, to reducing land loss
6 through urban sprawl. Early warning systems support farmer decision making on management strategies
7 (see Section 1.2) and are a good example of an adaptation measure with mitigation co-benefits such as
8 reducing carbon losses (see Section 1.3.6). Primarily designed to avoid yield losses, early warning
9 systems also support fire management strategies in forest ecosystems, which prevents financial as well as
10 carbon losses (de Groot et al. 2015). Given that over recent decades on average around 10% of cereal
11 production was lost through extreme weather events (Lesk et al. 2016), where available and affordable,
12 insurance can buffer farmers and foresters against the financial losses incurred through such weather and
13 other (fire, pests) extremes (Falco et al. 2014)(see Section 7.2, 7.4). Decisions to take up insurance are
14 influenced by a range of factors such as the removal of subsidies or targeted education (Falco et al. 2014).
15 Enhancing access and affordability of insurance in low-income countries is a specific objective of the
16 UNFCCC (Linnerooth-Bayer and Mechler 2006). A global mitigation co-benefit of insurance schemes
17 may also include incentives for future risk reduction (Surminski and Oramas-Dorta 2014).

18 **1.3.5 Economics of land-based mitigation pathways: Costs versus benefits of early action** 19 **under uncertainty**

20 The overarching societal costs associated with GHG emissions and the potential implications of
21 mitigation activities can be measured by various metrics (cost-benefit analysis, cost effectiveness
22 analysis) at different scales (project, technology, sector or the economy) (IPCC 2018; section 1.4). The
23 Social Cost of Carbon (SCC), measures the total net damages of an extra metric ton of CO₂ emissions due
24 to the associated climate change (Nordhaus 2014; Pizer et al. 2014). Both negative and positive impacts
25 are monetised and discounted to arrive at the net value of consumption loss. As the SCC depends on
26 discount rate assumptions and value judgements (e.g., relative weight given to current vs. future
27 generations), it is not a straightforward policy tool to compare alternative options. At the sectoral level,
28 marginal abatement cost curves (MACCs) are widely used for the assessment of costs related to GHG
29 emissions reduction. MACCs measure the cost of reducing one more GHG unit and are either expert-
30 based or model-derived and offer a range of approaches and assumptions on discount rates or available
31 abatement technologies (Kesicki 2013). In land-based sectors, Gillingham and Stock (2018) reported
32 short term static abatement costs for afforestation of between 1 and 10 USD 2017/tCO₂, soil management
33 at 57 and livestock management at 71 USD 2017/tCO₂. MACCs are more reliable when used to rank
34 alternative options compared to a baseline (or business as usual) rather than offering absolute numerical
35 measures (Huang et al. 2016). The economics of land-based mitigation options encompass also the "costs
36 of inaction" that arise either from the economic damages due to continued accumulation of GHGs in the
37 atmosphere and from the diminution in value of ecosystem services or the cost of their restoration where
38 feasible (Rodriguez-Labajos 2013; Ricke et al. 2018). Overall, it remains challenging to estimate the costs
39 of alternative mitigation options owing to the context- and scale specific interplay between multiple
40 drivers (technological, economic, and socio-cultural) and enabling policies and institutions (IPCC
41 2018)(section 1.4).

42 The costs associated with mitigation (both project-linked such as capital costs or land rental rates or
43 sometimes social costs) generally increase with stringent mitigation targets and over time. Sources of
44 uncertainty include the future availability, cost and performance of technologies (Rosen and Guenther

1 2015; Chen et al. 2016) or lags in decision making, which have been demonstrated by the uptake of land
2 use and land utilisation policies (Alexander et al. 2013; Hull et al. 2015; Brown et al. 2018b). There is
3 growing evidence of significant mitigation gains through conservation, restoration and improved land
4 management practices (Griscom et al. 2017; Kindermann et al. 2008; Golub et al. 2013; Favero et al.
5 2017)(see Chapter 4 and Chapter 6), but the mitigation cost efficiency can vary according to region and
6 specific ecosystem (Albanito et al. 2016). Recent model developments that treat process-based, human-
7 environment interactions have recognised feedbacks that reinforce or dampen the original stimulus for
8 land use change (Robinson et al. 2017; Walters and Scholes 2017). For instance, land mitigation
9 interventions that rely on large-scale, land use change (i.e., afforestation) would need to account for the
10 rebound effect (which dampens initial impacts due to feedbacks) in which raising land prices also raises
11 the cost of land-based mitigation (Vivanco et al. 2016). Although there are few direct estimates, indirect
12 assessments strongly point to much higher costs if action is delayed or limited in scope (*medium*
13 *confidence*). Quicker response options are also needed to avoid loss of high-carbon ecosystems and other
14 vital ecosystem services that provide multiple services that are difficult to replace (peatlands, wetlands,
15 mangroves, forests) (Yirdaw et al. 2017; Pedrozo-Acuña et al. 2015). Delayed action would raise relative
16 costs in the future or could make response options less feasible (Goldstein et al. 2019; Butler et al.
17 2014)(*medium confidence*).

18 **1.3.6 Adaptation measures and scope for co-benefits with mitigation**

19 Adaptation and mitigation have generally been treated as two separate discourses, both in policy and
20 practice with mitigation addressing cause and adaptation dealing with the consequences of climate change
21 (Hennessey et al. 2017). While adaptation (e.g., reducing flood risks) and mitigation (e.g., reducing non-
22 CO₂ emissions from agriculture) may have different objectives and operate at different scales, they can
23 also generate joint outcomes (Locatelli et al. 2015b) with adaptation generating mitigation co-benefits.
24 Seeking to integrate strategies for achieving adaptation and mitigation goals is attractive in order to
25 reduce competition for limited resources and trade-offs (Lobell et al. 2013; Berry et al. 2015; Kongsager
26 and Corbera 2015). Moreover, determinants that can foster adaptation and mitigation practices are
27 similar. These tend to include available technology and resources, and credible information for policy
28 makers to act on (Yohe 2001).

29 Four sets of mitigation-adaptation interrelationships can be distinguished: 1) mitigation actions that can
30 result in adaptation benefits; 2) adaptation actions that have mitigation benefits; 3) processes that have
31 implications for both adaptation and mitigation; 4) strategies and policy processes that seek to promote an
32 integrated set of responses for both adaptation and mitigation (Klein et al. 2007). A high level of adaptive
33 capacity is a key ingredient to developing successful mitigation policy. Implementing mitigation action
34 can result in increasing resilience especially if it is able to reduce risks. Yet, mitigation and adaptation
35 objectives, scale of implementation, sector and even metrics to identify impacts tend to differ (Ayers and
36 Huq 2009), and institutional setting, often does not enable an environment where synergies are sought
37 (Kongsager et al. 2016). Trade-offs between adaptation and mitigation exist as well and need to be
38 understood (and avoided) to establish win-win situations (Porter et al. 2014; Kongsager et al. 2016).

39 Forestry and agriculture offer a wide range of lessons for the integration of adaptation and mitigation
40 actions given the vulnerability of forest ecosystems or cropland to climate variability and change (Keenan
41 2015; Gaba et al. 2015)(see Section 5.6, 4.8). Increasing adaptive capacity in forested areas has the
42 potential to prevent deforestation and forest degradation (Locatelli et al. 2011). Reforestation projects, if
43 well managed, can increase community economic opportunities that encourage conservation (Nelson and
44 de Jong 2003), build capacity through training of farmers and installation of multifunctional plantations

1 with income generation (Reyer et al. 2009), strengthen local institutions (Locatelli et al. 2015a) and
2 increase cash-flow to local forest stakeholders from foreign donors (West 2016). A forest plantation that
3 sequesters carbon for mitigation can also reduce water availability to downstream populations and
4 heighten their vulnerability to drought. Inversely, not recognising mitigation in adaptation projects may
5 yield adaptation measures that increase greenhouse gas emissions, a prime example of ‘maladaptation’.
6 Analogously, ‘mal-mitigation’ would result in reducing greenhouse gas emissions, but increasing
7 vulnerability (Barnett and O’Neill 2010; Porter et al. 2014). For instance, the cost of pursuing large scale
8 adaptation and mitigation projects has been associated with higher failure risks, onerous transactions costs
9 and the complexity of managing big projects (Swart and Raes 2007).

10 Adaptation encompasses both biophysical and socio-economic vulnerability and underlying causes
11 (informational, capacity, financial, institutional, and technological; Huq et al. 2014) and it is increasingly
12 linked to resilience and to broader development goals (Huq et al. 2014). Adaptation measures can
13 increase performance of mitigation projects under climate change and legitimise mitigation measures
14 through the more immediately felt effects of adaptation (Locatelli et al. 2011; Campbell et al. 2014;
15 Locatelli et al. 2015b). Effective climate policy integration in the land sector is expected to gain from 1)
16 internal policy coherence between adaptation and mitigation objectives, 2) external climate coherence
17 between climate change and development objectives, 3) policy integration that favours vertical
18 governance structures to foster effective mainstreaming of climate change into sectoral policies, and 4)
19 horizontal policy integration through overarching governance structures to enable cross-sectoral co-
20 ordination (see Sections 1.4, 7.4).

21 **1.4 Enabling the response**

22 Climate change and sustainable development are challenges to society that require action at local,
23 national, transboundary and global scales. Different time-perspectives are also important in decision
24 making, ranging from immediate actions to long-term planning and investment. Acknowledging the
25 systemic link between food production and consumption, and land-resources more broadly is expected to
26 enhance the success of actions (Bazilian et al. 2011; Hussey and Pittock 2012). Because of the complexity
27 of challenges and the diversity of actors involved in addressing these challenges, decision making would
28 benefit from a portfolio of policy instruments. Decision making would also be facilitated by overcoming
29 barriers such as inadequate education and funding mechanisms, as well as integrating international
30 decisions into all relevant (sub)national sectoral policies (see Section 7.4).

31 ‘Nexus thinking’ emerged as an alternative to the sector-specific governance of natural resource use to
32 achieve global securities of water (D’Odorico et al. 2018), food and energy (Hoff 2011; Allan et al.
33 2015), and also to address biodiversity concerns (Fischer et al. 2017). Yet, there is no agreed definition of
34 “nexus” nor a uniform framework to approach the concept, which may be land-focused (Howells et al.
35 2013), water-focused (Hoff 2011) or food-centred (Ringler and Lawford 2013; Biggs et al. 2015).
36 Significant barriers remain to establish nexus approaches as part of a wider repertoire of responses to
37 global environmental change, including challenges to cross-disciplinary collaboration, complexity,
38 political economy and the incompatibility of current institutional structures (Hayley et al. 2015; Wichelns
39 2017)(see Section 7.5.6, 7.6.2).

40 **1.4.1 Governance to enable the response**

41 Governance includes the processes, structures, rules and traditions applied by formal and informal actors
42 including governments, markets, organisations, and their interactions with people. Land governance
43 actors include those affecting policies and markets, and those directly changing land use (Hersperger et al.

1 2010). The former includes governments and administrative entities, large companies investing in land,
2 non-governmental institutions and international institutions. It also includes UN agencies that are working
3 at the interface between climate change and land management, such as the FAO and the World Food
4 Programme that have *inter alia* worked on advancing knowledge to support food security through the
5 improvement of techniques and strategies for more resilient farm systems. Farmers and foresters directly
6 act on land (actors in proximate causes) (Hersperger et al. 2010)(see also Chapter 7.).

7 Policy design and formulation has often been strongly sectoral. For example, agricultural policy might be
8 concerned with food security, but have little concern for environmental protection or human health. As
9 food, energy and water security and the conservation of biodiversity rank highly on the Agenda 2030 for
10 Sustainable Development, the promotion of synergies between and across sectoral policies is important
11 (IPBES 2018a). This can also reduce the risks of anthropogenic climate forcing through mitigation, and
12 bring greater collaboration between scientists, policy makers, the private sector and land managers in
13 adapting to climate change (FAO 2015a). Polycentric governance (see Section 7.6) has emerged as an
14 appropriate way of handling resource management problems, in which the decision- making centers take
15 account of one another in competitive and cooperative relationships and have recourse to conflict
16 resolution mechanisms (Carlisle and Gruby 2017). Polycentric governance is also multi-scale and allows
17 the interaction between actors at different levels (local, regional, national, and global) in managing
18 common pool resources such as forests or aquifers.

19 Implementation of systemic, nexus approaches has been achieved through socio-ecological systems (SES)
20 frameworks that emerged from studies of how institutions affect human incentives, actions and outcomes
21 (Ostrom and Cox 2010). Recognition of the importance of SES laid the basis for alternative formulations
22 to tackle the sustainable management of land resources focusing specifically on institutional and
23 governance outcomes (Lebel et al. 2006; Bodin 2017). The SES approach also addresses the multiple
24 scales in which the social and ecological dimensions interact (Veldkamp et al. 2011; Myers et al. 2016;
25 Azizi et al. 2017) (see Section 6.1).

26 Adaptation or resilience pathways within the SES frameworks require several attributes, including
27 indigenous and local knowledge (ILK) and trust building for deliberative decision making and effective
28 collective action, polycentric and multi-layered institutions and responsible authorities that pursue just
29 distributions of benefits to enhance the adaptive capacity of vulnerable groups and communities (Lebel et
30 al. 2006). The nature, source, and mode of knowledge generation are critical to ensure that sustainable
31 solutions are community-owned and fully integrated within the local context (Mistry and Berardi 2016;
32 Schneider and Buser 2018). Integrating ILK with scientific information is a prerequisite for such
33 community-owned solutions (see Cross-Chapter Box 13: ILK, Chapter 7). ILK is context-specific,
34 transmitted orally or through imitation and demonstration, adaptive to changing environments,
35 collectivised through a shared social memory (Mistry and Berardi 2016). ILK is also holistic since
36 indigenous people do not seek solutions aimed at adapting to climate change alone, but instead look for
37 solutions to increase their resilience to a wide range of shocks and stresses (Mistry and Berardi 2016).
38 ILK can be deployed in the practice of climate governance especially at the local level where actions are
39 informed by the principles of decentralisation and autonomy (Chanza and de Wit 2016). ILK need not be
40 viewed as needing confirmation or disapproval by formal science, but rather it can complement scientific
41 knowledge (Klein et al. 2014).

42 The capacity to apply individual policy instruments and policy mixes is influenced by governance modes.
43 These modes include hierarchical governance that is centralised and imposes policy through top-down
44 measures, decentralised governance in which public policy is devolved to regional or local government,

1 public-private partnerships that aim for mutual benefits for the public and private sectors and self or
2 private governance that involves decisions beyond the realms of the public sector (IPBES 2018a). These
3 governance modes provide both constraints and opportunities for key actors that affect the effectiveness,
4 efficiency and equity of policy implementation.

5 **1.4.2 Gender agency as a critical factor in climate and land sustainability outcomes**

6 Environmental resource management is not gender neutral. Gender is an essential variable in shaping
7 ecological processes and change, building better prospects for livelihoods and sustainable development
8 (Resurrección 2013)(see Cross-Chapter Box 11: Gender, Chapter 7). Entrenched legal and social
9 structures and power relations constitute additional stressors that render women's experience of natural
10 resources disproportionately negative than men. Socio-economic drivers and entrenched gender
11 inequalities affect land-based management (Agarwal 2010). The intersections between climate change,
12 gender and climate adaptation takes place at multiple scales: household, national, international, and
13 adaptive capacities are shaped through power and knowledge.

14 Germaine to the gender inequities are the unequal access to land-based resources. Women play a
15 significant role in agriculture (Boserup 1989; Darity 1980) and rural economies globally (FAO 2011), but
16 are well below their share of labour in agriculture globally (FAO 2011). In 59% of 161 surveyed
17 countries, customary, traditional and religious practices hinder women land rights (OECD 2014).
18 Moreover, women typically shoulder disproportionate responsibility for unpaid domestic work including
19 care-giving activities (Beuchelt and Badstue 2013) and the provision of water and firewood (UNEP
20 2016). Exposure to violence restricts in large regions their mobility for capacity-building activities and
21 productive work outside the home (Day et al. 2005; UNEP 2016). Large-scale development projects can
22 erode rights, and lead to over-exploitation of natural resources. Hence, there are cases where reforms
23 related to land-based management, instead of enhancing food security, have tended to increase the
24 vulnerability of both women and men and reduce their ability to adapt to climate change (Pham et al.
25 2016). Access to, and control over, land and land-based resources is essential in taking concrete action to
26 land based mitigation, and inadequate access can affect women's rights and participation in land
27 governance and management of productive assets.

28 Timely information, such as from early warning systems, is critical in managing risks, disasters, and land
29 degradation, and in enabling land-based adaptation. Gender, household resources and social status, are all
30 determinants that influence the adoption of land-based strategies (Theriault et al. 2017). Climate change is
31 not a lone driver in the marginalisation of women, their ability to respond swiftly to its impacts will
32 depend on other socio-economic drivers that may help or hinder action towards adaptive governance.
33 Empowering women and removing gender-based inequities constitutes a mechanism for greater
34 participation in the adoption of sustainable practices of land management (Mello and Schmink 2017).
35 Improving women's access to land (Arora-Jonsson 2014) and other resources (water) and means of
36 economic livelihoods (such as credit and finance) are the prerequisites to enable women to participate in
37 governance and decision-making structures (Namubiru-Mwaura 2014). Still women are not a
38 homogenous group, and distinctions through elements of ethnicity, class, age and social status, require a
39 more nuanced approach and not a uniform treatment through vulnerability lenses only. An intersectional
40 approach that accounts for various social identifiers under different situation of power (Rao 2017) is
41 considered suitable to integrate gender into climate change research and helps to recognise overlapping
42 and interdependent systems of power (Djoudi et al. 2016; Kaijser and Kronsell 2014; Moosa and Tuana
43 2014; Thompson-Hall et al. 2016).

1 **1.4.3 Policy Instruments**

2 Policy instruments enable governance actors to respond to environmental and societal challenges through
3 policy action. Examples of the range of policy instruments available to public policy-makers is discussed
4 below based on four categories of instruments: legal and regulatory instruments, rights-based instruments
5 and customary norms, economic and financial instruments and social and cultural instruments.

6 **1.4.3.1 Legal & regulatory instruments**

7 Legal and regulatory instruments deal with all aspects of intervention by public policy organisations to
8 correct market failures, expand market reach, or intervene in socially relevant areas with inexistent
9 markets. Such instruments can include legislation to limit the impacts of intensive land management, for
10 example, protecting areas that are susceptible to nitrate pollution or soil erosion. Such instruments can
11 also set standards or threshold values, for example, mandated water quality limits, organic production
12 standards, or geographically defined regional food products. Legal and regulatory instruments may also
13 define liability rules, for example, where environmental standards are not met, as well as establishing
14 long-term agreements for land resource protection with land owners and land users.

15 **1.4.3.2 Economic and financial instruments**

16 Economic (such as taxes, subsidies) and financial (weather-index insurance) instruments deal with the
17 many ways in which public policy organisations can intervene in markets. A number of instruments are
18 available to support climate mitigation actions including public provision, environmental regulations,
19 creating property rights and markets, using markets (Sterner 2003). Market-based policies such as carbon
20 taxes, fuel taxes, cap and trade systems or green payments have been promoted (mostly in industrial
21 economies) to encourage markets and businesses to contribute to climate mitigation, but their
22 effectiveness to date has not always matched expectations (Grolleau et al. 2016) (see Section 7.4.4).
23 Market-based instruments in ecosystem services generate both positive (incentives for conservation), but
24 also negative environmental impacts, and also push food prices up or increase price instability (Gómez-
25 Baggethun and Muradian 2015; Farley and Voinov 2016). Footprint labels can be an effective means of
26 shifting consumer behaviour. However, private labels focusing on a single metric (e.g., carbon) may give
27 misleading signals if they target a portion of the life cycle (e.g., transport) (Appleton 2009) or ignore
28 other ecological indicators (water, nutrients, biodiversity)(van Noordwijk and Brussaard 2014).

29 Effective and durable, market-led responses for climate mitigation depend on business models that
30 internalise the cost of emissions into economic calculations. Such “business transformation” would itself
31 require integrated policies and strategies that aim to account for emissions in economic activities (Biagini
32 and Miller 2013; Weitzman 2014; Eidelwein et al. 2018). International initiatives such as REDD+ and
33 agricultural commodity roundtables (beef, soybeans, palm oil, sugar) are expanding the scope of private
34 sector participation in climate mitigation (Nepstad et al. 2013), but their impacts have not always been
35 effective (Denis et al. 2014). Payments for environmental services (PES) defined as “*voluntary*
36 *transactions between service users and service providers that are conditional on agreed rules of natural*
37 *resource management for generating offsite services*” (Wunder 2015) have not been widely adopted and
38 have not yet been demonstrated to deliver as effectively as originally hoped (Börner et al. 2017)(see
39 Sections 7.4, 7.5). PES in forestry were shown to be effective only when coupled with appropriate
40 regulatory measures (Alix-Garcia and Wolff 2014). Better designed and expanded PES schemes would
41 encourage integrated soil-water-nutrient management packages (Stavi et al. 2016), services for pollinator
42 protection (Nicole 2015), water use governance under scarcity and engage both public and private actors
43 (Loch et al. 2013). Effective PES also requires better economic metrics to account for human-directed

1 losses in terrestrial ecosystems and to food potential, and to address market failures or externalities
2 unaccounted for in market valuation of ecosystem services.

3 Resilient strategies for climate adaptation can rely on the construction of markets through social networks
4 as in the case of livestock systems (Denis et al. 2014) or when market signals encourage adaptation
5 through land markets or supply chain incentives for sustainable land management practices (Anderson et
6 al. 2018). Adequate policy (through regulations, investments in research and development or support to
7 social capabilities) can support private initiatives for effective solutions to restore degraded lands (Reed
8 and Stringer 2015), or mitigate against risk and to avoid shifting risks to the public (Biagini and Miller
9 2013). Governments, private business, and community groups could also partner to develop sustainable
10 production codes (Chartres and Noble 2015), and in co-managing land-based resources (Baker and
11 Chapin 2018), while private-public partnerships can be effective mechanisms in deploying infrastructure
12 to cope with climatic events (floods) and for climate-indexed insurance (Kunreuther 2015). Private
13 initiatives that depend on trade for climate adaptation and mitigation require reliable trading systems that
14 do not impede climate mitigation objectives (Elbehri et al 2015; Mathews 2017).

15 ***1.4.3.3 Rights-based instruments and customary norms***

16 Rights-based instruments and customary norms deal with the equitable and fair management of land
17 resources for all people (IPBES 2018a). These instruments emphasise the rights in particular of
18 indigenous peoples and local communities, including for example, recognition of the rights embedded in
19 the access to, and use of, common land. Common land includes situations without legal ownership (e.g.,
20 hunter-gathering communities in south America or Africa and bushmeat), where the legal ownership is
21 distinct from usage rights (Mediterranean transhumance grazing systems), or mixed ownership-common
22 grazing systems (e.g., Crofting in Scotland). A lack of formal (legal) ownership has often led to the loss
23 of access rights to land, where these rights were also not formally enshrined in law, which especially
24 effects indigenous communities, for example, deforestation in the Amazon basin. Overcoming the
25 constraints associated with common-pool resources (forestry, fisheries, water) are often of economic and
26 institutional nature (Hinkel et al. 2014) and require tackling the absence or poor functioning of institutions
27 and the structural constraints that they engender through access and control levers using policies and
28 markets and other mechanisms (Schut et al. 2016). Other examples of rights-based instruments include
29 the protection of heritage sites, sacred sites and peace parks (IPBES 2018a). Rights-based instruments and
30 customary norms are consistent with the aims of international and national human rights, and the critical
31 issue of liability in the climate change problem.

32 ***1.4.3.4 Social and cultural norms***

33 Social and cultural instruments are concerned with the communication of knowledge about conscious
34 consumption patterns and resource-effective ways of life through awareness raising, education and
35 communication of the quality and the provenance of land-based products. Examples of the latter include
36 consumption choices aided by ecolabelling (see 1.4.3.2) and certification. Cultural indicators (such as
37 social capital, cooperation, gender equity, women's knowledge, socio-ecological mobility) contribute to
38 the resilience of social-ecological systems (Sterling et al. 2017). Indigenous communities (such as the
39 Inuit and Tsleil Waututh Nation in Canada) that continue to maintain traditional foods exhibit greater
40 dietary quality and adequacy (Sheehy et al. 2015). Social and cultural instruments also include approaches
41 to self-regulation and voluntary agreements, especially with respect to environmental management and
42 land resource use. This is becoming especially important in the increasingly important domain of
43 corporate social responsibility (Halkos and Skouloudis 2016).

1 **1.5 The interdisciplinary nature of the SRCCL**

2 Assessing the land system in view of the multiple challenges that are covered by the SRCCL requires a
3 broad, inter-disciplinary perspective. Methods, core concepts and definitions are used differently in
4 different sectors, geographic regions, and across academic communities addressing land systems, and
5 these concepts and approaches to research are also undergoing a change in their interpretation through
6 time. These differences reflect varying perspectives, in nuances or emphasis, on land as component of the
7 climate and socio-economic systems. Because of its inter-disciplinary nature, the SRCCL can take
8 advantage of these varying perspectives and the diverse methods that accompany them. That way, the
9 report aims to support decision makers across sectors and world regions in the interpretation of its main
10 findings and support the implementation of solutions.

11

12 **Frequently Asked Questions**

13 **FAQ 1.1 What are the approaches to study the interactions between land and climate?**

14 Climate changes shapes the way land is able to support supply of food and water for humans. At the same
15 time the land surface interacts with the overlying atmosphere, thus human modifications of land use, land
16 cover and urbanisation affect global, regional and local climate. The complexity of the land-climate
17 interactions requires multiple study approaches embracing different spatial and temporal scales.
18 Observations of land atmospheric exchanges, such as of carbon, water, nutrients and energy can be
19 carried out at leaf level and soil with gas exchange systems, or at canopy scale by means of
20 micrometeorological techniques (i.e. eddy covariance). At regional scale, atmospheric measurements by
21 tall towers, aircraft and satellites can be combined with atmospheric transport models to obtain spatial
22 explicit maps of relevant greenhouse gases fluxes. At longer temporal scale (> 10 years) other approaches
23 are more effective such as tree ring chronologies, satellite records, population and vegetation dynamics
24 and isotopic studies. Models are important to bring information from measurement together and to extend
25 the knowledge in space and time, including the exploration of scenarios of future climate-land
26 interactions.

27

28 **FAQ 1.2 How region-specific are the impact of different land-based adaptation and mitigation 29 options?**

30 Land based adaptation and mitigation options are closely related to regional specific features for several
31 reasons. Climate change has a definite regional pattern with some regions already suffering from
32 enhanced climate extremes and others being impacted little, or even benefiting. From this point of view
33 increasing confidence in regional climate change scenarios is becoming a critical step forward towards the
34 implementation of adaptation and mitigation options. Biophysical and socio-economic impacts of climate
35 change depend on the exposures of natural ecosystems and economic sectors, which are again specific to
36 a region, reflecting regional sensitivities due to governance. The overall responses in terms of adaptation
37 or mitigation capacities to avoid and reduce vulnerabilities and enhance adaptive capacity, depend on
38 institutional arrangements, socio-economic conditions, and implementation of policies, many of them
39 having definite regional features. However global drivers, such as agricultural demand, food prices,
40 changing dietary habits associated with rapid social transformations (i.e. urban versus rural, meat versus

1 vegetarian) may interfere with regional specific policies for mitigation and adaptation options and require
2 the global level to be addressed.

3
4 **FAQ 1.3 What is the difference between desertification and land degradation? And where are they**
5 **happening?**

6 The difference between land degradation and desertification is geographic. Land degradation is a general
7 term used to describe a negative trend in land condition caused by direct or indirect human-induced
8 processes (including anthropogenic climate change). Degradation can be identified by the long-term
9 reduction or loss in biological productivity, ecological integrity or value to humans. Desertification is land
10 degradation when it occurs in arid, semi-arid, and dry sub-humid areas, which are also called drylands.
11 Contrary to some perceptions, desertification is not the same as the expansion of deserts. Desertification
12 is also not limited to irreversible forms of land degradation.

2 **Supplementary Material**3 **Table SM.1.1 Observations related to variables indicative of land management, and their**
4 **uncertainties**

LM-related process	Observations methodology	Scale of observations (space and time)	Uncertainties ²	Pros and cons	Select literature
GHG emissions	Micrometeorological fluxes (CO ₂)	1-10 ha 0.5hr- >10 y	5-15%	<u>Pros</u> Larger footprints Continuous monitoring Less disturbance on monitored system	(Richardson et al. 2006; Luysaert et al. 2007; Foken and Napo 2008; Mauder et al. 2013; Peltola et al. 2014; Wang et al. 2015;
	Micrometeorological fluxes (CH ₄)		10-40%	Detailed protocols	Rannik et al. 2015;
	Micrometeorological fluxes (N ₂ O)		20-50%	<u>Cons</u> Limitations by fetch and turbulence scale Not all trace gases	Campioli et al. 2016; Rannik et al. 2016; Wang et al. 2017a; Brown and Wagner-Riddle 2017; Desjardins et al. 2018)
	Soil chambers (CO ₂)	0.01-1 ha 0.5hr - 1 y	5%-15%	<u>Pros</u> Relatively inexpensive	(Vargas and Allen 2008; Lavoie et al. 2015; Barton et al. 2015; Dossa et al. 2015;
	Soil chambers (CH ₄)		5% - 25%	Possibility of manipulation experiments	Ogle et al. 2016;
	Soil chambers (N ₂ O)		53%- 100% ³	Large range of trace gases	Pirk et al. 2016; Morin et al. 2017;
				<u>Cons</u> Smaller footprint Complicate upscaling Static pressure interference	Lammirato et al. 2018)
	Atmospheric inversions (CO ₂)	Regional 1->10 y	50%	<u>Pros</u> Integration on large scale	(Wang et al. 2017b)
	Atmospheric inversions		3-8%	Attribution detection (with	(Pison et al. 2018)

² FOOTNOTE: Uncertainty here is defined as the coefficient of variation CV. In the case of micrometeorological fluxes they refer to random errors and CV of daily average

³ FOOTNOTE: > 100 for fluxes less than 5g N₂O-N ha⁻¹ d⁻¹

(CH ₄)				14C)	
Carbon balance	Soil carbon point measurements	0.01ha-1ha >5 y	5-20%	<p>Rigorously derived uncertainty</p> <p><u>Cons</u></p> <p>Not suited at farm scale</p> <p>Large high precision observation network required</p> <p><u>Pros</u></p> <p>Easy protocol</p> <p>Well established analytics</p> <p><u>Cons</u></p> <p>Need high number of samples for upscaling</p> <p>Detection limit is high</p>	(Chiti et al. 2018; Castaldi et al. 2018; Chen et al. 2018; Deng et al. 2018)
	Biomass measurements	0.01ha – 1ha 1-5 y	2-8%	<p><u>Pros</u></p> <p>Well established allometric equations</p> <p>High accuracy at plot level</p> <p><u>Cons</u></p> <p>Difficult to scale up</p> <p>Labour intensive</p>	(Pelletier et al. 2012; Henry et al. 2015; Vanguelova et al. 2016; Djomo et al. 2016; Forrester et al. 2017; Xu et al. 2017; Marziliano et al. 2017; Clark et al. 2017; Disney et al. 2018; Urbazaev et al. 2018; Paul et al. 2018)
Water balance	Soil moisture (IoT sensors, Cosmic rays, Thermo-optical sensing etc.)	0.01ha – regional 0.5hr- <1y	3-5% vol	<p><u>Pros</u></p> <p>New technology</p> <p>Big data analytics</p> <p>Relatively inexpensive</p> <p><u>Cons</u></p> <p>Scaling problems</p>	(Yu et al. 2013; Zhang and Zhou 2016; Iwata et al. 2017; McJannet et al. 2017; Karthikeyan et al. 2017; Iwata et al. 2017; Cao et al. 2018; Amaral et al. 2018; Moradizadeh and Saradjian 2018; Strati et al. 2018)
	Evapotranspiration	0.01ha – Regional 0.5hr- >10y	10-20%	<p><u>Pros</u></p> <p>Well established methods</p> <p>Easy integration in models and DSS</p> <p><u>Cons</u></p> <p>Partition of fluxes need additional measurements</p>	(Zhang et al. 2017; Papadimitriou et al. 2017; Kaushal et al. 2017; Valayamkunnath et al. 2018; Valayamkunnath et al. 2018; Tie et al. 2018; Wang et al. 2018)
Soil Erosion	Sediment transport	1 ha – Regional 1d - >10y	-21-34%	<p><u>Pros</u></p> <p>Long history of</p>	(Efthimiou 2018; García-Barrón et al.

				methods	2018; Fiener et al.
				Integrative tools	2018)
				<u>Cons</u>	
				Validation is	
				lacking	
				Labour intensive	
Land cover	Satellite	0.01ha – Regional 1d - >10y	16 - 100%	<u>Pros</u>	(Olofsson et al. 2014;
				Increasing platforms	Liu et al. 2018; Yang
				available	et al. 2018)
				Consolidated	
				algorithms	
				<u>Cons</u>	
				Need validation	
				Lack of common	
				Land Use	
				definitions

1 **Table SM. 1.2 Possible uncertainties decision making faces** (following (Hansson and Hadorn 2016))

2

Type	Knowledge gaps	Understanding the uncertainties
Uncertainty of consequences	Do the model(s) adequately represent the target system? What are the numerical values of input parameters, boundary conditions, or initial conditions? What are all potential events that we would take into account if we were aware of them? Will future events relevant for our decisions, including expected impacts from these decisions, in fact take place?	Ensemble approaches; downscaling Benchmarking, sensitivity analyses Scenario approaches
Moral uncertainty	How to (ethically) evaluate the decisions? What values to base the decision on (→ often unreliable ranking of values not doing justice to the range of values at stake, cp. Sen 1992), including choice of discount rate, risk attitude (risk aversion, risk neutral, ...) Which ethical principles? (i.e. utilitarian, deontic, virtue, or other?)	Possibly scenario analysis Identification of lock-in effects and path-dependency (e.g. Kinsley et al 2016)
Uncertainty of demarcation	What are the options that we can actually choose between? (not fully known because “decision costs” may be high, or certain options are not “seen” as they are outside current ideologies). How can the mass of decisions divided into individual decisions? e.g. how this influences international negotiations and the question who does what and when (cp. Hammond et al. 1999).	Possibly scenario analysis
Uncertainty of consequences & uncertainty of demarcation	What effects does a decision have when combined with the decision of others? (e.g. other countries may follow the inspiring example in climate reduction of country X, or they use it solely in their own economic interest)	Games
Uncertainty of demarcation & moral uncertainty	How would we decide in the future? (Spohn 1977; Rabinowicz 2002)

Chapter 2: Land-Climate Interactions

Coordinating Lead Authors: Gensuo Jia (China), Elena Shevliakova (The United States of America)

Lead Authors: Paulo Artaxo (Brazil), Nathalie De Noblet-Ducoudré (France), Richard Houghton (The United States of America), Joanna House (United Kingdom), Kaoru Kitajima (Japan), Christopher Lennard (South Africa), Alexander Popp (Germany), Andrey Sirin (The Russian Federation), Raman Sukumar (India), Louis Verchot (Colombia/The United States of America)

Contributing Authors: William Anderegg (The United States of America), Edward Armstrong (United Kingdom), Ana Bastos (Portugal/Germany), Terje Koren Bernsten (Norway), Peng Cai (China), Katherine Calvin (The United States of America), Francesco Cherubini (Italy), Sarah Connors (France/United Kingdom), Annette Cowie (Australia), Edouard Davin (Switzerland/ France), Cecile De Klein (New Zealand), Giacomo Grassi (Italy/EU), Rafiq Hamdi (Belgium), Florian Humpenöder (Germany), David Kanter (The United States of America), Gerhard Krinner (France), Sonali McDermid (India/The United States of America), Devaraju Narayanappa (India/France), Josep Peñuelas (Spain), Prajal Pradhan (Nepal), Benjamin Quesada (Colombia), Stephanie Roe (The Philippines/The United States of America), Robert A. Rohde (The United States of America), Martijn Slot (Panama), Rolf Sommer (Germany), Moa Sporre (Norway), Benjamin Sulman (The United States of America), Alasdair Sykes (United Kingdom), Phil Williamson (United Kingdom), Yuyu Zhou (China/The United States of America)

Review Editors: Pierre Bernier (Canada), Jhan Carlo Espinoza (Peru), Sergey Semenov (The Russian Federation)

Chapter Scientist: Xiyang Xu (China)

Date of Draft: 27/4/2019

1	Table of Contents	
2	Chapter 2: Land-Climate Interactions	1
3	Executive Summary.....	3
4	2.1 Introduction: Land – climate interactions.....	9
5	2.1.1 Recap of previous IPCC and other relevant reports as baselines.....	9
6	2.1.2 Introduction to the chapter structure	11
7	Box 2.1: Processes underlying land-climate interactions.....	12
8	2.2 The effect of climate variability and change on land	14
9	2.2.1 Overview of climate impacts on land	14
10	2.2.2 Climate driven changes in aridity	16
11	2.2.3 The influence of climate change on food security	17
12	2.2.4 Climate-driven changes in terrestrial ecosystems	17
13	2.2.5 Climate extremes and their impact on land functioning	19
14	Cross-Chapter Box 3: Fire and Climate Change	25
15	2.3 Greenhouse gas fluxes between land and atmosphere.....	28
16	2.3.1 Carbon Dioxide.....	29
17	2.3.2 Methane	36
18	2.3.3 Nitrous Oxide.....	40
19	Box 2.2: Methodologies for estimating national to global scale anthropogenic land carbon fluxes..	43
20	2.4 Emissions and impacts of short-lived climate forcers (SLCF) from land	46
21	2.4.1 Mineral dust	47
22	2.4.2 Carbonaceous Aerosols.....	49
23	2.4.3 Biogenic Volatile Organic Compounds (BVOCs).....	51
24	2.5 Land impacts on climate and weather through biophysical and GHGs effects	53
25	2.5.1 Impacts of historical and future anthropogenic land cover changes	54
26	2.5.2 Impacts of specific land use changes	60
27	2.5.3 Amplifying / dampening climate changes via land responses	68
28	2.5.4 Non-local and downwind effects resulting from changes in land cover	72
29	Cross-Chapte Box 4: Climate Change and Urbanisation	73
30	2.6 Climate consequences of response options	77
31	2.6.1 Climate impacts of individual response options	77
32	2.6.2 Integrated pathways for climate change mitigation	85
33	2.6.3 The contribution of response options to the Paris Agreement	91
34	2.7 Plant and soil processes underlying land-climate interactions	94
35	2.7.1 Temperature responses of plant and ecosystem production.....	94
36	2.7.2 Water transport through soil-plant-atmosphere continuum and drought mortality.....	95
37	2.7.3 Soil microbial effects on soil nutrient dynamics and plant responses to elevated CO ₂	96
38	2.7.4 Vertical distribution of soil organic carbon	97
39	2.7.5 Soil carbon responses to warming and changes in soil moisture	97
40	2.7.6 Soil carbon responses to changes in organic-matter inputs by plants	98

1 **Executive Summary**

2
3 Land and climate interact in complex ways through changes in forcing and multiple biophysical and
4 biogeochemical feedbacks across different spatial and temporal scales. This chapter assesses climate impacts
5 on land and land impacts on climate, the human contributions to these changes, as well as land-based
6 adaptation and mitigation response options to combat projected climate changes.
7

8 ***Implications of climate change, variability, and extremes for land systems***

9
10 **It is certain that globally averaged land surface air temperature (LSAT) has risen faster than the**
11 **global mean surface temperature (i.e., combined LSAT and sea surface temperature) from**
12 **preindustrial (1850–1900) to present day (1999–2018). According to the single longest and most**
13 **extensive dataset, the LSAT increase between the preindustrial period and present day was 1.52°C**
14 **(the *very likely* range of 1.39°C to 1.66°C). For the 1880–2018 period, when four independently**
15 **produced datasets exist, the LSAT increase was 1.41°C (1.31°C–1.51°C), where the range represents**
16 **the spread in the datasets' median estimates.** Analyses of paleo records, historical observations, model
17 simulations, and underlying physical principles are all in agreement that LSATs are increasing at a higher
18 rate than SST as a result of differences in evaporation, land-climate feedbacks, and changes in the aerosol
19 forcing over land (*very high confidence*). For the 2000–2016 period, the land-to-ocean warming ratio (about
20 1.6) is in close agreement between different observational records and the CMIP5 climate model simulations
21 (the *likely* range of 1.54 to 1.81). {2.2.1}

22
23 **Anthropogenic warming has resulted in shifts of climate zones, primarily as an increase in dry**
24 **climates and decrease of polar climates (*high confidence*). Ongoing warming is projected to result in**
25 **new, hot climates in tropical regions and to shift climate zones poleward in the mid- to high latitudes**
26 **and upward in regions of higher elevation (*high confidence*).** Ecosystems in these regions will become
27 increasingly exposed to temperature and rainfall extremes beyond climate regimes they are currently adapted
28 to (*high confidence*), which can alter their structure, composition and functioning. Additionally, high-latitude
29 warming is projected to accelerate permafrost thawing and increase disturbance in boreal forests through
30 abiotic (e.g., drought, fire) and biotic (e.g., pests, disease) agents (*high confidence*). {2.2.1, 2.2.2, 2.5.3}

31
32 **Globally, greening trends (trends of increased photosynthetic activity in vegetation) have increased**
33 **over the last 2-3 decades by 22–33%, particularly over China, India, many parts of Europe, central**
34 **North America, southeast Brazil and southeast Australia (*high confidence*).** This results from a
35 combination of direct (i.e., land use and management, forest conservation and expansion) and indirect factors
36 (i.e., CO₂ fertilisation, extended growing season, global warming, nitrogen deposition, increase of diffuse
37 radiation) linked to human activities (*high confidence*). Browning trends (trends of decreasing photosynthetic
38 activity) are projected in many regions where increases in drought and heat waves are projected in a warmer
39 climate. There is *low confidence* in the projections of global greening and browning trends. {2.2.4, Cross-
40 Chapter Box 4: Climate change and urbanisation, in this chapter}

41
42 **The frequency and intensity of some extreme weather and climate events have increased as a**
43 **consequence of global warming and will continue to increase under medium and high emission**
44 **scenarios (*high confidence*).** Recent heat-related events, e.g., heat waves, have been made more frequent or
45 intense due to anthropogenic greenhouse gas emissions in most land regions and the frequency and intensity
46 of drought has increased in Amazonia, north-eastern Brazil, the Mediterranean, Patagonia, most of Africa
47 and north-eastern China (*medium confidence*). Heat waves are projected to increase in frequency, intensity
48 and duration in most parts of the world (*high confidence*) and drought frequency and intensity is projected to
49 increase in some regions that are already drought prone, predominantly in the Mediterranean, central Europe,
50 the southern Amazon and southern Africa (*medium confidence*). These changes will impact ecosystems, food
51 security and land processes including greenhouse gas (GHG) fluxes (*high confidence*). {2.2.5}

1
2 **Climate change is playing an increasing role in determining wildfire regimes along-side human**
3 **activity (*medium confidence*), with future climate variability expected to enhance the risk and severity**
4 **of wildfires in many biomes such as tropical rainforests (*high confidence*).** Fire weather seasons have
5 lengthened globally between 1979 and 2013 (*low confidence*). Global land area burned has declined in recent
6 decades, mainly due to less burning in grasslands and savannahs (*high confidence*). While drought remains
7 the dominant driver of fire emissions, there has recently been increased fire activity in some tropical and
8 temperate regions during normal to wetter than average years due to warmer temperatures that increase
9 vegetation flammability (*medium confidence*). The boreal zone is also experiencing larger and more frequent
10 fires, and this may increase under a warmer climate (*medium confidence*). {Cross-Chapter Box 4: Climate
11 change and urbanisation, in this chapter}

12 ***Terrestrial greenhouse gas fluxes on unmanaged and managed lands***

13 **Agriculture, Forestry and Other Land Use (AFOLU) is a significant net source of GHG emissions**
14 **(*high confidence*), contributing to about 22% of anthropogenic emissions of carbon dioxide (CO₂),**
15 **methane (CH₄), and nitrous oxide (N₂O) combined as CO₂ equivalents in 2007 to 2016 (*medium***
16 ***confidence*).** AFOLU results in both emissions and removals of CO₂, CH₄, and N₂O to and from the
17 atmosphere (*high confidence*). These fluxes are affected simultaneously by natural and human drivers,
18 making it difficult to separate natural from anthropogenic fluxes (*very high confidence*). {2.3}

19 **The total net land-atmosphere flux of CO₂ on both managed and unmanaged lands very likely**
20 **provided a global net removal from 2008 to 2017 according to models, (-6.2 ± 3.7 GtCO₂ yr⁻¹, *medium***
21 ***confidence*).** This net removal is comprised of two major components: i) modelled net anthropogenic
22 emissions from AFOLU are *likely* 5.5 ± 2.6 GtCO₂ yr⁻¹ driven by land cover change, including deforestation
23 and afforestation/reforestation, and wood harvesting (accounting for about 13% of total net anthropogenic
24 emissions of CO₂) (*medium confidence*); and ii) modelled net removals due to non-anthropogenic processes
25 are *likely* 11.7 ± 2.6 GtCO₂ yr⁻¹ on managed and unmanaged lands, driven by environmental changes such as
26 increasing CO₂, nitrogen deposition, and changes in climate (accounting for a removal of 29% of the CO₂
27 emitted from all anthropogenic activities (fossil fuel, industry and AFOLU) (*medium confidence*). {2.3.1}

28 **The anthropogenic emissions of CO₂ from AFOLU reported in countries' GHG inventories were 0.1 ±**
29 **1.0 GtCO₂ yr⁻¹ globally during 2005 to 2014 (*low confidence*), much lower than emission estimates**
30 **from global models of 5.1 ± 2.6 GtCO₂ yr⁻¹ over the same time period. Reconciling these differences**
31 **can support consistency and transparency in assessing global progress towards meeting modelled**
32 **mitigation pathway such as under the Paris Agreement's global stocktake (*medium confidence*).** This
33 discrepancy is consistent with understanding of the different approaches used to defining anthropogenic
34 fluxes. Inventories consider larger areas of forested lands as managed than models do, and report all fluxes
35 on managed lands as anthropogenic, including a large net sink due to the indirect effects of changing
36 environmental conditions (e.g., climate change, and change in atmospheric CO₂ and N). In contrast, the
37 models assign part of this indirect forest sink to the non-anthropogenic sink on unmanaged lands. {2.3.1}

38 **The gross emissions from AFOLU (one third of total global emissions) are more indicative of**
39 **mitigation potential of reduced deforestation than the global net emissions (13% of total global**
40 **emissions), which include compensating deforestation and afforestation fluxes (*high confidence*).** The
41 net flux of CO₂ from AFOLU is composed of two opposing gross fluxes: gross emissions (20 GtCO₂ yr⁻¹)
42 from deforestation, cultivation of soils, and oxidation of wood products; and gross removals (-14 GtCO₂ yr⁻¹)
43 largely from forest growth following wood harvest and agricultural abandonment (*medium confidence*).
44 {2.3.1}

45 **Land is a net source of CH₄, accounting for 61% of anthropogenic CH₄ emissions for the 2005–2015**

1 **period (*medium confidence*)**. The pause in the rise of atmospheric CH₄ concentrations between 2000 and
2 2006 and the subsequent renewed increase appear to be partially associated with land use and land use
3 change. The recent depletion trend of the ¹³C isotope in the atmosphere indicates that higher biogenic sources
4 explain part of the current CH₄ increase and that biogenic sources make up a larger proportion of the source
5 mix than they did before 2000 (*high confidence*). In agreement with the findings of AR5, tropical wetlands
6 and peatlands continue to be important drivers of inter-annual variability and current CH₄ concentration
7 increases (*medium evidence, high agreement*). Ruminants and the expansion of rice cultivation are also
8 important contributors to the current trend (*medium evidence, high agreement*). There is significant and
9 ongoing accumulation of CH₄ in the atmosphere (*very high confidence*). {2.3.2}

10
11 **AFOLU is the main anthropogenic sources of N₂O primarily due to nitrogen (N) application to soils**
12 (*high confidence*). In croplands, the main driver of N₂O emissions is a lack of synchronisation between crop
13 N demand and soil N supply, with approximately 50% of the N applied to agricultural land not taken up by
14 the crop. Cropland soils emit over 3 Mt N₂O-N yr⁻¹ (*medium confidence*). Because the response of N₂O
15 emissions to fertiliser application rates is non-linear, in regions of the World where low N application rates
16 dominate, such as sub-Saharan Africa and parts of Eastern Europe, increases in N fertiliser use would
17 generate relatively small increases in agricultural N₂O emissions. Decreases in application rates in regions
18 where application rates are high and exceed crop demand for parts of the growing season will have very
19 large effects on emissions reductions (*medium evidence, high agreement*). {2.3.3}

20
21 **While managed pastures make up only one-quarter of grazing lands, they contributed more than**
22 **three-quarters of N₂O emissions from grazing lands between 1961 and 2014 with rapid recent**
23 **increases of N inputs resulting in disproportionate growth in emissions from these lands (*medium***
24 ***confidence*)**. Grazing lands (pastures and rangelands) are responsible for more than one-third of total
25 anthropogenic N₂O emissions or more than one-half of agricultural emissions (*high confidence*). Emissions
26 are largely from North America, Europe, East Asia, and South Asia, but hotspots are shifting from Europe to
27 southern Asia (*medium confidence*). {2.3.3}

28
29 **Increased emissions from vegetation and soils due to climate change in the future are expected to**
30 **counteract potential sinks due to CO₂ fertilisation (*low confidence*)**. Responses of vegetation and soil
31 organic carbon (SOC) to rising atmospheric CO₂ concentration and climate change are not well constrained
32 by observations (*medium confidence*). Nutrient (e.g., nitrogen, phosphorus) availability can limit future plant
33 growth and carbon storage under rising CO₂ (*high confidence*). However, new evidence suggests that
34 ecosystem adaptation through plant-microbe symbioses could alleviate some nitrogen limitation (*medium*
35 *evidence, high agreement*). Warming of soils and increased litter inputs will accelerate carbon losses through
36 microbial respiration (*high confidence*). Thawing of high-latitude/altitude permafrost will increase rates of
37 SOC loss and change the balance between CO₂ and CH₄ emissions (*medium confidence*). The balance
38 between increased respiration in warmer climates and carbon uptake from enhanced plant growth is a key
39 uncertainty for the size of the future land carbon sink (*medium confidence*). {2.3.1, 2.7.2, Box 2.3}

40 41 ***Biophysical and biogeochemical land forcing and feedbacks to the climate system***

42
43 **Changes in land conditions from human use or climate change in turn affect regional and global**
44 **climate (*high confidence*)**. On the global scale, this is driven by changes in emissions or removals of CO₂,
45 CH₄, and N₂O by land (biogeochemical effects) and by changes in the surface albedo (*very high confidence*).
46 Any local land changes that redistribute energy and water vapour between the land and the atmosphere
47 influence regional climate (biophysical effects; *high confidence*). However, there is *no confidence* in whether
48 such biophysical effects influence global climate. {2.1, 2.3, 2.5.1, 2.5.2}

49
50 **Changes in land conditions modulate the likelihood, intensity and duration of many extreme events**
51 **including heat waves (*high confidence*) and heavy precipitation events (*medium confidence*)**. Dry soil

1 conditions favour or strengthen summer heat wave conditions through reduced evapotranspiration and
2 increased sensible heat. By contrast wet soil conditions, for example from irrigation, or crop management
3 practices that maintain a cover crop all year round, can dampen extreme warm events through increased
4 evapotranspiration and reduced sensible heat. Droughts can be intensified by poor land management.
5 Urbanisation increases extreme rainfall events over or downwind of cities (*medium confidence*). {2.5.1,
6 2.5.2, 2.5.3}

7
8 **Historical changes in anthropogenic land cover have resulted in a mean annual global warming of**
9 **surface air from biogeochemical effects (*very high confidence*), dampened by a cooling from**
10 **biophysical effects (*medium confidence*).** Biogeochemical warming results from increased emissions of
11 GHGs by land, with model-based estimates of $+0.20\pm 0.05^{\circ}\text{C}$ (global climate models) and $+0.24\pm 0.12^{\circ}\text{C}$
12 (dynamic global vegetation models, DGVMs) as well as an observation-based estimate of $+0.25\pm 0.10^{\circ}\text{C}$. A
13 net biophysical cooling of $-0.10\pm 0.14^{\circ}\text{C}$ has been derived from global climate models in response to the
14 increased surface albedo and decreased turbulent heat fluxes, but it is smaller than the warming effect from
15 land-based emissions. However when both biogeochemical and biophysical effects are accounted for within
16 the same global climate model, the models do not agree on the sign of the net change in mean annual surface
17 air temperature. {2.3, 2.5.1, Box 2.1}

18
19 **The future projected changes in anthropogenic land cover that have been examined for AR5 would**
20 **result in a biogeochemical warming and a biophysical cooling whose magnitudes depend on the**
21 **scenario (*high confidence*).** Biogeochemical warming has been projected for RCP8.5 by both global climate
22 models ($+0.20\pm 0.15^{\circ}\text{C}$) and DGVMs ($+0.28\pm 0.11^{\circ}\text{C}$) (*high confidence*). A global biophysical cooling of
23 $0.10\pm 0.14^{\circ}\text{C}$ is estimated from global climate models, and projected to dampen the land-based warming (*low*
24 *confidence*). For RCP4.5 the biogeochemical warming estimated from global climate models ($+0.12\pm 0.17^{\circ}\text{C}$)
25 is stronger than the warming estimated by DGVMs ($+0.01\pm 0.04^{\circ}\text{C}$) but based on *limited evidence*, as is the
26 biophysical cooling ($-0.10\pm 0.21^{\circ}\text{C}$). {2.5.2}

27
28 **Regional climate change can be dampened or enhanced by changes in local land cover and land use**
29 **(*high confidence*) but this depends on the location and the season (*high confidence*).** In boreal regions,
30 for example, where projected climate change will migrate treeline northward, increase the growing season
31 length and thaw permafrost, regional winter warming will be enhanced by decreased surface albedo and
32 snow, whereas warming will be dampened during the growing season due to larger evapotranspiration (*high*
33 *confidence*). In the tropics, wherever climate change will increase rainfall, vegetation growth and associated
34 increase in evapotranspiration will result in a dampening effect on regional warming (*medium confidence*).
35 {2.5.2, 2.5.3}

36
37 **According to model-based studies, changes in local land cover or available water from irrigation**
38 **affect climate in regions as far as few hundreds of kilometres downwind (*high confidence*).** The local
39 redistribution of water and energy following the changes on land affect the horizontal and vertical gradients
40 of temperature, pressure and moisture, thus alter regional winds and consequently moisture and temperature
41 advection and convection, and this affects precipitation. {2.5.2, 2.5.4, Cross-Chapter Box 4: Climate
42 Change and Urbanisation}

43
44 **Future increases in both climate change and urbanisation will enhance warming in cities and their**
45 **surroundings (urban heat island), especially during heat waves (*high confidence*).** Urban and peri-urban
46 agriculture, and more generally urban greening, can contribute to mitigation (*medium confidence*) as well as
47 to adaptation (*high confidence*), with co-benefits for food security and reduced soil-water-air pollution.
48 {Cross-Chapter Box 4: Climate Change and Urbanisation}

49
50 **Regional climate is strongly affected by natural land aerosols (*medium confidence*) (e.g., mineral dust,**
51 **black, brown and organic carbon), but there is *low confidence* in historical trends, interannual and**

1 **decadal variability, and future changes.** Forest cover affects climate through emissions of biogenic
2 volatile organic compounds (BVOC) and aerosols (*low confidence*). The decrease in the emissions of
3 BVOC resulting from the historical conversion of forests to cropland has resulted in a positive radiative
4 forcing through direct and indirect aerosol effects, a negative radiative forcing through the reduction in the
5 atmospheric lifetime of methane and it has contributed to increased ozone concentrations in different
6 regions (*low confidence*). {2.4, 2.5}

7
8 ***Consequences for the climate system of land-based adaptation and mitigation options, including carbon
9 dioxide removal (negative emissions)***

10
11 **About one quarter of the 2030 mitigation pledged by countries in their initial Nationally Determined
12 Contributions (NDCs) under the Paris Agreement is expected to come from land-based mitigation
13 options (*medium confidence*).** Most of the Nationally Determined Contributions (NDCs) submitted by
14 countries include land-based mitigation, although many lack details. Several refer explicitly to reduced
15 deforestation and forest sinks, while a few include soil carbon sequestration, agricultural management and
16 bioenergy. Full implementation of NDCs (submitted by February 2016) is expected to result in net
17 removals of 0.4–1.3 GtCO₂ y⁻¹ in 2030 compared to the net flux in 2010, where the range represents low to
18 high mitigation ambition in pledges, not uncertainty in estimates (*medium confidence*). {2.6.3}

19
20 **Several mitigation response options have technical potential for >3 GtCO₂-eq yr⁻¹ by 2050 through
21 reduced emissions and Carbon Dioxide Removal (CDR) (*high confidence*), some of which compete
22 for land and other resources, while others may reduce the demand for land (*high confidence*).**
23 Estimates of the technical potential of individual response options are not necessarily additive. The largest
24 potential for reducing AFOLU emissions are through reduced deforestation and forest degradation (0.4–5.8
25 GtCO₂-eq yr⁻¹) (*high confidence*), a shift towards plant-based diets (0.7–8.0 GtCO₂-eq yr⁻¹) (*high
26 confidence*) and reduced food and agricultural waste (0.8–4.5 CO₂-eq yr⁻¹) (*high confidence*). Agriculture
27 measures combined could mitigate 0.3–3.4 GtCO₂-eq yr⁻¹ (*medium confidence*). The options with largest
28 potential for CDR are afforestation/reforestation (0.5–10.1 CO₂-eq yr⁻¹) (*medium confidence*), soil carbon
29 sequestration in croplands and grasslands (0.4–8.6 CO₂-eq yr⁻¹) (*high confidence*) and Bioenergy with
30 Carbon Capture and Storage (BECCS) (0.4–11.3 CO₂-eq yr⁻¹) (*medium confidence*). While some estimates
31 include sustainability and cost considerations, most do not include socio-economic barriers, the impacts of
32 future climate change or non-GHG climate forcings. {2.6.1}

33
34 **Response options intended to mitigate global warming will also affect the climate locally and
35 regionally through biophysical effects (*high confidence*).** Expansion of forest area, for example, typically
36 removes CO₂ from the atmosphere and thus dampens global warming (biogeochemical effect, *high
37 confidence*), but the biophysical effects can dampen or enhance regional warming depending on location,
38 season and time of day. During the growing season, afforestation generally brings cooler days from
39 increased evapotranspiration, and warmer nights (*high confidence*). During the dormant season, forests are
40 warmer than any other land cover, especially in snow-covered areas where forest cover reduces albedo
41 (*high confidence*). At the global level, the temperature effects of boreal afforestation/reforestation run
42 counter to GHG effects, while in the tropics they enhance GHG effects. In addition, trees locally dampen
43 the amplitude of heat extremes (*medium confidence*). {2.5.2, 2.5.4, 2.7, Cross-Chapter Box 4: Climate
44 Change and Urbanisation}

45
46 **Mitigation response options related to land use are a key element of most modelled scenarios that
47 provide strong mitigation, alongside emissions reduction in other sectors (*high confidence*).** More
48 stringent climate targets rely more heavily on land-based mitigation options, in particular, CDR
49 (*high confidence*). Across a range of scenarios in 2100, CDR is delivered by both afforestation (median
50 values of -1.3, -1.7 and -2.4 GtCO₂yr⁻¹ for scenarios RCP4.5, RCP2.6 and RCP1.9 respectively) and
51 bioenergy with carbon capture and storage (BECCS) (-6.5, -11 and -14.9 GtCO₂ yr⁻¹). Emissions of CH₄

1 and N₂O are reduced through improved agricultural and livestock management as well as dietary shifts
2 away from emission-intensive livestock products by 133.2, 108.4 and 73.5 MtCH₄yr⁻¹; and 7.4, 6.1 and 4.5
3 MtN₂O yr⁻¹ for the same set of scenarios in 2100 (*high confidence*). High levels of bioenergy crop
4 production can result in increased N₂O emissions due to fertiliser use. The Integrated Assessment Models
5 that produce these scenarios mostly neglect the biophysical effects of land-use on global and regional
6 warming. {2.5, 2.6.2}

7
8 **Large-scale implementation of mitigation response options that limit warming to 1.5 or 2°C would**
9 **require conversion of large areas of land for afforestation/reforestation and bioenergy crops, which**
10 **could lead to short-term carbon losses (*high confidence*).** The change of global forest area in mitigation
11 pathways ranges from about -0.2 to +7.2 Mkm² between 2010 and 2100 (median values across a range of
12 models and scenarios: RCP4.5, RCP2.6, RCP1.9), and the land demand for bioenergy crops ranges from
13 about 3.2–6.6 Mkm² in 2100 (*high confidence*). Large-scale land-based CDR is associated with multiple
14 feasibility and sustainability constraints (Chapters 6, 7). In high carbon lands such as forests and peatlands,
15 the carbon benefits of land protection are greater in the short-term than converting land to bioenergy crops
16 for BECCS, which can take several harvest cycles to ‘pay-back’ the carbon emitted during conversion
17 (carbon-debt), from decades to over a century (*medium confidence*). {2.6.2, Chapters 6, 7}

18
19 **It is possible to achieve climate change targets with low need for land-demanding CDR such as**
20 **BECCS, but such scenarios rely more on rapidly reduced emissions or CDR from forests, agriculture**
21 **and other sectors.** Terrestrial CDR has the technical potential to balance emissions that are difficult to
22 eliminate with current technologies (including food production). Scenarios that achieve climate change
23 targets with less need for terrestrial CDR rely on agricultural demand-side changes (diet change, waste
24 reduction), and changes in agricultural production such as agricultural intensification. Such pathways that
25 minimise land use for bioenergy and BECCS are characterised by rapid and early reduction of GHG
26 emissions in all sectors, as well as earlier CDR in through afforestation. In contrast, delayed mitigation
27 action would increase reliance on land-based CDR (*high confidence*). {2.6.2}

2.1 Introduction: Land – climate interactions

This chapter assesses the literature on two-way interactions between climate and land, with focus on scientific findings published since AR5 and some aspects of the land-climate interactions that were not assessed in previous IPCC reports. Previous IPCC assessments recognised that climate affects land cover and land surface processes, which in turn affect climate. However, previous assessments mostly focused on the contribution of land to global climate change via its role in emitting and absorbing greenhouse gases (GHGs) and short-lived climate forcers (SLCFs), or via implications of changes in surface reflective properties (i.e., albedo) for solar radiation absorbed by the surface. This chapter examines scientific advances in understanding the interactive changes of climate and land, including impacts of climate change, variability and extremes on managed and unmanaged lands. It assesses climate forcing of land changes from direct (e.g., land use change and land management) and indirect (e.g., increasing atmospheric CO₂ concentration and nitrogen deposition) effects at local, regional, and global scale.

2.1.1 Recap of previous IPCC and other relevant reports as baselines

The evidence that land cover matters for the climate system have long been known, especially from early paleoclimate modelling studies and impacts of human-induced deforestation at the margin of deserts (de Noblet et al. 1996; Kageyama et al. 2004). The understanding of how land use activities impact climate has been put forward by the pioneering work of (Charney 1975) who examined the role of overgrazing-induced desertification on the Sahelian climate.

Since then there have been many modelling studies that reported impacts of idealised or simplified land cover changes on weather patterns (e.g., Pielke et al. 2011). The number of studies dealing with such issues has increased significantly over the past 10 years, with more studies that address realistic past or projected land changes. However, very few studies have addressed the impacts of land cover changes on climate as very few land surface models embedded within climate models (whether global or regional), include a representation of land management. Observation-based evidence of land-induced climate impacts emerged even more recently (e.g., Alkama and Cescatti 2016; Bright et al. 2017; Lee et al. 2011; Li et al. 2015; Duveiller et al. 2018; Forzieri et al. 2017) and the literature is therefore limited.

In previous IPCC reports, the interactions between climate change and land were covered separately by three working groups. AR5 WGI assessed the role of land use change in radiative forcing, land-based GHGs source and sink, and water cycle changes that focused on changes of evapotranspiration, snow and ice, runoff, and humidity. AR5 WGII examined impacts of climate change on land, including terrestrial and freshwater ecosystems, managed ecosystems, and cities and settlements. AR5 WGIII assessed land-based climate change mitigation goals and pathways in the AFOLU. Here, this chapter assess land-climate interactions from all three working groups. It also builds on previous special reports such as the Special Report on Global Warming of 1.5°C (SR15). It links to the IPCC Guidelines on National Greenhouse Gas Inventories in the land sector. Importantly, this chapter assesses knowledge that has never been reported in any of those previous reports. Finally, the chapter also tries to reconcile the possible inconsistencies across the various IPCC reports.

Land-based water cycle changes: AR5 reported an increase in global evapotranspiration from the early 1980s to 2000s, but a constraint on further increases from low of soil moisture availability. Rising CO₂ concentration limits stomatal opening and thus also reduces transpiration, a component of evapotranspiration. Increasing aerosol levels, and declining surface wind speeds and levels of solar radiation reaching the ground are additional regional causes of the decrease in evapotranspiration.

Land area precipitation change: Averaged over the mid-latitude land areas of the Northern Hemisphere, precipitation has increased since 1901 (*medium confidence* before and *high confidence* after 1951). For other

1 latitudes, area-averaged long-term positive or negative trends have *low confidence*. There are *likely* more
2 land regions where the number of heavy precipitation events has increased than where it has decreased.
3 Extreme precipitation events over most of the mid-latitude land masses and over wet tropical regions will
4 very likely become more intense and more frequent (IPCC 2013a).

5
6 **Land-based GHGs:** AR5 reported that annual net CO₂ emissions from anthropogenic land use change were
7 0.9 [0.1–1.7] GtC yr⁻¹ on average during 2002 to 2011 (*medium confidence*). From 1750 to 2011, CO₂
8 emissions from fossil fuel combustion have released an estimated 375 [345–405] GtC to the atmosphere,
9 while deforestation and other land use change have released an estimated 180 [100–260] GtC. Of these
10 cumulative anthropogenic CO₂ emissions, 240 [230–250] GtC have accumulated in the atmosphere, 155
11 [125–185] GtC have been taken up by the ocean and 160 [70–250] GtC have accumulated in terrestrial
12 ecosystems (i.e., the cumulative residual land sink) (Ciais et al. 2013a). Updated assessment and knowledge
13 gaps are covered in Section 2.3.

14
15 **Future terrestrial carbon source/sink:** AR5 projected with *high confidence* that tropical ecosystems will
16 uptake less carbon and with *medium confidence* that at high latitudes, land carbon sink will increase in a
17 warmer climate. Thawing permafrost in the high latitudes is potentially a large carbon source at warmer
18 climate, but the magnitude of CO₂ and CH₄ emissions due to permafrost thawing is still uncertain. The SR15
19 further indicates that constraining warming to 1.5°C would prevent the melting of an estimated permafrost
20 area of 2 million km² over the next centuries compared to 2°C. Updates to these assessments are found in
21 Sections 2.3.

22
23 **Land use change altered albedo:** AR5 stated with *high confidence* that anthropogenic land use change has
24 increased the land surface albedo, which has led to a RF of $-0.15 \pm 0.10 \text{ W m}^{-2}$. However, it also underlined
25 that the sources of the large spread across independent estimates was caused by differences in assumptions
26 for the albedo of natural and managed surfaces and for the fraction of land use change before 1750.
27 Generally, our understanding of albedo changes from land use change has been enhanced from AR4 to AR5,
28 with a narrower range of estimates and a higher confidence level. The radiative forcing from changes in
29 albedo induced by land use changes was estimated in AR5 at -0.15 W m^{-2} (-0.25 to about -0.05), with
30 *medium confidence* in AR5 (Shindell et al. 2013). This was an improvement over AR4 in which it was
31 estimated at -0.2 W m^{-2} (-0.4 to about 0), with *low to medium confidence* (Forster et al. 2007). Section 2.5
32 shows that albedo is not the only source of biophysical land-based climate forcing to be considered.

33
34 **Hydrological feedback to climate:** Land use changes also affect surface temperatures through non-radiative
35 processes, and particularly through the hydrological cycle. These processes are less well known and are
36 difficult to quantify, but tend to offset the impact of albedo changes. As a consequence, there is low
37 agreement on the sign of the net change in global mean temperature as a result of land use change (Hartmann
38 et al. 2013a). An updated assessment on these points is covered in Section 2.5 and 2.2

39
40 **Climate-related extremes on land:** AR5 reported that impacts from recent climate-related extremes reveal
41 significant vulnerability and exposure of some ecosystems to current climate variability. Impacts of such
42 climate-related extremes include alteration of ecosystems, disruption of food production and water supply,
43 damage to infrastructure and settlements, morbidity and mortality, and consequences for mental health and
44 human well-being (Burkett et al. 2014). The SR15 further indicates that limiting global warming to 1.5°C
45 limits the risks of increases in heavy precipitation events in several regions (*high confidence*). In urban areas
46 climate change is projected to increase risks for people, assets, economies and ecosystems (*very high*
47 *confidence*). These risks are amplified for those lacking essential infrastructure and services or living in
48 exposed areas. Updated assessment and knowledge gap for this chapter are covered in Section 2.2 and Cross-
49 Chapter Box 4: Climate Change and Urbanisation.

50
51 **Land-based climate change adaptation and mitigation:** AR5 reported that adaptation and mitigation

1 choices in the near-term will affect the risks related to climate change throughout the 21st century (Burkett et
2 al. 2014). Agriculture, forestry and other land use (AFOLU) are responsible for about 10–12 GtCO₂eq yr⁻¹
3 anthropogenic greenhouse gas emissions mainly from deforestation and agricultural production. Global CO₂
4 emissions from forestry and other land use have declined since AR4, largely due to increased afforestation.
5 The SR15 further indicates that afforestation and bioenergy with carbon capture and storage (BECCS) are
6 important land-based carbon dioxide removal (CDR) options. It also states that land use and land-use change
7 emerge as a critical feature of virtually all mitigation pathways that seek to limit global warming to 1.5°C.
8 Climate Change 2014 Synthesis Report concluded that co-benefits and adverse side effects of mitigation
9 could affect achievement of other objectives such as those related to human health, food security,
10 biodiversity, local environmental quality, energy access, livelihoods and equitable sustainable development.
11 Updated assessment and knowledge gaps are covered in Section 2.6 and Chapter 7.

12
13 Overall, sustainable land management is largely constrained by climate change and extremes, but also puts
14 bounds on the capacity of land to effectively adapt to climate change and mitigate its impacts. Scientific
15 knowledge has advanced on how to optimise our adaptation and mitigation efforts while coordinating
16 sustainable land management across sectors and stakeholder. Details are assessed in subsequent sections.

17 **2.1.2 Introduction to the chapter structure**

18
19
20 This chapter assess the consequences of changes in land cover and functioning, resulting from both land use
21 and climate change, to global and regional climates. The chapter starts by an assessment of the historical and
22 projected responses of land-based and processes to climate change and extremes (Section 2.2). Subsequently,
23 the chapter assesses historical and future changes in terrestrial GHG fluxes (Section 2.3), non-GHG fluxes
24 and precursors of SLCFs (Section 2.4. Section 2.4 focuses on how historical and future changes in land use
25 and land cover influence climate change/variability through biophysical and biogeochemical forcing and
26 feedbacks, how specific land management affects climate, and how in turn climate-induced land changes
27 feedback to climate. Section 2.6 assesses consequences of land-based adaptation and mitigation options for
28 the climate system in GHG and non-GHG exchanges. Sections 2.3 and 2.6 addresses implications of the
29 Paris Agreement for land-climate interactions, and the scientific evidence base for ongoing negotiations
30 around the Paris rulebook, the Global Stocktake, and credibility in measuring, reporting and verifying the
31 climate impacts of anthropogenic activities on land. The chapter also examines how land use and
32 management practices may affect climate change through biophysical feedbacks and radiative forcing
33 (Section 2.5), and assesses policy relevant projected land use changes and sustainable land management for
34 mitigation and adaptation (Section 2.6). Finally, the chapter concludes with a brief assessment of advances in
35 the understanding of ecological and biogeochemical processes underlying land-climate interactions (Section
36 2.7).

37
38 The chapter includes three chapter boxes providing general overview of (i) processes underlying land-
39 climate interactions (Box 2.1.); (ii) methodological approaches for estimating anthropogenic land carbon
40 fluxes from national to global scales (Box 2.2.); (iii) CO₂ fertilisation and enhanced terrestrial uptake of
41 carbon (Box 2.3). In addition this chapter includes two cross-chapter boxes on climate change and fire
42 (Cross-Chapter Box 3); and on urbanisation and climate change (Cross-Chapter Box 4).

43
44 In summary, the chapter assesses scientific understanding related to: 1) how a changing climate affects
45 terrestrial ecosystems, including those on managed lands; 2) how land affects climate through biophysical
46 and biogeochemical feedbacks; and 3) how land use or cover change and land management play an
47 important and complex role in the climate system. This chapter also pays special attention to advances in
48 understanding cross-scale interactions, emerging issues, heterogeneity, and teleconnections.

Box 2.1: Processes underlying land-climate interactions

Land continuously interacts with the atmosphere through exchanges of, for instance, greenhouse gases (e.g., CO₂, CH₄, N₂O), water, energy, or precursors of short lived-climate forcers (e.g., biogenic volatile organic compounds, dust, black carbon). The terrestrial biosphere also interacts with oceans through processes such as the influx of freshwater, nutrients, carbon and particles. These interactions affect where and when rain falls and thus irrigation needs for crops, frequency and intensity of heat waves, and air quality. They are modified by global and regional climate change, decadal, interannual and seasonal climatic variations, and weather extremes, as well as human actions on land (e.g., crop and forest management, afforestation and deforestation). This in turn affects atmospheric composition, surface temperature, hydrological cycle and thus local, regional and global climate. This box introduces some of the fundamental land processes governing biophysical and biogeochemical effects and feedbacks to the climate (Box 2.1 Figure 1)

Box 2.1 Figure 1 The structure and functioning of managed and unmanaged ecosystems that affect local, regional, and global climate. Land surface characteristics such as albedo and emissivity determine the amount of solar and long-wave radiation absorbed by land and reflected or emitted to the atmosphere. Surface roughness influences turbulent exchanges of momentum, energy, water, and biogeochemical tracers. Land ecosystems modulate the atmospheric composition through emissions and removals of many GHGs and precursors of SLCFs, including biogenic volatile organic compounds (BVOCs) and mineral dust. Atmospheric aerosols formed from these precursors affect regional climate by altering amounts of precipitation and of radiation reaching land surfaces through their role in clouds physics.

‘Biophysical interactions’ are exchanges of water and energy between the land and the atmosphere (Section 2.5). Land warms up from absorbing solar and long-wave radiation; it cools down through transfers of sensible heat (*via* conduction and convection) and latent heat (energy associated with water evapotranspiration) to the atmosphere and through longwave radiation emission from the land surface (Box 2.1 Figure 1). These interactions between the land and the atmosphere depend on the land surface characteristics, including reflectivity of short-wave radiation (albedo), emissivity of long wave radiation by vegetation and soils, surface roughness, and soil water access by vegetation, which depends on both soil characteristics and amounts of roots. Over seasonal, interannual and decadal time scales, these characteristics vary among different land cover and land-use types and are affected by both natural processes and land management (Anderson et al. 2011). A dense vegetation with high leaf area index, like forests, may absorb more energy than nearby herbaceous vegetation partly due to differences in surface albedo (especially when snow is on the ground). However, denser vegetation also sends more energy back to the atmosphere in the form of evapotranspiration (Bonan, 2008; Burakowski et al., 2018; Ellison et al., 2017; Section 2.5.2) and this contributes to changes in atmospheric water vapour content, affecting and rainfall.

Particularly in extra-tropical regions, these characteristics exhibit strong seasonal patterns with the development and senescence of the vegetation (e.g., leaf colour change and drop). For example, in deciduous forests, seasonal growth increases albedo by 20–50% from the spring minima to growing season maxima, followed by rapid decrease during leaf fall, whereas in grasslands, spring greening causes albedo decreases and only increases with vegetation browning (Hollinger et al. 2010). The seasonal patterns of sensible and

1 latent heat fluxes are also driven by the cycle of leaf development and senescence in temperate deciduous
2 forests: sensible heat fluxes peak in spring and autumn and latent heat fluxes peak in mid-summer (Moore et
3 al. 1996; Richardson et al. 2013).

4
5 Exchanges of greenhouse gases between the land and the atmosphere are referred to as ‘biogeochemical
6 interactions’ (Section 2.3), which are driven mainly by the balance between photosynthesis and respiration
7 by plants, and by the decomposition of soil organic matter by microbes. The conversion of atmospheric
8 carbon dioxide into organic compounds by plant photosynthesis, known as terrestrial net primary
9 productivity, is the source of plant growth, food for human and other organisms, and soil organic carbon.
10 Due to strong seasonal patterns of growth, northern hemisphere terrestrial ecosystems are largely responsible
11 for the seasonal variations in global atmospheric CO₂ concentrations. In addition to CO₂, soils emit
12 methane (CH₄) and nitrous oxide (N₂O) (Section 2.3). Soil temperature and moisture strongly affect
13 microbial activities and resulting fluxes of these three greenhouse gases.

14
15 Much like fossil fuel emissions, GHG emissions from anthropogenic land cover change and land
16 management are ‘forcers’ on the climate system. Other land-based changes to climate are described as
17 ‘feedbacks’ to the climate system - a process by which climate change influences some property of land,
18 which in turn diminishes (negative feedback) or amplifies (positive feedback) climate change. Examples of
19 feedbacks include the changes in the strength of land carbon sinks or sources, soil moisture and plant
20 phenology (Section 2.5.3).

21
22 Incorporating these land-climate processes into climate projections allows for increased understanding of the
23 land’s response to climate change (Section 2.2), and to better quantify the potential of land-based response
24 options for climate change mitigation (Section 2.6). However, to date Earth system models (ESMs)
25 incorporate some combined biophysical and biogeochemical processes only to limited extent and many
26 relevant processes about how plants and soils interactively respond to climate changes are still to be
27 included. (Section 2.7). And even within this class of models, the spread in ESM projections is large, in part
28 because of their varying ability to represent land-climate processes (Hoffman et al. 2014). Significant
29 progress in understanding of these processes has nevertheless been made since AR5.

2.2 The effect of climate variability and change on land

2.2.1 Overview of climate impacts on land

2.2.1.1 Climate drivers of land form and function

Energy is redistributed from the warm equator to the colder poles through large-scale atmospheric and oceanic processes driving the Earth's weather and climate (Oort and Peixóto 1983; Carissimo et al. 1985; Yang et al. 2015a). Subsequently, a number of global climate zones have been classified ranging from large-scale primary climate zones (tropical, sub-tropical, temperate, sub-polar, polar) to much higher-resolution, regional climate zones (e.g., the Köppen-Geiger classification, Kottek et al. 2006). Biomes are adapted to regional climates (Figure 2.1) and may shift as climate, land surface characteristics (e.g., geomorphology, hydrology), CO₂ fertilisation, and fire interact. These biomes and processes therein are subject to modes of natural variability in the ocean-atmosphere system that result in regionally wetter/drier or hotter/cooler periods having temporal scales from weeks to months (e.g., Southern Annular Mode), months to seasons (e.g., Madden-Julian Oscillation), years (e.g., El Niño Southern Oscillation) and decades (e.g. Pacific Decadal Oscillation). Furthermore, climate and weather extremes (such as drought, heat waves, very heavy rainfall, strong winds), whose frequency, intensity and duration are often a function of large-scale modes of variability, impact ecosystems at various space and time scales.

It is *very likely* that changes to natural climate variability as a result of global warming has and will continue to impact terrestrial ecosystems with subsequent impacts on land processes (Hulme et al. 1999; Parmesan and Yohe 2003; Di Lorenzo et al. 2008; Kløve et al. 2014; Berg et al. 2015; Lemordant et al. 2016; Pecl et al. 2017). This chapter assesses climate variability and change, particularly extreme weather and climate, in the context of desertification, land degradation, food security and terrestrial ecosystems more generally. This section does specifically assess the impacts of climate variability and climate change on desertification, land degradation and food security as these impacts are assessed respectively in Chapters 3, 4 and 5. This chapter begins with an assessment of observed warming on land.

Online at <http://www.globalbioclimatics.org>.

2.2.1.2 Changes in global land surface air temperature

Based on analysis of several global and regional land surface air temperature (LSAT) datasets, AR5 concluded that the global LSAT had increased over the instrumental period of record, with the warming rate approximately double that reported over the oceans since 1979 and that "it is certain that globally averaged LSAT has risen since the late 19th century and that this warming has been particularly marked since the

1 1970s". Warming found in the global land datasets is also in a broad agreement with station observations
 2 (Hartmann et al. 2013a).

3
 4 Since AR5, LSAT datasets have been improved and extended. The National Center for Environmental
 5 Information, which is a part of the US National Oceanic and Atmospheric Administration (NOAA),
 6 developed a new version of the Global Historical Climatology Network (GHCNm, version 4) dataset. The
 7 dataset provides an expanded set of station temperature records with more than 25,000 total monthly
 8 temperature stations compared to 7200 in versions v2 and v3 (Menne et al. 2018). Goddard Institute for
 9 Space Studies, which is a part of the US National Aeronautics and Space Administration, (NASA/GISS)
 10 provides estimate of land and ocean temperature anomalies (GISTEMP). The GISTEMP land temperature
 11 anomalies are based upon primarily NOAA/GHCN version 3 dataset (Lawrimore et al. 2011) and account for
 12 urban effects through nightlight adjustments (Hansen et al. 2010). The Climatic Research Unit of the
 13 University of East Anglia, UK (CRUTEM) dataset, now version CRUTEM4.6, incorporates additional
 14 stations (Jones et al. 2012). Finally, the Berkeley Earth Surface Temperature (BEST) dataset provides LSAT
 15 from 1750 to present based on almost 46,000 time series and has the longest temporal coverage of the four
 16 datasets (Rohde et al. 2013). This dataset was derived with methods distinct from those used for
 17 development of the NOAA and NASA datasets and the CRU dataset.
 18
 19

20

 26 **annual mean Global Mean Surface Temperature (GMST) in the HadCRUT4, NOAA Global Temp,**
 27 **GISTEMP and Cowtan&Way datasets (monthly values of which were reported in the Special Report on**
 28 **Global Warming of 1.5°C (Allen et al. 2018)).**
 29

30 According to the available observations in the four datasets, the globally averaged LSAT increased by
 31 1.44°C from the preindustrial period (1850–1900) to present (1999–2018). The warming from the late 19th
 32 century (1881–1900) to present (1999–2018) was 1.41°C (1.31°C–1.51°C) (Table 2.1). The 1.31°C–1.51°C
 33 range represents the spread in median estimates from the four available land datasets and does not reflect
 34 uncertainty in data coverage or methods used. Based on the Berkeley dataset (the longest dataset with the
 35 most extensive land coverage) the total increase in LSAT between the average of the 1850–1900 period and

1 the 1999–2018 period was 1.52°C, (1.39°C–1.66°C; 95% confidence).

2 The extended and improved land datasets reaffirmed the AR5 conclusion that it is certain that globally
3 averaged LSAT has risen since the preindustrial period and that this warming has been particularly marked
4 since the 1970s (Figure 2.2).

5
6 **Table 2.1 Increases in land surface air temperature (LSAT) from preindustrial
7 period and the late 19th century to present (1999–2018).**

Reference period	Dataset of LSAT increase (C°)			
	Berkeley	CRUTEM4	GHCNm, v4	GISTEMP
<i>Preindustrial</i>	1.52	1.31	NA	NA
1850–1900	1.39–1.66 (95% confidence)			
<i>Late 19th century</i>	1.51	1.31	1.37	1.45
1881–1900	1.40–1.63 (95% confidence)			

8
9 Recent analyses of LSAT and sea surface temperature (SST) observations as well as analyses of climate
10 model simulations have refined our understanding of underlying mechanisms responsible for a faster rate of
11 warming over land than over oceans. Analyses of paleo records, historical observations, model simulations,
12 and underlying physical principles are all in agreement that that land is warming faster than the oceans as a
13 result of differences in evaporation, land-climate feedbacks (Section 2.5), and changes in the aerosol forcing
14 over land (Braconnot et al. 2012; Joshi et al. 2013; Sejas et al. 2014; Byrne and O’Gorman 2013, 2015;
15 Wallace and Joshi 2018; Allen et al. 2019) (*very high confidence*). There is also *high confidence* that
16 difference in land and ocean heat capacity is not the primary reason for a faster land than ocean warming.
17 For the recent period the land-to-ocean warming ratio is in close agreement between different observational
18 records (about 1.6) and the CMIP5 climate model simulations (the *likely* range of 1.54°C to 1.81°C). Earlier
19 studies analysing slab ocean models (models in which it is assumed that the deep ocean has equilibrated)
20 produced a higher land temperature increases than sea surface temperature (Manabe et al. 1991; Sutton et al.
21 2007).

22
23 It is certain that globally averaged LSAT has risen faster than GMST from preindustrial (1850–1900) to
24 present day (1999–2018). This is because the warming rate of the land compared to the ocean is substantially
25 higher over the historical period (by approximately 60%) and because Earth surface is approximately one
26 third land and two thirds ocean. This enhanced land warming impacts land processes with implications for
27 desertification (Section 2.2.2, Chapter 3), food security (Section 2.2.3, Chapter 5), terrestrial ecosystems
28 (Section 2.2.4), and GHG and non-GHG fluxes between the land and climate (Section 2.3, Section 2.4).
29 Future changes in land characteristics through adaptation and mitigation processes and associated land-
30 climate feedbacks can dampen warming in some regions and enhance warming in others (Section 2.5).

31 32 **2.2.2 Climate driven changes in aridity**

33
34 Desertification is defined and discussed at length in Chapter 3 of this report and is a function of both human
35 activity and climate variability and change. There are uncertainties in distinguishing between historical
36 climate-caused aridification and desertification and also future projections of aridity as different
37 measurement methods of aridity do not agree on historical or projected changes (3.1.1, 3.2.1). However,
38 warming trends over drylands are twice the global average (Lickley and Solomon 2018) some temperate
39 drylands are projected to convert to subtropical drylands as a result of an increased drought frequency
40 causing reduced soil moisture availability in the growing season (Engelbrecht et al. 2015; Schlaepfer et al.
41 2017). We therefore assess with *medium confidence* that a warming climate will result in regional increases
42 in the spatial extent of drylands under mid- and high emission scenarios and that these regions will warm
43 faster than the global average warming rate.

2.2.3 The influence of climate change on food security

Food security and the various components thereof is addressed in depth in Chapter 5. Climate variables relevant to food security and food systems are predominantly temperature and precipitation-related, but also include integrated metrics that combine these and other variables (like solar radiation, wind, humidity) and extreme weather and climate events including storm surge (see 5.2.1). The impact of climate change through changes in these variables is projected to negatively impact all aspects of food security (food availability, access, utilisation and stability), leading to complex impacts on global food security (Chapter 5) (Table 5.1) (*high confidence*).

Climate change will have regionally distributed impacts, even under aggressive mitigation scenarios (Howden et al. 2007; Rosenzweig et al. 2013; Challinor et al. 2014; Parry et al. 2005; Lobell and Tebaldi 2014; Wheeler and Von Braun 2013). For example, in the northern hemisphere the northward expansion of warmer temperatures in the middle and higher latitudes will lengthen the growing season (Gregory and Marshall 2012; Yang et al. 2015b) which may benefit crop productivity (Parry et al. 2004; Rosenzweig et al., 2014; Deryng et al. 2016). However, continued rising temperatures are expected to impact global wheat yields by about 4–6% reductions for every degree of temperature rise (Liu et al. 2016a; Asseng et al. 2015) and across both mid- and low latitude regions, rising temperatures are also expected to be a constraining factor for maize productivity by the end of the century (Bassu et al. 2014; Zhao et al. 2017). Although there has been a general reduction in frost occurrence during winter and spring and a lengthening of the frost free season in response to growing concentrations of greenhouse gases (Fischer and Knutti 2014; Wypych et al. 2017), there are regions where the frost season length has increased e.g. southern Australia (Crimp et al. 2016). Despite the general reduced frost season length, late spring frosts may increase risk of damage to warming induced precocious vegetation growth and flowering (Meier et al. 2018). Observed and projected warmer minimum temperatures have and will continue to reduce the number of winter chill units required by particularly fruit crops (Luedeling 2012). Crop yields are impacted negatively by increases of seasonal rainfall variability in the tropics, sub-tropics, water-limited and high elevation environments, drought severity and growing season temperatures have a negative impact on crop yield (IFPRI 2009; Schlenker and Lobell 2010; Müller et al. 2017; Parry et al. 2004; Wheeler and Von Braun 2013; Challinor et al. 2014).

Changes in extreme weather and climate (Section 2.2.5) have negative impacts on food security through regional reductions of crop yields. A recent study shows that between 18-43% of the explained yield variance of four crops (maize, soybeans, rice and spring wheat) is attributable to extremes of temperature and rainfall, depending on the crop type (Vogel et al. 2019). Climate shocks, particularly severe drought impact low-income small-holder producers disproportionately (Vermeulen et al. 2012b; Rivera Ferre 2014). Extremes also compromise critical food supply chain infrastructure, making the transport and access to harvested food more difficult (Brown et al. 2015; Fanzo et al. 2018). There is *high confidence* that the impacts of enhanced climate extremes, together with non-climate factors such as nutrient limitation, soil health and competitive plant species, generally outweighs the regionally positive impacts of warming (Lobell et al. 2011; Leakey et al. 2012; Porter et al. 2014; Gray et al. 2016; Pugh et al. 2016; Wheeler and Von Braun 2013; Beer 2018).

2.2.4 Climate-driven changes in terrestrial ecosystems

Previously, the IPCC AR5 reported high confidence that the Earth's biota composition and ecosystem processes have been strongly affected by past changes in global climate, but the rates of the historic climate change are lower than those projected for the 21st century under high warming scenarios like RCP8.5

1 (Settele et al. 2015a). There is *high confidence* that as a result of climate changes over recent decades many
2 plant and animal species have experienced range size and location changes, altered abundances, and shifts in
3 seasonal activities (Urban 2015a; Ernakovich et al. 2014; Elsen and Tingley 2015; Hatfield and Prueger
4 2015; Urban 2015b; Savage and Vellend 2015; Yin et al. 2016; Pecl et al. 2017; Gonsamo et al. 2017;
5 Fadrique et al. 2018; Laurance et al. 2018). There is high confidence that climate zones have already shifted
6 in many parts of the world primarily as an increase of dry, arid climates accompanied by a decrease of polar
7 climates (Chan and Wu 2015; Chen and Chen 2013; Spinoni et al. 2015b). Regional climate zones shifts
8 have been observed over the Asian monsoon region (Son and Bae 2015), Europe (Jylhä et al. 2010), China
9 (Yin et al. 2019), Pakistan (Adnan et al. 2017), the Alps (Rubel et al. 2017) and North-Eastern Brazil,
10 Southern Argentina, the Sahel, Zambia and Zimbabwe, the Mediterranean area, Alaska, Canada and North-
11 Eastern Russia (Spinoni et al. 2015b).

12
13 There is *high confidence* that bioclimates zones will further shift as the climate warms (Williams et al. 2007;
14 Rubel and Kottek 2010; Garcia et al. 2016; Mahony et al. 2017; Law et al. 2018). There is also high
15 confidence that novel, unprecedented climates (climate conditions with no analog in the observational
16 record) will emerge, particularly the tropics (Williams and Jackson 2007; Colwell et al. 2008a; Mora et al.
17 2013, 2014; Hawkins et al. 2014; Mahony et al. 2017; Maule et al. 2017). It is *very likely* that terrestrial
18 ecosystems and land processes will be exposed to disturbances beyond the range of current natural
19 variability as a result of global warming, even under low- to medium-range warming scenarios, and these
20 disturbances will alter the structure, composition and functioning of the system (Settele et al. 2015b;
21 Gauthier et al. 2015; Seddon et al. 2016).

22
23 In a warming climate many species will be unable to track their climate niche as it moves, especially those in
24 extensive flat landscapes with low dispersal capacity and in the tropics whose thermal optimum is already
25 near current temperature (Diffenbaugh and Field 2013; Warszawski et al. 2013). Range expansion in higher
26 latitudes and elevations as a result of warming often, but not exclusively occurs in abandoned lands (Harsch
27 et al. 2009; Landh usser et al. 2010; Gottfried et al. 2012; Boisvert-Marsh et al. 2014; Bryn and Potthoff
28 2018; Rumpf et al. 2018; Buitenwerf et al. 2018; Steinbauer et al. 2018). This expansion typically favours
29 thermophilic species at the expense of cold adapted species as climate becomes suitable for lower
30 latitude/altitude species (Rumpf et al. 2018). In temperate drylands, however, range expansion can be
31 countered by intense and frequent drought conditions which result in accelerated rates of taxonomic change
32 and spatial heterogeneity in an ecotone (Tietjen et al. 2017).

33
34 Since the advent of satellite observation platforms, a global increase in vegetation photosynthetic activity
35 (i.e. greening) as evidenced through remotely sensed indices such as leaf area index (LAI) and normalised
36 difference vegetation index (NDVI). Three satellite-based leaf area index (GIMMS3g, GLASS and
37 GLOMAP) records imply increased growing season LAI (greening) over 25–50% and browning over less
38 than 4% of the global vegetated area, resulting in greening trend of $0.068 \pm 0.045 \text{ m}^2 \text{ m}^{-2} \text{ yr}^{-1}$ over 1982–2009
39 (Cao et al. 2016). Greening has been observed in southern Amazonia, southern Australia, the Sahel and
40 central Africa, India, eastern China and the northern extratropical latitudes (Myneni et al. 1997; de Jong et al.
41 2012; Los 2013; Piao et al. 2015; Mao et al. 2016; Zhu et al. 2016; Carlson et al. 2017; Forzieri et al. 2017;
42 Pan et al. 2018; Chen et al. 2019). Greening has been attributed to direct factors, namely human land use
43 management and indirect factors such as CO₂ fertilisation, climate change, nitrogen deposition (Donohue et
44 al. 2013; Keenan et al. 2016; Zhu et al. 2016). Indirect factors have been used to explain most greening
45 trends primarily through CO₂ fertilisation in the tropics and through an extended growing season and
46 increased growing season temperatures as a result of climate change in the high latitudes (Fensholt et al.
47 2012; Zhu et al. 2016). The extension of the growing season in high latitudes has occurred together with an
48 earlier spring greenup (the time at which plants begin to produce leaves in northern mid- and high-latitude
49 ecosystems) (Goetz et al. 2015; Xu et al. 2016a, 2018) with subsequent earlier spring carbon uptake (2.3
50 days per decade) and gross primary productivity (GPP) (Pulliainen et al. 2017). The role of direct factors of

1 greening are being increasingly investigated and a recent study has attributed over a third of observed global
2 greening between 2000 and 2017 to direct factors, namely afforestation and croplands, in China and India
3 (Chen et al. 2019).

4
5 It should be noted that as measured greening is a product of satellite-derived radiance data, and as such does
6 not provide information on ecosystem health indicators such as species composition and richness,
7 homeostasis, absence of disease, vigor, system resilience and the different components of ecosystems
8 (Jørgensen et al. 2016). For example, a regional greening attributable to croplands expansion or
9 intensification might occur at the expense of ecosystem biodiversity.

10
11 Within the global greening trend are also detected regional decreases in vegetation photosynthetic activity
12 (i.e. browning) in northern Eurasia, the southwestern USA, boreal forests in North America, Inner Asia and
13 the Congo Basin, largely as a result of intensified drought stress. Since the late-1990s rates and extents of
14 browning have exceeded those of greening in some regions, the collective result of which has been a
15 slowdown of the global greening rate (de Jong et al. 2012; Pan et al. 2018). Within these long-term trends,
16 interannual variability of regional greening and browning is attributable to regional climate variability,
17 responses to extremes such as drought, disease and insect infestation and large-scale teleconnective controls
18 such as ENSO and the Atlantic Multi-decadal Organization (Verbyla 2008; Revadekar et al. 2012; Epstein et
19 al. 2018; Zhao et al. 2018).

20
21 Projected increases in drought conditions in many regions suggest long-term global vegetation greening
22 trends are at risk of reversal to browning in a warmer climate (de Jong et al. 2012; Pan et al. 2018; Pausas
23 and Millán 2018). On the other hand, in higher latitudes vegetation productivity is projected to increase as a
24 result of higher atmospheric CO₂ concentrations and longer growing periods as a result of warming here (Ito
25 et al. 2016)(Section 2.3, Box 2.3). Additionally, climate-driven transitions of ecosystems, particularly range
26 changes, can take years to decades for the equilibrium state to be realised and the rates of these “committed
27 ecosystem changes” (Jones et al. 2009) vary between low and high latitudes (Jones et al. 2010). Furthermore,
28 as direct factors are poorly integrated into Earth systems models (ESMs) uncertainties in projected trends of
29 greening and browning are further compounded (Buitenwerf et al. 2018; Chen et al. 2019). Therefore, there
30 is *low confidence* in the projection of global greening and browning trends.

31
32 Increased atmospheric CO₂ concentrations have both direct and indirect effects on terrestrial ecosystems (see
33 Sections 2.2.2 and 2.2.3, Box 2.3). The direct effect is primarily through increased vegetation photosynthetic
34 activity as described above. Indirect effects include decreased evapotranspiration that may offset the
35 projected impact of drought in some water-stressed plants through improved water use efficiency in
36 temperate regions suggesting that some rain-fed cropping systems and grasslands will benefit from elevated
37 atmospheric CO₂ concentrations (Roy et al. 2016a; Milly and Dunne 2016; Swann et al. 2016; Chang et al.
38 2017; Zhu et al. 2017). In tropical regions increased flowering activity is associated primarily with
39 increasing atmospheric CO₂ suggesting a long-term increase in flowering activity may persist in some
40 vegetation, particularly mid-story trees and tropical shrubs, and enhance reproduction levels until limited by
41 nutrient availability or climate factors like drought frequency, rising temperatures and reduced insolation
42 (Pau et al. 2018).

43 44 **2.2.5 Climate extremes and their impact on land functioning**

45
46 Extreme weather events are generally defined as the upper or lower statistical tails of the observed range of
47 values of climate variables or climate indicators (e.g., temperature/rainfall or drought/aridity indices
48 respectively). Previous IPCC reports have reported with *high confidence* on the increase of many types of
49 observed extreme temperature events (Seneviratne et al. 2012b; Hartmann et al. 2013b; Hoegh-Guldberg et
50 al. 2018). However, as a result of observational constraints, increases in precipitation extremes are less

1 confident, except in observation rich regions with dense, long-lived station networks such as Europe and
 2 North America where there have been likely increases in the frequency or intensity of heavy rainfall.

3
 4 Extreme events occur across a wide range of time and space scales (Figure 2.3) and may include individual,
 5 relatively short-lived weather events (e.g., extreme thunderstorms storms) or a combination or accumulation
 6 of non-extreme events (Colwell et al. 2008b; Kundzewicz and Germany 2012) e.g., moderate rainfall in a
 7 saturated catchment having the flood peak at mean high tide (Leonard et al. 2014). Combinatory processes
 8 leading to a significant impact are referred to as a compound event and are a function of the nature and
 9 number of physical climate and land variables, biological agents such as pests and disease, the range of
 10 spatial and temporal scales, the strength of dependence between processes, and the perspective of the
 11 stakeholder who defines the impact (Leonard et al. 2014; Millar and Stephenson 2015). Current *confidence*
 12 in the impact of compound events on land is *low* as the multi-disciplinary approaches needed to address the
 13 problem are few (Zscheischler et al. 2018) and the rarity of compound extreme climatic events renders the
 14 analysis of impacts difficult.

16
 17
 18 **Figure 2.3** Spatial and temporal scales of typical extreme weather and climate events and the biological
 19 systems they impact (shaded grey). Individuals, populations and ecosystems within these space-time
 20 ranges respond to relevant climate stressors. Red (blue) labels indicate an increase (decrease) in the
 21 frequency or intensity of the event, with bold font reflecting confidence in the change. Non-bold black
 22 labels indicate low confidence in observed changes in frequency or intensity of these events. Each event
 23 type indicated in the figure is likely to affect biological systems at all temporal and spatial scales located
 24 to the left and below the specific event position in the figure. From Ummerhofer and Meehl (2017).

25 26 2.2.5.1 Changes in extreme temperatures, heat waves and drought

27 It is *very likely* that most land areas have experienced a decrease in the number of cold days and nights, and
 28 an increase in the number of warm days and unusually hot nights (Orlowsky and Seneviratne 2012;
 29 Seneviratne et al. 2012; Mishra et al. 2015; Ye et al. 2018). Although there is no consensus definition of heat
 30 waves as some heat wave indices have relative thresholds and others absolute thresholds, trends between
 31 indices of the same type show that recent heat-related events have been made more frequent or more intense
 32 due to anthropogenic greenhouse gas emissions in most land regions (Lewis and Karoly 2013; Smith et al.
 33 2013b; Scherer and Diffenbaugh 2014; Fischer and Knutti 2015; Ceccherini et al. 2016; King et al. 2016;

1 Bador et al. 2016; Stott et al. 2016; King 2017; Hoegh-Guldberg et al. 2018). Globally, 50–80 % of the land
2 fraction is projected to experience significantly more intense hot extremes than historically recorded (Fischer
3 and Knutti 2014; Diffenbaugh et al. 2015; Seneviratne et al. 2016). There is *high confidence* that heat waves
4 will increase in frequency, intensity and duration into the 21st century (Russo et al. 2016; Ceccherini et al.
5 2017; Herrera-Estrada and Sheffield 2017) and under high emission scenarios heat waves by the end of the
6 century may become extremely long (more than 60 consecutive days) and frequent (once every two years) in
7 Europe, North America, South America, Africa, Indonesia, the Middle East, south and south east Asia and
8 Australia (Rusticucci 2012; Cowan et al. 2014; Russo et al. 2014; Scherer and Diffenbaugh 2014; Pal and
9 Eltahir 2016; Rusticucci et al. 2016; Schär 2016; Teng et al. 2016; Dosio 2017; Mora et al. 2017; Dosio et al.
10 2018; Lehner et al. 2018; Lhotka et al. 2018; Lopez et al. 2018; Tabari and Willems 2018). Furthermore,
11 unusual heat wave conditions today will occur regularly by 2040 under the RCP 8.5 scenario (Russo et al.
12 2016). The intensity of heat events may be modulated by the land cover and soil characteristics (Miralles et
13 al. 2014; Lemordant et al. 2016; Ramarao et al. 2016). Where temperature increase results in decreased soil
14 moisture, latent heat flux is reduced while sensible heat fluxes is increased allowing surface air temperature
15 to rise further. However, this feedback may be diminished if the land surface is irrigated through the
16 enhanced evapotranspiration (Mueller et al. 2015; Siebert et al. 2017)(Section 2.5.2.2).

17
18 Drought (Qin et al. 2013), including megadroughts of the last century, e.g., the Dustbowl drought (Hegerl et
19 al. 2018), Chapter 5), is a normal component of climate variability (Hoerling et al. 2010; Dai 2011) and may
20 be seasonal, multi-year (Van Dijk et al. 2013) or multi-decadal (Hulme 2001) with increasing degrees of
21 impact on the regional activities. This interannual variability is controlled particularly through remote sea
22 surface temperature (SST) forcings such as the Inter-decadal Pacific Oscillation (IPO) and the Atlantic
23 Multi-decadal Oscillation (AMO), El Niño/Southern Oscillation (ENSO) and Indian Ocean Dipole (IOD),
24 that cause drought as a result of reduced rainfall (Kelley et al. 2015; Dai 2011; Hoell et al. 2017; Espinoza et
25 al. 2018). In some cases however, large scale SST modes do not fully explain the severity of drought some
26 recent event attribution studies have identified a climate change fingerprint in several regional droughts, e.g.,
27 the western Amazon (Erfanian et al. 2017), southern Africa (Funk et al. 2018; Yuan et al. 2018), southern
28 Europe and the Mediterranean including North Africa (Kelley et al. 2015; Wilcox et al. 2018), parts of North
29 America (Williams et al. 2015; Mote et al. 2016), Russia (Otto et al. 2012), India (Ramarao et al. 2015) and
30 Australia (Lewis and Karoly 2013).

31
32 Long-term global trends in drought are difficult to determine because of this natural variability, potential
33 deficiencies in drought indices (especially in how evapotranspiration is treated) and the quality and
34 availability of precipitation data (Sheffield et al. 2012; Dai 2013; Trenberth et al. 2014; Nicholls and
35 Seneviratne 2015; Mukherjee et al. 2018). However, regional trends in frequency and intensity of drought
36 are evident in several parts of the world, particularly in low latitude land areas, such as the Mediterranean,
37 North Africa and Middle East (Vicente-Serrano et al. 2014; Spinoni et al. 2015a; Dai and Zhao 2017; Páscoa
38 et al. 2017), many regions of sub-Saharan Africa (Masih et al. 2014; Dai and Zhao 2017), Central China
39 (Wang et al. 2017e), the southern Amazon (Fu et al. 2013; Espinoza et al. 2018), India (Ramarao et al.
40 2016), east and south Asia, parts of North America and eastern Australia (Dai and Zhao 2017). A recent
41 analysis of 4500 meteorological droughts globally found increased drought frequency over the U.S. East
42 Coast, Amazonia and north-eastern Brazil, Patagonia, the Mediterranean region, most of Africa and north-
43 eastern China with decreased drought frequency over northern Argentina, Uruguay and northern Europe
44 (Spinoni et al. 2019). The study also found drought intensity has become more severe over north-western
45 U.S., parts of Patagonia and southern Chile, the Sahel, the Congo River basin, southern Europe, north-
46 eastern China, and south-eastern Australia, whereas the eastern U.S., south-eastern Brazil, northern Europe,
47 and central-northern Australia experienced less severe droughts. In addition to the IPCC SR15 assessment of
48 medium confidence in increased drying over the Mediterranean region (Hoegh-Guldberg et al. 2018), It is
49 further assessed with *medium confidence* an increased frequency and intensity of drought in Amazonia and
50 north-eastern Brazil, Patagonia, most of Africa and north-eastern China.

1 There is *low confidence* on how large-scale modes of variability will respond to a warming climate (Deser et al. 2012; Liu 2012; Christensen et al. 2013; Hegerl et al. 2015; Newman et al. 2016). Although, there is evidence for an increased frequency of extreme ENSO events, such as the 1997/98 El Niño and 1988/89 La Niña (Cai et al. 2014a, 2015) and extreme positive phases of the IOD (Christensen et al. 2013; Cai et al. 2014b). However, The assessment by the SR15 was retained on an increased regional drought risk (*medium confidence*), specifically over the Mediterranean and South Africa at both 1.5°C and 2°C warming levels compared to present day, with drought risk at 2°C being significantly higher than at 1.5°C (Hoegh-Guldberg et al. 2018).

2.2.5.2 *Impacts of heat extremes and drought on land*

11 There is *high confidence* that heat extremes such as unusually hot nights, extremely high daytime temperatures, heat waves and drought are damaging to crop production (Chapter 5). Extreme heat events impact a wide variety of tree functions including reduced photosynthesis, increased photooxidative stress, leaves abscise, a decreased growth rate of remaining leaves and decreased growth of the whole tree (Teskey et al. 2015). Although trees are more resilient to heat stress than grasslands (Teuling et al. 2010), it has been observed that different types of forest (e.g., needleleaf vs. broadleaf) respond differently to drought and heat waves (Babst et al. 2012). For example, in the Turkish Anatolian forests net primary productivity (NPP) generally decreased during drought and heat waves events between 2000 and 2010 but in a few other regions, NPP of needle leaf forests increased (Erşahin et al. 2016). However, forests may become less resilient to heat stress in future due to the long recovery period required to replace lost biomass and the projected increased frequency of heat and drought events (Frank et al. 2015a; McDowell and Allen 2015; Johnstone et al. 2016; Stevens-Rumann et al. 2018). Additionally, widespread regional tree mortality may be triggered directly by drought and heat stress (including warm winters) and exacerbated by insect outbreak and fire (Neuvonen et al. 1999; Breshears et al. 2005; Berg et al. 2006; Soja et al. 2007; Kurz et al. 2008b; Allen et al. 2010) .

27 Gross primary production (GPP) and soil respiration form the first and second largest carbon fluxes from terrestrial ecosystems to the atmosphere in the global carbon cycle (Beer et al. 2010; Bond-Lamberty and Thomson 2010). Heat extremes impact the carbon cycle through altering these and change ecosystem-atmosphere CO₂ fluxes and the ecosystem carbon balance. Compound heat and drought events result in a stronger carbon sink reduction compared to single-factor extremes as GPP is strongly reduced and ecosystem respiration less so (Reichstein et al. 2013; Von Buttlar et al. 2018). In forest biomes, however, GPP may increase temporarily as a result of increased insolation and photosynthetic activity as was seen during the 2015-2016 ENSO related drought over Amazonia (Zhu et al. 2018). Longer extreme events (heat wave or drought or both) result in a greater reduction in carbon sequestration and may also reverse long-term carbon sinks (Ciais et al. 2005; Phillips et al. 2009; Wolf et al. 2016b; Ummenhofer and Meehl 2017; Von Buttlar et al. 2018; Reichstein et al. 2013). Furthermore, extreme heat events may impact the carbon cycle beyond the lifetime of the event. These lagged effects can slow down or accelerate the carbon cycle: it will slow down if reduced vegetation productivity and/or widespread mortality after an extreme drought are not compensated by regeneration, or speed up if productive tree and shrub seedlings cause rapid regrowth after windthrow or fire (Frank et al. 2015a). Although some ecosystems may demonstrate resilience to a single heat climate stressor like drought, e.g. forests, compound effects of, e.g., deforestation, fire and drought potentially can result in changes to regional precipitation patterns and river discharge, losses of carbon storage and a transition to a disturbance-dominated regime (Davidson et al. 2012). Additionally, adaptation to seasonal drought may be overwhelmed by multi-year drought and their legacy effects (Brando et al. 2008; da Costa et al. 2010).

48 Under medium and high emission scenarios, global warming will exacerbate heat stress thereby amplifying deficits in soil moisture and runoff despite uncertain precipitation changes (Ficklin and Novick 2017; Berg and Sheffield 2018; Cook et al. 2018; Dai et al. 2018; Engelbrecht et al. 2015; Ramarao et al. 2015; Grillakis

2019). This will increase the rate of drying causing drought to set in quicker, become more intense and widespread, last longer and could result in an increased global aridity (Dai 2011; Prudhomme et al. 2014).

The projected changes in the frequency and intensity of extreme temperatures and drought is expected to result in decreased carbon sequestration by ecosystems and degradation of ecosystems health and loss of resilience (Trumbore et al. 2015). Also affected are many aspects of land functioning and type including agricultural productivity (Lesk et al. 2016a), hydrology (Mosley 2015; Van Loon and Laaha 2015), vegetation productivity and distribution (Xu et al. 2011; Zhou et al. 2014), carbon fluxes and stocks and other biogeochemical cycles (Frank et al. 2015b; Doughty et al. 2015; Schlesinger et al. 2016). Carbon stocks are particularly vulnerable to extreme events due to their large carbon pools and fluxes, potentially large lagged impacts and long recovery times to regain lost stocks (Frank et al. 2015a)(Section 2.2).

2.2.5.3 *Changes in heavy precipitation*

A large number of extreme rainfall events have been documented over the past decades (Coumou and Rahmstorf 2012; Seneviratne et al. 2012a; Trenberth 2012; Westra et al. 2013; Espinoza et al. 2014; Guhathakurta et al. 2017; Taylor et al. 2017; Thompson et al. 2017; Zilli et al. 2017). The observed shift in the trend distribution of precipitation extremes is more distinct than for annual mean precipitation and the global land fraction experiencing more intense precipitation events is larger than expected from internal variability (Fischer and Knutti 2014; Espinoza et al. 2018; Fischer et al. 2013) . As a result of global warming the number of record-breaking rainfall events globally has increased significantly by 12% during the period 1981 to 2010 compared to those expected due to natural multi-decadal climate variability (Lehmann et al. 2015) and the IPCC SR15 reports robust increases in observed precipitation extremes for annual maximum 1-day precipitation (RX1day) and consecutive 5-day precipitation (RX5day) (Hoegh-Guldberg et al. 2018; Schleussner et al. 2017). A number of extreme rainfall events have been attributed to human influence (Min et al. 2011; Pall et al. 2011; Sippel and Otto 2014; Trenberth et al. 2015; Krishnan et al. 2016) and the largest fraction of anthropogenic influence is evident in the most rare and extreme events (Fischer and Knutti 2014).

A warming climate is expected to intensify the hydrological cycle as a warmer climate facilitates more water vapour in the atmosphere, as approximated by the Clausius-Clapeyron (C-C) relationship, with subsequent effects on regional extreme precipitation events (Christensen and Christensen 2003; Pall et al. 2007; Berg et al. 2013; Wu et al. 2013; Guhathakurta et al. 2017; Thompson et al. 2017; Taylor et al. 2017; Zilli et al. 2017)(Manola et al. 2018). Furthermore, changes to the dynamics of the atmosphere amplify or weaken future precipitation extremes at the regional scale (O’Gorman 2015; Pfahl et al. 2017). Continued anthropogenic warming is very likely to increase the frequency and intensity of extreme rainfall in many regions of the globe (Seneviratne et al. 2012a; Mohan and Rajeevan 2017; Prein et al. 2017; Stott et al. 2016) although many GCMs underestimate observed increased trends in heavy precipitation suggesting a substantially stronger intensification of future heavy rainfall than the multi-model mean (Borodina et al. 2017; Min et al. 2011). Furthermore, the response of extreme convective precipitation to warming remains uncertain because GCMs and regional climate models (RCMs) are unable to explicitly simulate sub-grid scale processes such as convection, the hydrological cycle and surface fluxes and have to rely on parameterisation schemes for this (Crétat et al. 2012; Rossow et al. 2013; Wehner 2013; Kooperman et al. 2014; O’Gorman 2015; Larsen et al. 2016; Chawla et al. 2018; Kooperman et al. 2018; Maher et al. 2018; Rowell and Chadwick 2018). High-resolution regional climate models that explicitly resolve convection have a better representation of extreme precipitation but are dependent on the GCM to capture large scale environment in which the extreme event may occur (Ban et al. 2015; Prein et al. 2015; Kendon et al. 2017) . Interannual variability of precipitation extremes in the convective tropics are not well captured by global models (Allan and Liu 2018).

There is low confidence in the detection of long-term observed and projected seasonal and daily trends of extreme snowfall. The narrow rain–snow transition temperature range at which extreme snowfall can occur

1 that is relatively insensitive to climate warming and subsequent large interdecadal variability (Kunkel et al.
2 2013; O’Gorman 2014, 2015).

3 4 **2.2.5.4 Impacts of precipitation extremes on different land cover types**

5 More intense rainfall leads to water redistribution between surface and ground water in catchments as water
6 storage in the soil decreases (green water) and runoff and reservoir inflow increases (blue water) (Liu and
7 Yang 2010; Eekhout et al. 2018). This results in increased surface flooding and soil erosion, increased plant
8 water stress and reduced water security, which in terms of agriculture means an increased dependency on
9 irrigation and reservoir storage (Nainggolan et al. 2012; Favis-Mortlock and Mullen 2011; García-Ruiz et al.
10 2011; Li and Fang 2016; Chagas and Chaffe 2018). As there is high confidence of a positive correlation
11 between global warming and future flood risk, land cover and processes are likely to be negatively impacted,
12 particularly near rivers and in floodplains (Kundzewicz et al. 2014; Alfieri et al. 2016; Winsemius et al.
13 2016; Arnell and Gosling 2016; Alfieri et al. 2017; Wobus et al. 2017).

14
15 In agricultural systems heavy precipitation and inundation can delay planting, increases soil compaction, and
16 causes crop losses through anoxia and root diseases (Posthumus et al. 2009). In tropical regions flooding
17 associated with tropical cyclones can lead to crop failure from both rainfall and storm surge. In some cases
18 flooding can affect yield more than drought, particularly in tropical regions (e.g. India) and in some mid/high
19 latitude regions such as China and central and northern Europe (Zampieri et al. 2017). Waterlogging of
20 croplands and soil erosion also negatively affect farm operations and block important transport routes (Vogel
21 and Meyer 2018; Kundzewicz and Germany 2012). Flooding can be beneficial in drylands if the floodwaters
22 infiltrate and recharge alluvial aquifers along ephemeral river pathways, extending water availability into dry
23 seasons and drought years and support riparian systems and human communities (Kundzewicz and Germany
24 2012; Guan et al. 2015). Globally, the impact of rainfall extremes on agriculture is less than that of
25 temperature extremes and drought, although in some regions and for some crops, extreme precipitation
26 explains a greater component of yield variability, e.g. of maize in the Mid-Western USA and southern Africa
27 (Ray et al. 2015; Lesk et al. 2016b; Vogel et al. 2019) .

28
29 Although many soils on floodplains regularly suffer from inundation, the increases in the magnitude of flood
30 events means that new areas with no recent history of flooding are now becoming severely affected (Yellen
31 et al. 2014). Surface flooding and associated soil saturation often results in decreased soil quality through
32 nutrient loss, reduced plant productivity, stimulates microbial growth and microbial community composition,
33 negatively impacts soil redox and increases greenhouse gas emissions (Bossio and Scow 1998; Niu et al.
34 2014; Barnes et al. 2018; Sánchez-Rodríguez et al. 2019). The impact of flooding on soil quality is
35 influenced by management systems that may mitigate or exacerbate the impact. Although soils tend to
36 recover quickly after floodwater removal, the impact of repeated extreme flood events over longer timescales
37 on soil quality and function is unclear (Sánchez-Rodríguez et al. 2017).

38
39 Flooding in ecosystems may be detrimental through erosion or permanent habitat loss, or beneficial, as a
40 flood pulse brings nutrients to downstream regions (Kundzewicz et al. 2014). Riparian forests can be
41 damaged through flooding; however, increased flooding may also be of benefit to forests where upstream
42 water demand has lowered stream flow, but this is difficult to assess and the effect of flooding on forests is
43 not well studied (Kramer et al. 2008; Pawson et al. 2013). Forests may mitigate flooding, however flood
44 mitigation potential is limited by soil saturation and rainfall intensity (Pilaš et al. 2011; Ellison et al. 2017b).
45 Some grassland species under heavy rainfall and soil saturated conditions responded negatively with
46 decreased reproductive biomass and germination rates (Gellesch et al. 2017), however overall productivity in
47 grasslands remains constant in response to heavy rainfall (Grant et al. 2014).

48
49 Extreme rainfall alters responses of soil CO₂ fluxes and CO₂ uptake by plants within ecosystems and
50 therefore result in changes in ecosystem carbon cycling (Fay et al. 2008; Frank et al. 2015a). Extreme
51 rainfall and flooding limits oxygen in soil which may suppress the activities of soil microbes and plant roots

1 and lower soil respiration and therefore carbon cycling (Knapp et al. 2008; Rich and Watt 2013; Philben et
2 al. 2015). However, the impact of extreme rainfall on carbon fluxes in different biomes differs. For example,
3 extreme rainfall in mesic biomes reduces soil CO₂ flux to the atmosphere and GPP whereas in xeric biomes
4 the opposite is true, largely as a result of increased soil water availability (Knapp and Smith 2001; Heisler
5 and Knapp 2008; Heisler-White et al. 2009; Zeppel et al. 2014; Xu and Wang 2016; Liu et al. 2017b; Connor
6 and Hawkes 2018).

7
8 As shown above greenhouse gas fluxes between the land and atmosphere are affected by climate. The next
9 section assesses these fluxes in greater detail and the potential for land as a carbon sink.

13 **Cross-Chapter Box 3: Fire and Climate Change**

14
15 Raman Sukumar (India), Almut Arneth (Germany), Werner Kurz (Canada), Andrey Sirin (Russian
16 Federation), Louis Verchot (Colombia/The United States of America)

17
18 Fires have been a natural part of Earth's geological past and its biological evolution since at least the late
19 Silurian, about 400 million years ago (Scott 2000). Presently, roughly 3% of the Earth's land surface burns
20 annually which affects both energy and matter exchanges between the land and atmosphere (Stanne et al.
21 2009). Climate is a major determinant of fire regimes through its control of fire weather, as well as through
22 its interaction with vegetation productivity (fuel availability) and structure (fuel distribution and
23 flammability) (Archibald et al. 2013) at the global (Krawchuk and Moritz 2011), regional (Pausas and Paula
24 2012) and local landscape (Mondal and Sukumar 2016) scales. Presently, humans are the main cause of fire
25 ignition with lightning playing a lesser role globally (Bowman et al. 2017; Harris et al. 2016), although the
26 latter factor has been predominantly responsible for large fires in regions such as the North American boreal
27 forests (Veraverbeke et al. 2017). Humans also influence fires by actively extinguishing them, reducing
28 spread and managing fuels.

30 ***Historical trends and drivers in land area burnt***

31 While precipitation has been the major influence on wildfire regimes in pre-Industrial times, human
32 activities have become the dominant drivers since then. There was less biomass burning during the 20th
33 century than at any time during the past two millennia as inferred from charcoal sedimentary records (Doerr
34 and Santín 2016), though there has been an increase in the most recent decades (Marlon et al. 2016). Trends
35 in land area burnt have varied regionally (Giglio et al. 2013). Northern Hemisphere Africa has experienced a
36 fire decrease of 1.7 Mha yr⁻¹ (-1.4% yr⁻¹) since 2000, while Southern Hemisphere Africa saw an increase of
37 2.3 Mha yr⁻¹ (+1.8% yr⁻¹) during the same period. Southeast Asia witnessed a small increase of 0.2 Mha yr⁻¹
38 (+2.5% yr⁻¹) since 1997, while Australia experienced a sharp decrease of about 5.5 Mha yr⁻¹ (-10.7% yr⁻¹)
39 during 2001–2011, followed by an upsurge in 2011 that exceeded the annual area burned in the previous 14
40 years. A recent analysis using the Global Fire Emissions Database v.4 (GFED4s) that includes small fires
41 concluded that the net reduction in land area burnt globally during 1998–2015 was -24.3±8.8% (-
42 1.35±0.49% yr⁻¹) (Andela et al. 2017). However, from the point of fire emissions it is important to consider
43 the land cover types which have experienced changes in area burned; in this instance, most of the declines
44 have come from grasslands, savannas and other non-forest land cover types (Andela et al. 2017). Significant
45 increases in forest area burned (with higher fuel consumption per unit area) have been recorded in western
46 and boreal North America (Abatzoglou and Williams 2016; Ansmann et al. 2018) and in boreal Siberia
47 (Ponomarev et al. 2016) in recent times. The 2017 and 2018 fires in British Columbia, Canada, were the
48 largest ever recorded since the 1950s with 1.2 Mha and 1.4 Mha of forest burnt, respectively (Hanes et al.
49 2018) and smoke from these fires reaching the stratosphere over central Europe (Ansmann et al. 2018).

50
51 Climate variability and extreme climatic events such as severe drought, especially those associated with the

1 El Niño Southern Oscillation (ENSO), play a major role in fire upsurges as in equatorial Asia (Huijnen et al.
2 2016). Fire emissions in tropical forests increased by 133% on average during and following six El Niño
3 years compared to six La Niña years during 1997–2016, due to reductions in precipitation and terrestrial
4 water storage (Chen et al. 2017). The expansion of agriculture and deforestation in the humid tropics has also
5 made these regions more vulnerable to drought-driven fires (Davidson et al. 2012; Brando et al. 2014). Even
6 when deforestation rates were overall declining, as in the Brazilian Amazon during 2003–2015, the incidence
7 of fire increased by 36% during the drought of 2015 (Aragão et al. 2018).

9 ***GHG emissions from fires***

10 Emissions from wildfires and biomass burning are a significant source of greenhouse gases (CO₂, CH₄,
11 N₂O), carbon monoxide (CO), carbonaceous aerosols, and an array of other gases including non-methane
12 volatile organic compounds (NMVOC) (Akagi et al. 2011; Van Der Werf et al. 2010). GFED4s has updated
13 fire-related carbon emission estimates biome-wise, regionally and globally, using higher resolution input
14 data gridded at 0.25°, a new burned area dataset with small fires, improved fire emission factors (Akagi et al.
15 2011; Urbanski 2014) and better fire severity characterisation of boreal forests (van der Werf et al. 2017).
16 The estimates for the period 1997–2016 are 2.2 GtC yr⁻¹, being highest in the 1997 El Niño (3.0 GtC yr⁻¹)
17 and lowest in 2013 (1.8 GtC yr⁻¹). Furthermore, fire emissions during 1997–2016 were dominated by
18 savanna (65.3%), followed by tropical forest (15.1%), boreal forest (7.4%), temperate forest (2.3%), peatland
19 (3.7%) and agricultural waste burning (6.3%) (van der Werf et al. 2017).

20
21 Fires not only transfer carbon from land to the atmosphere but also between different terrestrial pools: from
22 live to dead biomass to soil, including partially charred biomass, charcoal and soot constituting 0.12–0.39
23 GtC yr⁻¹ or 0.2–0.6% of annual terrestrial NPP (Doerr and Santín 2016). Carbon from the atmosphere is
24 sequestered back into regrowing vegetation at rates specific to the type of vegetation and other
25 environmental variables (Loehman et al. 2014). Fire emissions are thus not necessarily a net source of carbon
26 into the atmosphere, as post-fire recovery of vegetation can sequester a roughly equivalent amount back into
27 biomass over a time period of one to a few years (in grasslands and agricultural lands) to decades (in forests)
28 (Landry and Matthews 2016). Fires from deforestation (for land use change) and on peatlands (which store
29 more carbon than terrestrial vegetation) obviously are a net source of carbon from the land to the atmosphere
30 (Turetsky et al. 2014); these types of fires were estimated to emit 0.4 GtC yr⁻¹ in recent decades (van der
31 Werf et al. 2017). Peatland fires dominated by smouldering combustion under low temperatures and high
32 moisture conditions can burn for long periods (Turetsky et al. 2014).

34 ***Fires, land degradation/desertification and land-atmosphere exchanges***

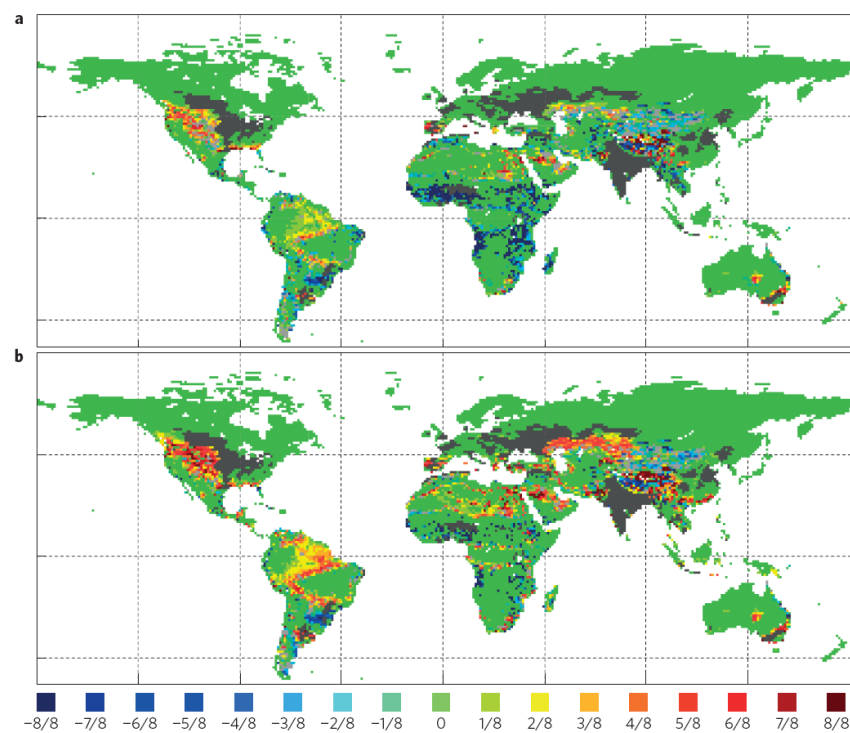

35 Flammable ecosystems are generally adapted to their specific fire regimes (Bond et al. 2005). A fire regime
36 shift alters vegetation and soil properties in complex ways, both in the short- and the long-term, with
37 consequences for carbon stock changes, albedo, fire-atmosphere-vegetation feedbacks and the ultimate
38 biological capacity of the burnt land (Bond et al. 2004; Bremer and Ham 1999; MacDermott et al. 2016;
39 Tepley et al. 2018; Moody et al. 2013; Veraverbeke et al. 2012) A fire-driven shift in vegetation from a
40 forested state to an alternative stable state such as a grassland (Fletcher et al. 2014; Moritz 2015) with much
41 less carbon stock is a distinct possibility. Fires cause soil erosion through action of wind and water (Moody
42 et al. 2013) thus resulting in land degradation (see Chapter 4) and eventually desertification (see Chapter 3).
43 Fires also affect carbon exchange between land and atmosphere through ozone (retards photosynthesis) and
44 aerosol (slightly increases diffuse radiation) emissions; the net effect on global GPP during 2002–2011 is
45 estimated to be -0.86 ± 0.74 GtC yr⁻¹ (Yue and Unger 2018).

47 ***Fires under future climate change***

48 Temperature increase and precipitation decline would be the major driver of fire regimes under future
49 climates as evapotranspiration increases and soil moisture decreases (Pechony and Shindell 2010; Aldersley
50 et al. 2011; Abatzoglou and Williams 2016; Fernandes et al. 2017). The risk of wildfires in future could be
51 expected to change, increasing significantly in North America, South America, central Asia, southern

1 Europe, southern Africa, and Australia (Liu et al. 2010). There is emerging evidence that recent regional
2 surges in wildland fires are being driven by changing weather extremes, thereby signalling geographical
3 shifts in fire proneness (Jolly et al. 2015). Fire weather season has already lengthened by 18.7% globally
4 between 1979 and 2013, with statistically significant increases across 25.3% but decreases only across
5 10.7% of Earth's land surface covered with vegetation; even sharper changes have been observed during the
6 second half of this period (Jolly et al. 2015). Correspondingly, the global area experiencing long fire weather
7 season (defined as experiencing fire weather season greater than one standard deviation (SD) from the mean
8 global value) has increased by 3.1% per annum or 108.1% during 1979–2013. Fire frequencies under 2050
9 conditions are projected to increase by approximately 27% globally, relative to the 2000 levels, with changes
10 in future fire meteorology playing the most important role in enhancing global wildfires, followed by land
11 cover changes, lightning activities and land use, while changes in population density exhibit the opposite
12 effects (Huang et al. 2014).

13
14 However, climate is only one driver of a complex set of environmental, ecological and human factors in
15 influencing fire regimes (Bowman et al. 2011a). While these factors lead to complex projections of future
16 burnt area and fire emissions (Knorr et al. 2016a,b), human exposure to wildland fires could still increase
17 because of population expansion into areas already under high risk of fires (Knorr et al. 2016a,b). There are
18 still major challenges in projecting future fire regimes, and how climate, vegetation and socio/economic
19 factors will interact (Hantson et al. 2016; Harris et al. 2016). There is also need for integrating various fire
20 management strategies, such as fuel-reduction treatments in natural and planted forests, with other
21 environmental and societal considerations to achieve the goals of carbon emissions reductions, maintain
22 water quality, biodiversity conservation and human safety (Moritz et al. 2014; Gharun et al. 2017).

23
24

Cross-Chapter Box 3, Figure 1: The probability of low-fire regions becoming fire prone (positive values), or of fire-prone areas changing to a low-fire state (negative values) between 1971–2000 and 2017–2100 based on eight-Earth system model (ESM) ensembles, two Shared Socio-economic Pathways (SSPs; see (Jiang 2014)) and two Representative Concentration Pathways (RCPs). Light grey: areas where at least one ensemble simulation predicts a positive and one a negative change (lack of agreement). Dark grey: area with >50% past or future cropland. Fire-prone areas are defined as having a fire frequency of >0.01 yr⁻¹ a RCP4.5 emissions with SSP3 demographics. b, RCP8.5 emissions with SSP5 demographics (Knorr et al. 2016a)

In summary, climate change is playing an increasing role in determining wildfire regimes along-side human activity (*medium confidence*), with future climate variability expected to enhance the risk and severity of wildfires in many biomes such as tropical rainforests (*high confidence*). Fire weather seasons have lengthened globally between 1979 and 2013 (*low confidence*). Global land area burned has declined in recent decades, mainly due to less burning in grasslands and savannas (*high confidence*). While drought remains the dominant driver of fire emissions, there has recently been increased fire activity in some tropical and temperate regions during normal to wetter than average years due to warmer temperatures that increase vegetation flammability (*medium confidence*). The boreal zone is also experiencing larger and more frequent fires, and this may increase under a warmer climate (*medium confidence*)

2.3 Greenhouse gas fluxes between land and atmosphere

Land is simultaneously a source and sink for several greenhouse gases (GHGs). Moreover, both natural and anthropogenic processes determine fluxes of GHGs, making it difficult to separate “anthropogenic” and “non-anthropogenic” emissions and removals. A meeting report by the (IPCC 2010a) divided the processes responsible for fluxes from land into three categories: (1) the *direct effects* of anthropogenic activity due to changing land cover and land management; (2) the *indirect effects* of anthropogenic environmental change, such as climate change, carbon dioxide (CO₂) fertilisation, nitrogen deposition; and (3) *natural* climate variability and natural disturbances (e.g. wildfires, windrow, disease). The meeting report (IPCC 2010a) noted that it was impossible with any direct observation to separate direct anthropogenic effects from non-anthropogenic (indirect and natural) effects in the land sector. As a result, different approaches and methods for estimating the anthropogenic fluxes have been developed by different communities to suit their individual purposes, tools and data availability.

The major GHGs exchanged between land and the atmosphere discussed in this chapter are CO₂ (2.3.1), methane (CH₄, Section 2.3.2) and nitrous oxide (N₂O, Section 2.3.3). We estimate the total emissions from Agriculture, Forestry, and Other Land Use (AFOLU) to be responsible for approximately 22% of global anthropogenic GHG emissions over the period 2003-2012 (Smith et al. 2013a; Ciais et al. 2013a) (Table 2.2). The estimate is similar to that reported in AR5 (*high confidence*), with slightly more than half these emissions coming as non-CO₂ GHGs from agriculture. Emissions from AFOLU have remained relatively constant since AR4, although their relative contribution to anthropogenic emissions has decreased due to increases in emissions from the energy sector.

Table 2.2 Summary of average annual land use fluxes aggregated over the decades 2001 to 2010 and 2007 to 2016. We present averages to smooth the effects of inter-annual variability.

Land use emissions	Mt CH ₄ or N ₂ O	Gt CO ₂ e ¹	Mt CH ₄ or N ₂ O	Gt CO ₂ e
	2001-2010		2007-2016	
Land use CO ₂				
Bookkeeping model average		4.69		4.84
DGVM average		4.75		4.70
FAOSTAT		3.48		2.81
Non-CO ₂ GHGs				

Agricultural CH ₄				
FAOSTAT	130.44	3.65	135.42	3.79
USEPA ²	141.64	3.97	147.83	4.14
EDGAR ³	145.43	4.07	152.68	4.28
Average		3.90		3.97
Agricultural N ₂ O				
FAOSTAT	6.83	1.81	7.34	1.95
USEPA	8.69	2.30	9.32	2.47
EDGAR	5.92	1.57	6.31	1.67
Average		1.89		2.21
Total emissions from land use⁴		10.48		11.02
Total emissions from all sources ⁵		45.29		50.72
Land use emissions: Total emissions		23%		22%

1 Data sources: Bookkeeping models: Hansis et al. 2015; Houghton & Nassikas 2017; DGVM average: Le Quéré et al.
2 2018; FAOSTAT: Tubiello et al. 2013; USEPA: USEPA 2012; EDGAR: Janssens-Maenhout et al. 2017.

3 ¹ All values expressed in units of CO₂eq are based on AR5 100 year Global Warming Potential values without climate-
4 carbon feedbacks (N₂O = 265; CH₄ = 28).

5 ² USEPA data are calculated from country data using IPCC Tier 1 methods (IPCC 2003) at 5-year increments through
6 2005 and are projected estimates from 2010 through 2030

7 ³ EDGAR data are complete only through 2012; 2007-2012 averages were computed in the second data column, for
8 comparison purposes only. They were not used in the calculation of the average fluxes for the 2007-2016 period.

9 ⁴ Total land use emissions were calculated as the sum of the average emissions from the bookkeeping models and the
10 average non-CO₂ GHG data from the different data sources (values in bold).

11 ⁵ Total emissions from all sources were calculated as the sum of total CO₂e emissions values for energy, industrial
12 sources, waste and other emissions from the PRIMAP database (Gütschow et al. 2016). They do not include emissions
13 from international bunkers and shipping.

16 2.3.1 Carbon Dioxide

17
18 This section is divided into four sub-sections (**Figure 2.4**): (1) the total net flux of CO₂ between land and
19 atmosphere, (2) the contributions of AFOLU¹ fluxes and the non-AFOLU land sink to that total net CO₂ flux,
20 (3) the gross emissions and removals comprising the net AFOLU flux, and (4) the gross emissions and
21 removals comprising the land sink. Emissions to the atmosphere are positive; removals from the atmosphere
22 are negative.

24 2.3.1.1 The total net flux of CO₂ between land and atmosphere

25 The net effects of all anthropogenic and non-anthropogenic processes on managed and unmanaged land
26 result in a net removal of CO₂ from the atmosphere (*high confidence*). This total net land-atmosphere
27 removal (defined here as *the total net land flux*) is estimated to have averaged 6.2 ± 2.6 GtCO₂ yr⁻¹ from
28 2007 to 2016 (**Table 2.3**.) The estimate is determined from summing the AFOLU and non-AFOLU fluxes
29 fluxes due to transient climate change, CO₂ fertilisation, nitrogen deposition calculated by models in the
30 global carbon budget (Le Quéré et al. 2018) and is consistent with inverse modelling techniques based on
31 atmospheric CO₂ concentrations and air transport (range: 5.1–8.8 GtCO₂ yr⁻¹) (Peylin et al. 2013; Van Der
32 Laan-Luijkx et al. 2017; Saeki and Patra 2017; Le Quéré et al. 2018) (See Box 2.2: for methods). A recent
33 inverse analysis, considering carbon transport in rivers and oceans, found a net flux of CO₂ for land within
34 this range, but a lower source from southern lands and a lower sink in northern lands (Resplandy et al. 2018).

35
36 The net removal of CO₂ by land has generally increased over the last 60 years in proportion to total

No FOOTNOTE/FOOTNOTE deleted

1 emissions of CO₂ (*high confidence*). Although land has been a net sink for CO₂ since around the middle of
 2 last century, it was a net source to the atmosphere before that time, primarily as a result of emissions from
 3 AFOLU (Le Quéré et al. 2018).
 4

5
 6
 7 **Figure 2.4 Net and gross fluxes of CO₂ from land (annual averages for 2008-2017).** [Left]: The total net flux
 8 of CO₂ between land and atmosphere (blue) is shown with its two component fluxes: Net AFOLU
 9 emissions (red) and the net land sink (green) due to indirect environmental effects and natural effects on
 10 managed and unmanaged lands. [Middle]: The gross emissions and removals contributing to the net
 11 AFOLU flux. [Right]: The gross emissions and removals contributing to the land sink.

12
 13 **2.3.1.2 Separation of the total net land flux into AFOLU fluxes and the land sink**

14 The total net flux of carbon between land and the atmosphere can be divided into fluxes due to direct human
 15 activities (i.e., AFOLU) and fluxes due to indirect anthropogenic and natural effects (i.e., the land sink)
 16 (Table 2.3). These two components are less certain than their sums, the total net flux of CO₂ between
 17 atmosphere and land. The land sink, estimated with DGVMs, is least certain (Figure 2.5).
 18

19 **Table 2.3 Perturbation of the global carbon cycle caused by anthropogenic activities (GtCO₂ yr⁻¹) (from (Le**
 20 **Quéré et al. 2018)).**

	CO ₂ flux (GtCO ₂ yr ⁻¹), 10-year mean					
	1960–1969	1970–1979	1980–1989	1990–1999	2000–2009	2008–2017
Emissions

Total net land flux (AFOLU - Land sink)	+1.1 ± 3.2	-3.3 ± 3.0	-2.2 ± 3.4	-3.7 ± 2.2	-5.1 ± 3.2	-6.2 ± 3.7

2.3.1.2.1 Fluxes attributed to AFOLU

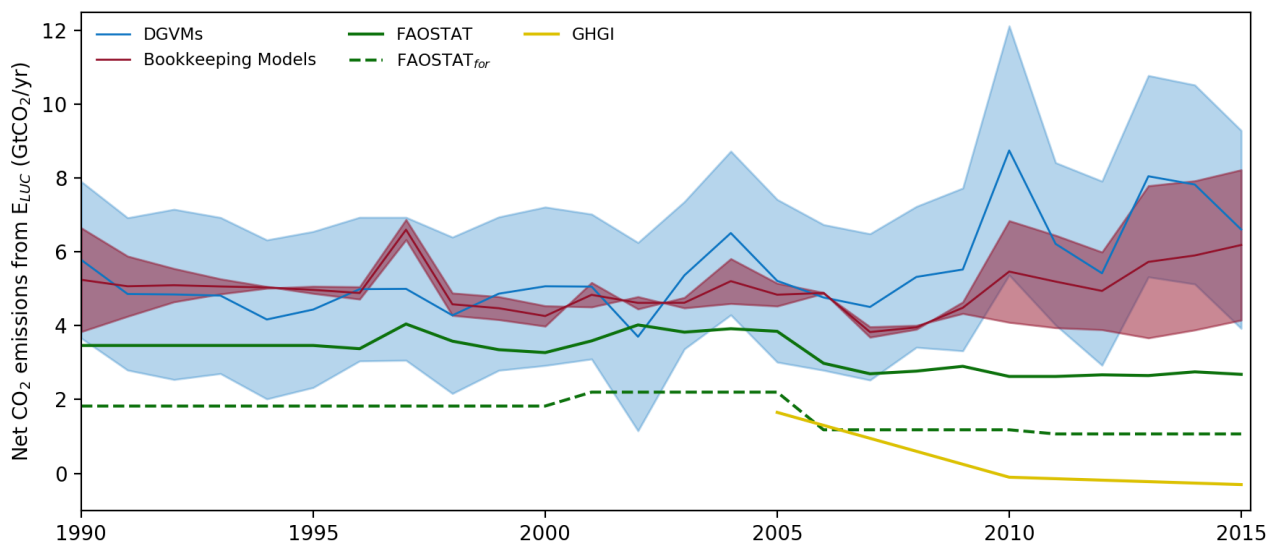

The modelled AFOLU flux was a net emission of $5.5 \pm 2.6 \text{ GtCO}_2 \text{ yr}^{-1}$ for 2008–2017, approximately 14% of total anthropogenic CO_2 emissions (Le Quéré et al. 2018, **Table 2.3**). This net flux was due to direct anthropogenic activities, predominately tropical deforestation, but also afforestation/reforestation, and fluxes due to forest management (e.g. wood harvest) and other types of land management, including agriculture, grasslands and scrub. The AFOLU flux is the mean of two estimates from bookkeeping models (Hansis et al. 2015; Houghton and Nassikas 2017), and this estimated mean is consistent with the mean obtained from an assemblage of Dynamic Global Vegetation Models (DGVMs) (Le Quéré et al. 2018, Box 2.2., **Figure 2.5**), although not all individual DGMVs include the same types of land use. Net CO_2 emissions from AFOLU have been relatively constant since 1900. AFOLU emissions were the dominant anthropogenic emissions until around the middle of the last century when fossil fuel emissions became dominant (Le Quéré et al. 2018). AFOLU activities have resulted in emissions of CO_2 over recent decades (*robust evidence, high agreement*) although there is a wide range of estimates from different methods and approaches (Smith et al. 2014; Houghton et al. 2012; Gasser and Ciais 2013; Pongratz et al. 2014; Tubiello et al. 2015; Grassi et al. 2018) (see Methods Box 2.2., **Figure 2.5** and **Figure 2.7**).

DGVMs and one bookkeeping model (Hansis et al. 2015) used spatially explicit, harmonised land-use change data (LUH2) (Hurt et al. 2017) based on HYDE 3.2. The HYDE data, in turn, are based on changes in the areas of croplands and pastures. In contrast, the Houghton bookkeeping approach (Houghton and Nassikas 2017) used primarily changes in forest area from the FAO Forest Resource Assessment (FAO 2015a) and FAOSTAT to determine changes in land use. To the extent that forests are cleared for land uses other than crops and pastures, estimates from Houghton and Nassikas (2017, 2018) are higher than estimates from DGMVs. In addition, both bookkeeping models (Hansis et al. 2015; Houghton and Nassikas 2017) included estimates of carbon emissions in SE Asia from peat burning from the Global Fire Emissions Database (GFED version 4, (Randerson et al. 2015)) and from peat drainage (Hooijer et al. 2010).

Satellite-based estimates of CO_2 emissions from loss of tropical forests during 2000–2010 corroborate the modelled emissions but are quite variable: $4.8 \text{ GtCO}_2 \text{ yr}^{-1}$ (Tyukavina et al. 2015), $3.0 \text{ GtCO}_2 \text{ yr}^{-1}$ (Harris et al. 2015), $3.2 \text{ GtCO}_2 \text{ yr}^{-1}$ (Achard et al. 2014) and $1.6 \text{ GtCO}_2 \text{ yr}^{-1}$ (Baccini et al. 2017). Differences in estimates can be explained to a large extent by the different approaches used. For example, the analysis by (Tyukavina et al. 2015) led to a higher estimate because they used a finer spatial resolution. Three of the estimates considered losses in forest area and ignored degradation and regrowth of forests. Baccini et al. (2017) in contrast, included both losses and gains in forest area and losses and gains of carbon within forests (i.e., forest degradation and growth). The four remote sensing studies cited above also reported committed emissions; i.e., all of the carbon lost from deforestation was assumed to be released to the atmosphere in the year of deforestation. In reality, only some of the carbon in trees is not released immediately to the atmosphere at the time of deforestation. The unburned portion is transferred to woody debris and wood products. Both bookkeeping models and DGVMs account for the delayed emissions in growth and decomposition. Finally, the satellite-based estimates do not include changes in soil carbon.

In addition to differences in land-cover data sets between models and satellites, there are many other methodological reasons for differences (See Box 2.2.) (Houghton et al. 2012; Gasser and Ciais 2013; Pongratz et al. 2014; Tubiello et al. 2015). There are different definitions of land-cover type, including forest (e.g. FAO uses a tree cover threshold for forests of 10%; Tyukavina et al. (2017) used 25%), different estimates of biomass and soil carbon density (Mg C ha^{-1}), different approaches to tracking emissions through time (legacy effects), and different types of activity included (e.g. forest harvest, peatland drainage and fires). Most DGVMs only recently (since AR5) included forest management processes, such as tree harvesting and land clearing for shifting cultivation, leading to larger estimates of CO_2 emissions than when

1 these processes are not considered (Arneth et al. 2017; Erb et al. 2018). Grazing management has likewise
 2 been found to have large effects (Sanderman et al. 2017), and is not included in most DGVMs (Pugh et al.
 3 2015; Pongratz et al., 2018).

4
 5 **Figure 2.5** Global net CO₂ emissions due to AFOLU from different approaches (in GtCO₂ yr⁻¹). Red line:
 6 the mean and individual estimates from two bookkeeping models (Houghton and Nassikas 2017; Hansis
 7 et al. 2015). Blue line: the mean from DGVMs run with the same driving data with the pale blue shading
 8 showing the ±1 standard deviation range. Green line: data downloaded from FAOSTAT website
 9 (Tubiello et al. 2013); the dashed line is primarily forest-related emissions, while the solid green line also
 10 includes emissions from peat fires and peat draining. Yellow line: Greenhouse Gas Inventories (GHGI)
 11 based on country reports to UNFCCC (Grassi et al. 2018), data are shown only from 2005 because
 12 reporting in many developing countries became more consistent/reliable after this date. For more details
 13 on methods see Box 2.2:
 14

15 2.3.1.2.2 Nationally reported Greenhouse Gas Inventories (GHGI) values versus global model estimates

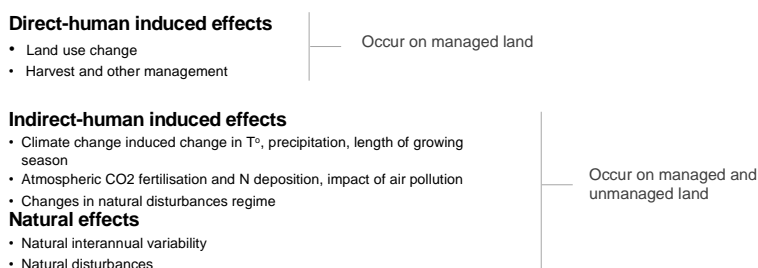

16 There are large differences globally (**Figure 2.5**), between estimates of net anthropogenic land-atmosphere
 17 fluxes of CO₂ from national GHGIs and from global models, and the same is true in many regions (**Figure**
 18 **2.5**). Fluxes reported to the UNFCCC through country GHGIs were noted as about 4.3 GtCO₂ yr⁻¹ lower
 19 (Grassi et al. 2018) than estimates from the bookkeeping model (Houghton et al. 2012a) used in the carbon
 20 budget for AR5 (Conway 2012; Ciais et al. 2013a). The anthropogenic emissions of CO₂ from AFOLU
 21 reported in countries' GHG inventories were 0.1 ± 1.0 GtCO₂ yr⁻¹ globally during 2005 to 2014 (*low*
 22 *confidence*) (Grassi et al. 2018) much lower than emission estimates from the two global bookkeeping
 23 models of 5.1 ± 2.6 GtCO₂ yr⁻¹ over the same time period (Quéré et al. 2018). Transparency and
 24 comparability in estimates can support measuring, reporting and verifying GHG fluxes under the UNFCCC,
 25 and also the global stocktake, which will assess globally the progress towards achieving the long-term goals
 26 of the Paris Agreement. These differences can be reconciled largely by taking account of the different
 27 approaches to defining anthropogenic in terms of different areas of land and treatment of indirect
 28 environmental change (Grassi et al. 2018).
 29

30 To date there has been one study that quantitatively reconciles the global model estimates with GHGIs
 31 (Grassi et al. 2018). The separation of anthropogenic from non-anthropogenic effects is impossible with
 32 direct observation (IPCC 2010a). The different approaches of models and GHGIs to estimating
 33 anthropogenic emissions and removals are shown in (**Figure 2.6**). The difficulty is that *indirect* effects of
 34 environmental changes (e.g. climate change and rising atmospheric CO₂) affect both managed and unmanaged
 35 lands, and some approaches treat these as anthropogenic while others do not. Bookkeeping models (e.g.
 36 Houghton and Nassikas 2017) attempt to estimate the fluxes of CO₂ driven by direct anthropogenic effects
 37 alone. DGVMs model the *indirect* environmental effects of climate and CO₂. If the indirect effects happen
 38 on land experiencing anthropogenic land cover change or management (harvest and regrowth), DGVMs treat
 39 this as anthropogenic. Country GHGIs separately report fluxes due to land conversion (e.g. forests to
 40 croplands) and fluxes due to land management (e.g. forest land remaining forest land). The “managed land
 41 proxy” is used as a pragmatic approach to estimate anthropogenic fluxes on managed lands, whereby

1 countries define the areas they consider managed, and include all of the emission and removals that occur on
 2 those lands. Emissions and removals are caused simultaneously by direct, indirect and natural drivers and are
 3 captured in the reporting, which often relies on inventories.
 4

5 Grassi et al. (2018) demonstrated that estimates of CO₂ emissions from global models and from nationally
 6 reported GHGIs were similar for deforestation and afforestation, but different for managed forests. Countries
 7 generally reported larger areas of managed forests than the models, and the carbon removals by these
 8 managed forests were also larger. The flux due to indirect effects on managed lands was quantified using
 9 post-processing of results from DGVMs, looking at the *indirect* effects of CO₂ and climate change on
 10 secondary forest areas. The derived DGVM *indirect* managed forest flux was found to account for most of
 11 the difference between the bookkeeping models and the inventories.

 15 **Figure 2.6 Summary of the main conceptual differences between GHG Inventories and global models in**
 16 **considering what is the “anthropogenic land CO₂ flux”.** Adapted from Grassi et al. (2018): a) Effects of
 17 **key processes on the land flux as defined by IPCC (2010) including where these effects occur (in**
 18 **managed and/or unmanaged lands); How these effects are captured in ‘(a) bookkeeping models that do**
 19 **not explicitly model the effects of environmental change, although some is implicitly captured in data on**
 20 **carbon densities and growth and decay rates; (b) Dynamic Global Vegetation Models (DGVMs) that**
 21 **include the effects of environmental change on all lands, and run the models with and without land use**
 22 **change to diagnose “land use change”, the “land sink” is then conceptually assumed to be a natural**
 23 **response of land to the anthropogenic perturbation of environmental change, models include the effects**
 24 **of inter-annual climate variability, and some include fires but no other natural disturbances (c) GHG**
 25 **Inventories reported by countries to the UNFCCC that report all fluxes in areas the countries define as**
 26 **“managed land” but do not report unmanaged land. This is the CO₂ flux due to Land Use Land Use**
 27 **Change and Forestry (LULUCF) which is a part of the overall AFOLU (Agriculture, Forestry and**
 28 **Other Land Use) flux. The area of land considered as managed in the inventories is greater than that**
 29 **considered as subject to direct management activities (harvest and regrowth) in the models.**
 30

31 **2.3.1.2.3 Regional differences**

32 Figure 2.7 shows regional differences in emissions due to AFOLU. Recent increases in deforestation rates in
 33 some tropical countries have been partially balanced by increases in forest area in India, China, the USA and

1 Europe (FAO-FRA 2015). The trend in emissions from AFOLU since the 1990s is *uncertain* because some
 2 data suggest a declining rate of deforestation (FAO-FRA 2015), while data from satellites suggest an
 3 increasing rate (Kim 2014; Hansen et al. 2012). The disagreement results in part from differences in the
 4 definition of forest and approaches to estimating deforestation. The FAO defines deforestation as the
 5 conversion of forest to another land use (FAO-FRA 2015), while the measurement of forest loss by satellite
 6 may include wood harvests (forests remaining forests) and natural disturbances that are not directly caused
 7 by anthropogenic activity (e.g., forest mortality from droughts and fires). Trends in anthropogenic and
 8 natural disturbances may be in opposite directions. For example, recent drought-induced fires in the Amazon
 9 have increased the emissions from wildfires at the same time that emissions from anthropogenic
 10 deforestation have declined (Aragão et al. 2018). Furthermore, there have been advances since AR5 in
 11 estimating the GHG effects of different types of forest management (e.g. (Valade et al. 2017). Overall, there
 12 is *robust evidence and high agreement* for a net loss of forest area and tree cover in the tropics and a net
 13 gain, mainly of secondary forests and sustainably managed forests, in the temperate and boreal zones
 14 (Chapter 1).

15

16
 17
 18

Figure 2.7 Regional trends in net anthropogenic land-atmosphere CO₂ flux from a range of different approaches (in GtCO₂ yr⁻¹). Red symbols: bookkeeping models (hexagon - Houghton and Nassikas 2017;

1 square - Hansis et al. 2015). Blue cross: the mean from DGVMs with the box showing the 1 standard
 2 deviation range. Green triangles: downloaded from FAOSTAT website; the open triangle is primarily
 3 forest-related emissions, while the closed triangle includes emission from peat fires and peat drainage.
 4 Yellow inverted triangle: Greenhouse Gas Inventories (GHGI) LULUCF flux (Land Use Land Use
 5 Change and Forestry – part of AFOLU) based on country reports to UNFCCC (Grassi et al. 2018) –
 6 data for developing countries is only shown for 2006-2015 because reporting in many developing
 7 countries became more consistent/reliable after 2005. For more details on methods see Box 2.2:.

9 2.3.1.2.4 Processes responsible for the land sink

10 Just over half of total net anthropogenic CO₂ emissions (AFOLU and fossil fuels) were taken up by oceanic
 11 and land sinks (Table 2.3) (*robust evidence, high agreement*). The land sink was referred to in AR5 as the
 12 “residual terrestrial flux,” as it was not estimated directly, but calculated by difference from the other directly
 13 estimated fluxes in the budget (Table 2.3). In the 2018 budget (Le Quéré et al. 2018), the land sink term was
 14 instead estimated directly by DGVMs, leaving a budget imbalance of 2.2 GtCO₂ yr⁻¹ (sources overestimated
 15 or sinks underestimated). The budget imbalance may result from variations in oceanic uptake, or from
 16 uncertainties in fossil fuel or AFOLU emissions, as well as from land processes not included in DGVMs.

17
 18 The land sink is thought to be driven largely by the indirect effects of environmental change (e.g., climate
 19 change, increased atmospheric CO₂ concentration nitrogen deposition) on unmanaged and managed lands
 20 (*robust evidence, high agreement*). The land sink has generally increased since 1900 and was a net sink of
 21 11.7 ± 3.7 GtCO₂ yr⁻¹ during the period 2008 to 2017 (Table 2.3), absorbing 29% of global anthropogenic
 22 emissions of CO₂. The land sink has slowed the rise in global land-surface air temperature by 0.09 ± 0.02°C
 23 since 1982 (*medium confidence*) (Zeng et al. 2017).

24
 25 The rate of CO₂ removal by land accelerated from -0.026 ± 0.24 GtCO₂ yr⁻¹ during the warming period (1982
 26 to 1998) to -0.436 ± 0.260 GtCO₂ yr⁻¹ during the warming hiatus (1998-2012). One explanation is that
 27 respiration rates were lower during the warming hiatus (Ballantyne et al. 2017). However, the lower rate of
 28 growth in atmospheric CO₂ during the warming hiatus may have resulted, not from lower rates of respiration,
 29 but from declining emissions from AFOLU (lower rates of tropical deforestation and increased forest growth
 30 in northern mid-latitudes (Piao et al. 2018). Changes in the growth rate of atmospheric CO₂, by themselves,
 31 do not identify the processes responsible, and the cause of the variation is uncertain.

32
 33 While year-to-year variability in the indirect land sink is high in response to climate variability, DGVM
 34 fluxes are far more influenced on decadal time scales by CO₂ fertilisation. A DGVM intercomparison (Sitch
 35 et al. 2015) for 1990 to 2009 found that CO₂ fertilisation alone contributed a mean global removal of -10.54
 36 ± 3.68 GtCO₂ yr⁻¹ (trend -0.444 ± 0.202 GtCO₂ yr⁻¹). Data from forest inventories around the world
 37 corroborate the modelled land sink (Pan et al. 2011a). The geographic distribution of the non-AFOLU land
 38 sink is less certain. While it seems to be distributed globally, its distribution between the tropics and non-
 39 tropics is estimated to be between 1:1 (Pan et al. 2011a) and 1:2 (Houghton et al. 2018).

40
 41 As described in Box 2.3, rising CO₂ concentrations have a fertilising effect on land, while climate has mixed
 42 effects; e.g., rising temperature increases respiration rates and may enhance or reduce photosynthesis
 43 depending on location and season, while longer growing seasons might allow for higher carbon uptake.
 44 However, these processes are not included in DGVMs, which may account for at least some of the land sink.
 45 For example, a decline in the global area burned by fires each year (Andela et al. 2017) accounts for an
 46 estimated net sink (and/or reduced emissions) of 0.5 GtCO₂ yr⁻¹ (Arora and Melton 2018) (*limited evidence,*
 47 *medium agreement*) (boreal forests represent an exception to this decline (Kelly et al. 2013)). The reduction
 48 in burning not only reduces emissions; it also allows more growth of recovering forests. There is also an
 49 estimated net carbon sink of about the same magnitude (0.5 GtCO₂ yr⁻¹) as a result of soil erosion from
 50 agricultural lands and redeposition in anaerobic environments where respiration is reduced (Wang et al.
 51 2017d) (*limited evidence, low agreement*). A recent study attributes an increase in land carbon to a longer-
 52 term (1860-2005) aerosol-induced cooling (Zhang et al. 2019). Recent evidence also suggests that DGVMs
 53 and Earth System Models underestimate the effects of drought on CO₂ emissions (Humphrey et al. 2018;
 54 Green et al. 2019; Kolus et al. 2019).

55 2.3.1.3 Gross emissions and removals contributing to AFOLU emissions

56 The modelled AFOLU flux of 5.5 ± 3.7 GtCO₂ yr⁻¹ over the period 2008 to 2017 represents a net value. It
 57

1 consists of both gross emissions of CO₂ from deforestation, forest degradation, and the oxidation of wood
2 products, as well as gross removals of CO₂ in forests and soils recovering from harvests and agricultural
3 abandonment (Figure 2.4). The uncertainty of these gross fluxes is high because few studies report gross
4 fluxes from AFOLU. Houghton and Nassikas (2017) estimated gross emissions to be as high as 20.2 GtCO₂
5 yr⁻¹ (*limited evidence, low agreement*) (Figure 2.4), and even this may be an underestimate because the land-
6 use change data used from FAOSTAT (Tubiello et al. 2013) is itself a net of all changes within a country.
7

8 Gross emissions and removals of CO₂ result from rotational uses of land, such as wood harvest and shifting
9 cultivation, including regrowth. These gross fluxes are more informative for assessing the timing and
10 potential for mitigation than estimates of net fluxes, because the gross fluxes include a more complete
11 accounting of individual activities. Gross emissions from rotational land use in the tropics are approximately
12 37% of total CO₂ emissions, rather than 14%, as suggested by net AFOLU emissions (Houghton and
13 Nassikas 2018). Further, if the forest is replanted or allowed to regrow, gross removals of nearly the same
14 magnitude would be expected to continue for decades.
15

16 **2.3.1.4 Gross emissions and removals contributing to the non-anthropogenic land sink**

17 The *net* land sink averaged 11.7 GtCO₂ yr⁻¹ over 2008-2017 (*robust evidence, medium agreement*) (Table
18 2.3.2), but its gross components have not been estimated at the global level. There are many studies that
19 suggest increasing emissions of carbon due to indirect environmental effects and natural disturbance, for
20 example temperature-induced increases in respiration rates (Bond-Lamberty et al. 2018); increased tree
21 mortality (Brienen et al. 2015; Berdanier and Clark 2016; McDowell et al. 2018); and thawing permafrost
22 (Schuur et al. 2015). The global carbon budget indicates that land and ocean sinks have *increased* over the
23 last six decades in proportion to total CO₂ emissions (Le Quéré et al. 2018) (*robust evidence, high*
24 *agreement*). That means that any emissions must have been balanced by even larger removals (likely driven
25 by CO₂ fertilisation, climate change, nitrogen deposition, erosion and redeposition of soil carbon, a reduction
26 in areas burned, aerosol-induced cooling, and changes in natural disturbances, Box 2.3)
27

28 Climate change is expected to impact terrestrial biogeochemical cycles via an array of complex feedback
29 mechanisms that will act to either enhance or decrease future CO₂ emissions from land. Because the gross
30 emissions and removals from environmental changes are not constrained at present, the balance of future
31 positive and negative feedbacks remains uncertain. Estimates from climate models included in AR5, CMIP5
32 (Coupled Model Intercomparison Project, 5), exhibit large differences for different carbon and nitrogen cycle
33 feedbacks and how they change in a warming climate (Anav et al. 2013; Friedlingstein et al. 2006;
34 Friedlingstein, et al. 2014) . The differences are in large part due to the uncertainty regarding how primary
35 productivity and soil respiration will respond to environmental changes, with many of the models not even
36 agreeing on the sign of change. Furthermore, many models do not include a nitrogen cycle, which may limit
37 the CO₂ fertilisation effect in the future (see Box 2.3). There is an increasing amount of observational data
38 available and methods to constrain models (e.g. Cox et al. 2013; Prentice, et al., 2015) which can reduce
39 uncertainty.
40

41 **2.3.1.5 Potential impact of mitigation on atmospheric CO₂ concentrations**

42 If CO₂ concentrations decline in the future as a result of low emissions and large negative emissions, the
43 global land and ocean sinks are expected to weaken (or even reverse). The oceans are expected to release
44 CO₂ back to the atmosphere when the concentration declines (Ciais et al. 2013a; Jones et al. 2016). This
45 means that to maintain atmospheric CO₂ and temperature at low levels, both the excess CO₂ from the
46 atmosphere and the CO₂ progressively outgassed from the ocean and land sinks will need to be removed.
47 This outgassing from the land and ocean sinks is called the “rebound effect” of the global carbon cycle (Ciais
48 et al. 2013a). It will reduce the effectiveness of negative emissions and increase the deployment level needed
49 to achieve a climate stabilisation target (Jackson et al. 2017; Jones et al. 2016) (*limited evidence, high*
50 *agreement*).
51

52 **2.3.2 Methane**

54 **2.3.2.1 Atmospheric trends**

55 In 2017, the globally averaged atmospheric concentration of CH₄ was 1850 ± 1 ppbv (Figure 2.8A).
56 Systematic measurements of atmospheric CH₄ concentrations began in the mid-1980s and trends show a

1 steady increase between the mid-1980s and early-1990s, slower growth thereafter until 1999, a period of no
 2 growth between 1999 and 2006, followed by a resumption of growth in 2007. The growth rates show very
 3 high inter-annual variability with a negative trend from the beginning of the measurement period until about
 4 2006, followed by a rapid recovery and continued high inter-annual variability through 2017 (Figure 2.8B).
 5 The growth rate has been higher over the past 4 years (*high confidence*) (Nisbet et al. 2019). The trend in
 6 $\delta^{13}\text{C}-\text{CH}_4$ prior to 2000 with less depleted ratios indicated that the increase in atmospheric concentrations
 7 was due to thermogenic (fossil) CH_4 emissions; the reversal of this trend after 2007 indicates a shift to
 8 biogenic sources (Figure 2.8C).

9
10
11 **Figure 2.8 Globally averaged atmospheric CH_4 mixing ratios (Frame A) and instantaneous rates of change**
 12 **(Frame B) and C isotope /variation (Frame C) Data sources: NOAA/ESRL**
 13 **(www.esrl.noaa.gov/gmd/ccgg/trends_ch4/)(Dlugokencky et al. 1994) and Schaefer et al. (2016).**
 14

15 Understanding the underlying causes of temporal variation in atmospheric CH_4 concentrations is an active
 16 area of research. Several studies concluded that inter-annual variability of CH_4 growth was driven by
 17 variations in natural emissions from wetlands (Rice et al. 2016; Bousquet et al. 2006; Bousquet et al. 2011;
 18 Bousquet et al. 2011b). These modelling efforts concluded that tropical wetlands were responsible for
 19 between 50 and 100% of the inter-annual fluctuations and the renewed growth in atmospheric concentrations
 20 after 2007. However, results were inconsistent for the magnitude and geographic distribution of the wetland
 21 sources between the models. Pison et al. (2013) used two atmospheric inversion models and the ORCHIDEE
 22 model and found greater uncertainty in the role of wetlands in inter-annual variability between 1990 and
 23 2009 and during the 1999-2006 pause. Poulter et al. (2017) used several of biogeochemical models and
 24 inventory-based wetland area data to show that wetland CH_4 emissions increases in the boreal zone have
 25 been offset by decreases in the tropics and concluded that wetlands have not contributed significantly to
 26 renewed atmospheric CH_4 growth.
 27

1 The models cited above assumed that atmospheric hydroxyl radical (OH) sink over the period analysed did
2 not vary. OH reacts with CH₄ as the first step toward oxidation to CO₂. In global CH₄ budgets, the
3 atmospheric OH sink has been difficult to quantify because its short lifetime (~1 second) and its distribution
4 is controlled by precursor species that have non-linear interactions (Taraborrelli et al., 2012; Prather et al.,
5 2017). Understanding of the atmospheric OH sink has evolved recently. The development of credible time
6 series of methyl chloroform (MCF: CH₃CCl₃) observations offered a way understand temporal dynamics of
7 OH abundance and applying this to global budgets further weakened the argument for the role of wetlands in
8 determining temporal trends since 1990. Several authors used the MCF approach and concluded that changes
9 in the atmospheric OH sink explained a large portion of the suppression in global CH₄ concentrations
10 relative to the pre-1999 trend (Turner et al. 2017; Rigby et al. 2013; McNorton et al. 2016). These studies
11 could not reject the null hypothesis that OH has remained constant in recent decades and they did not suggest
12 a mechanism for the inferred OH concentration changes (Nisbet et al. 2019). Nicely et al. (2018) used a
13 mechanistic approach and demonstrated that variation in atmospheric OH was much lower than what MCF
14 studies and found that positive trends in OH due to the effects of water vapour, nitrogen oxides (NO_x),
15 tropospheric ozone, and expansion of the tropical Hadley cells offsets the decrease in OH that is expected
16 from increasing atmospheric CH₄ concentrations.

17
18 The depletion of δ¹³C_{atm} beginning in 2009 could be due to changes in several sources. Decreased fire
19 emissions combined with increased tropical wetland emissions compared to earlier years could explain the
20 δ¹³C perturbations to atmospheric CH₄ sources (Worden et al. 2017; Schaefer et al. 2016). However, because
21 tropical wetland emissions are higher in the Southern Hemisphere, and the remote sensing observations show
22 that CH₄ emissions increases are largely in the north tropics (Bergamaschi et al. 2013; Melton et al. 2013;
23 Houweling et al. 2014), an increased wetland source does not fit well with the southern hemisphere δ¹³C
24 observations. New evidence shows that tropical wetland CH₄ emissions are significantly underestimated,
25 perhaps by a factor of 2, because estimates do not account for release by tree stems (Pangala et al. 2017).
26 Several authors have concluded that agriculture is a more probable source of increased emissions, and
27 particularly from rice and livestock in the tropics, which is consistent with inventory data (Wolf et al. 2017;
28 Patra et al. 2016; Schaefer et al. 2016).

29
30 The importance of fugitive emissions in the global atmospheric accumulation rate is growing (*medium*
31 *evidence, high agreement*). The increased production of natural gas in the US from the mid 2000's is of
32 particular interest because it coincides with renewed atmospheric CH₄ growth (Rice et al. 2016; Hausmann et
33 al. 2015). Reconciling increased fugitive emissions with increased isotopic depletion of atmospheric CH₄
34 indicates that there are *likely* multiple changes in emissions and sinks that affect atmospheric accumulation
35 (*medium confidence*).

36
37 With respect to atmospheric CH₄ growth rates, we conclude that there is significant and ongoing
38 accumulation of CH₄ in the atmosphere (*very high confidence*). The reason for the pause in growth rates and
39 subsequent renewed growth is at least partially associated with land use and land use change. Evidence that
40 variation in the atmospheric OH sink plays a role in the year to year variation of the CH₄ is accumulating,
41 but results are contradictory (*medium evidence, low agreement*) and refining this evidence is constrained by
42 lack of long-term isotopic measurements at remote sites, particularly in the tropics. Fugitive emissions *likely*
43 contribute to the renewed growth after 2006 (*medium evidence, high agreement*). Additionally, the recent
44 depletion trend of ¹³C isotope in the atmosphere indicates that growth in biogenic sources explains part of the
45 current growth and that biogenic sources make up a larger proportion of the source mix compared to the
46 period before 1997 (*robust evidence, high agreement*). In agreement with the findings of AR5, we conclude
47 that wetlands are important drivers of inter-annual variability and current growth rates (*medium evidence,*
48 *high agreement*). Ruminants and the expansion of rice cultivation are also important contributors to the
49 current growth trend (*medium evidence, high agreement*).

50 51 2.3.2.2 Land use effects

52 Agricultural emissions are predominantly from enteric fermentation and rice, with manure management and
53 waste burning contributing small amounts (Figure 2.9). Since 2000, livestock production has been
54 responsible for 33% of total global emissions and 66% of agricultural emissions (Source: EDGAR 4.3.2
55 database, accessed May 2018, (USEPA 2012; Tubiello et al. 2014; Janssens-Maenhout et al. 2017b). Asia
56 has the largest livestock emissions (37%) and emissions in the region have been growing by around 2% per

1 year over the same period. North America is responsible for 26% and emissions are stable; Europe is
 2 responsible for around 8% of emissions, and these are decreasing slightly (<1% per year). Africa is
 3 responsible for 14%, but emissions are growing fastest in this region at around 2.5% y^{-1} . In Latin America
 4 and the Caribbean, livestock emissions are decreasing at around 1.6% per year and the region makes up 16%
 5 of emissions. Rice emissions are responsible for about 24% of agricultural emissions, and 89% of these are
 6 from Asia. Rice emissions are increasing by 0.9% per year in that region. These trends are predicted to
 7 continue through 2030 (USEPA 2013).

8 **Figure 2.9 Average agricultural CH₄ emissions estimates from 1990. Sub-sectorial agricultural emissions are**
 9 **based on the Emissions Database for Global Atmospheric Research (EDGAR v4.3.2; Janssens-**
 10 **Maenhout et al. 2017a); FAOSTAT (Tubiello et al. 2013); and National GHGI data (Grassi et al. 2018).**
 11 **GHGI data are aggregate values for the sector.**

12 * Note that EDGAR data are complete only through 2012; the data in the right-hand panel represent the
 13 three years 2010-2012 and are presented for comparison.

31

32

Upland soils are a net sink of atmospheric CH₄, but soils both produce and consume the gas. On the global
 scale climatic zone, soil texture, and land cover have an important effect on CH₄ uptake in upland soils (Tate
 2015; Yu et al. 2017; Dutaur and Verchot 2007). Boreal soils take up less than temperate or tropical soils,
 coarse textured soils take up more CH₄ than medium and fine textured soils, and forests take up more than
 other ecosystems. Low levels of nitrogen fertilisation or atmospheric deposition can affect the soil microbial
 community and stimulate soil CH₄ uptake in nitrogen limited soils, while higher fertilisation rates decrease
 uptake (Edwards et al. 2018; Zhuang et al., 2013). Globally, N fertilisation on agricultural lands may have
 suppressed CH₄ oxidation by as much as 26 Tg between 1998 and 2004 (Zhuang et al., 2013)(*low confidence* ,
low agreement). The effect of N additions is cumulative and repeated fertilisation events have progressively
 greater suppression effects (*robust evidence, high agreement*) (Tate 2015). Other factors like higher
 temperatures, increased atmospheric concentrations, and changes in rainfall patterns stimulate soil CH₄
 consumption in unfertilised ecosystems. Several studies (Yu et al. 2017; Xu et al. 2016; Curry 2009) have
 shown that globally, uptake has been increasing during the second half of the 20th century and it is expected
 to continue to increase by as much as 1 Tg in the 21st century, particularly in forests and grasslands (*medium*
evidence, high agreement).

Northern peatlands (40°-70°N) are a significant source of atmospheric CH₄, emitting about 48 Tg CH₄, or

1 about 10% of the total emissions to the atmosphere (Zhuang et al. 2006; Wuebbles and Hayhoe 2002). CH₄
 2 emissions from natural northern peatlands are highly variable with the highest rate from fens (*medium*
 3 *evidence, high agreement*). Peatland management and restoration, alters the exchange of CH₄ with the
 4 atmosphere (*medium evidence, high agreement*). Management of peat soils typically converts them from CH₄
 5 sources to sinks (Augustin et al. 2011; Strack and Waddington 2008; Abdalla et al. 2016) (*robust evidence,*
 6 *high agreement*). While restoration decreases CO₂ emissions (see Section 4.9.4), CH₄ emissions often
 7 increase relative to the drained conditions (*robust evidence, high agreement*) (Osterloh et al. 2018; Christen
 8 et al. 2016; Koskinen et al. 2016; Tuittila et al. 2000; Vanselow-Algan et al. 2015; Abdalla et al. 2016).
 9 Drained peatlands are usually considered to be negligible methane sources, but they emit CH₄ under wet
 10 weather conditions and from drainage ditches (Drösler et al. 2013; Sirin et al. 2012). While ditches cover
 11 only a small percentage of the drained area, emissions can be sufficiently high that drained peatlands emit
 12 comparable CH₄ as undrained ones (*medium evidence, medium agreement*) (Sirin et al. 2012; Wilson et al.
 13 2016).

14
 15 Because of the large uncertainty in the tropical peatland area, estimates of the global flux are highly
 16 uncertain. A meta-analysis of the effect of conversion of primary forest to rice production showed that
 17 emissions increased by a factor of 4 (*limited evidence, high agreement*) (Hergoualc'h and Verchot, 2012).
 18 For land uses that required drainage, emissions decreased by a factor of 3 (*limited evidence, high*
 19 *agreement*). There are no representative measurements of emissions from drainage ditches in tropical
 20 peatlands.

21 2.3.3 Nitrous Oxide

22 2.3.3.1 Atmospheric trends

23
 24 The atmospheric abundance of N₂O has increased since 1750, from a pre-industrial concentration of 270
 25 ppbv to 330 ppbv in 2017 (U.S. National Oceanographic and Atmospheric Agency, Earth Systems Research
 26 Laboratory; Figure 2.10) (*high agreement, robust evidence*). The rate of increase has also increased, from
 27 approximately 0.15 ppbv yr⁻¹ 100 years ago, to 0.85 ppbv yr⁻¹ over the period 2001 to 2015 (Wells et al.
 28 2018). Atmospheric N₂O isotopic composition (^{14/15}N) was relatively constant during the pre-industrial
 29 period (Prokopiou et al. 2018) and shows a decrease in the δ¹⁵N as the N₂O mixing ratio in the atmosphere
 30 has increased between 1940 and 2005. This recent decrease indicates as that terrestrial sources are the
 31 primary driver of increasing trends and marine sources contribute around 25% (Snider et al. 2015).
 32 Microbial denitrification and nitrification processes are responsible for more than 80% of total global N₂O
 33 emissions, which includes natural soils, agriculture, and oceans, with the remainder coming from non-
 34 biological sources such as biomass burning and fossil-fuel combustion (Fowler et al. 2015). The isotopic
 35 trend also indicates a shift from denitrification to nitrification as the primary source of N₂O as a result of the
 36 use of synthetic nitrogen (N) fertiliser (*high evidence, high agreement*) (Park et al. 2012; Toyoda et al. 2013;
 37 Snider et al. 2015; Prokopiou et al. 2018).
 38

39
 40 **Figure 2.10 Globally averaged atmospheric N₂O mixing ratios since 1984. Data sources: NOAA/ESRL**

1 **Global Monitoring Division (<https://www.esrl.noaa.gov/gmd/hats/combined/N2O.html>).**

2
3 The three independent sources of N₂O emissions estimates from agriculture at global, regional, and national
4 levels are: U.S.E.P.A., EDGAR and FAOSTAT (USEPA 2013; Tubiello et al. 2015; Janssens-Maenhout et
5 al. 2017). EDGAR and FAOSTAT have temporal resolution beyond 2005 and we these databases compare
6 well with national inventory data (Figure 2.10). USEPA has historical estimates through 2005 and
7 projections thereafter. The independent data use IPCC methods, with Tier 1 emission factors and national
8 reporting of activity data. Tier 2 approaches are also available based on top-down and bottom-up
9 approaches. Recent estimates using inversion modelling and process models estimate total annual global
10 N₂O emissions of 16.1-18.7 (bottom-up) and 15.9-17.7 Tg N (top-down), demonstrating relatively close
11 agreement (Thompson et al. 2014). Agriculture is the largest source and has increased with the
12 extensification and intensification. Recent modelling estimates of terrestrial sources show a higher emissions
13 range that is slightly more constrained than what was reported in AR5: approximately 9 (7–11) Tg N₂O-N yr⁻¹
14 (Saikawa et al. 2014; Tian et al. 2016) compared to 6.6 (3.3–9.0) Tg N₂O-N yr⁻¹ (Ciais et al. 2013a).
15 Estimates of marine N₂O emissions are between 2.5 and 4.6 Tg N₂O-N yr⁻¹; (Buitenhuis et al., 2017;
16 Saikawa et al., 2014).

17
18 To conclude, N₂O is continuing to accumulate in the atmosphere at an increasingly higher rate (*very high*
19 *confidence*), driven primarily by increases in manure production and synthetic N fertiliser use from the mid-
20 20th century onwards (*high confidence*). Findings since AR5 have constrained regional and global estimates
21 of annual N₂O emissions and improved our understanding of the spatio-temporal dynamics of N₂O
22 emissions, with soil rewetting and freeze-thaw cycles, which important determinants of total annual emission
23 fluxes in some regions (*medium confidence*).

24
25 **Figure 2.11 Average agricultural N₂O emissions estimates from 1990. Sub-sectorial agricultural emissions**
26 **are based on the Emissions Database for Global Atmospheric Research (EDGAR v4.3.2; Janssens-**
27 **Maenhout et al. 2017a); FAOSTAT (Tubiello et al. 2013); and National GHGI data (Grassi et al. 2018).**
28 **GHGI data are aggregate values for the sector.**

29 * Note that EDGAR data are complete only through 2012; the EDGAR data in the right-hand panel
30 represent the three years 2010-2012 and are presented for comparison.

31
32 **2.3.3.2 Land use effects**

33 Agriculture is responsible for approximately two-thirds of N₂O emissions (*robust evidence, high agreement*)

1 (Janssens-Maenhout et al. 2017). Total emissions from this sector are the sum of direct and indirect
2 emissions. Direct emissions from soils are the result of mineral fertiliser and manure application, manure
3 management, deposition of crop residues, cultivation of organic soils and inorganic N inputs through
4 biological nitrogen fixation. Indirect emissions come from increased warming, enrichment of downstream
5 water bodies from runoff, and downwind N deposition on soils. The main driver of N₂O emissions in
6 croplands is a lack of synchronisation between crop N demand and soil N supply, with approximately 50%
7 of N applied to agricultural land not taken up by the crop (Zhang et al. 2017). Cropland soils emit over 3 Tg
8 N₂O-N yr⁻¹ (*medium evidence, high agreement*) (Janssens-Maenhout et al. 2017; Saikawa et al. 2014).
9 Regional inverse modelling studies show larger tropical emissions than the inventory approaches and they
10 show increases in N₂O emissions from the agricultural sector in South Asia, Central America, and South
11 America (Saikawa et al. 2014; Wells et al. 2018).

12
13 Emissions of N₂O from pasturelands and rangelands have increased by as much as 80% since 1960 due to
14 increased manure production and deposition (*robust evidence, high agreement*) (de Klein et al. 2014; Tian et
15 al. 2018; Chadwick et al. 2018; Dangal et al. 2019; Cardenas et al. 2019). Studies consistently report that
16 pasturelands and rangelands are responsible for around half of the total agricultural N₂O emissions
17 (Davidson 2009; Oenema et al. 2014; Dangal et al. 2019). An analysis by Dangal et al. (2019) shows that
18 while managed pastures make up around one-quarter of the global grazing lands, they contribute 86% of the
19 net global N₂O emissions from grasslands and that more than half of these emissions are related to direct
20 deposition of livestock excreta on soils.

21
22 Many studies calculate N₂O emissions from a linear relationship between nitrogen application rates and N₂O
23 emissions. New studies are increasingly finding nonlinear relationships, which means that N₂O emissions per
24 hectare are lower than the Tier 1 EFs (IPCC 2003) at low nitrogen application rates, and higher at high
25 nitrogen application rates (*robust evidence, high agreement*) (Shcherbak et al. 2014; van Lent et al. 2015;
26 Satria 2017). This not only has implications for how agricultural N₂O emissions are estimated in national and
27 regional inventories, which now often use a linear relationship between nitrogen applied and N₂O emissions,
28 it also means that in regions of the world where low nitrogen application rates dominate, increases in
29 nitrogen fertiliser use would generate relatively small increases in agricultural N₂O emissions. Decreases in
30 application rates in regions where application rates are high and exceed crop demand for parts of the growing
31 season are likely to have very large effects on emissions reductions (*medium evidence, high agreement*).

32
33 Deforestation and other forms of land-use change alter soil N₂O emissions. Typically, N₂O emissions
34 increase following conversion of native forests and grasslands to pastures or croplands (McDaniel et al.
35 2019; van Lent et al. 2015). This increase lasts from a few years to a decade or more, but there is a trend
36 toward decreased N₂O emissions with time following land use change and ultimately lower N₂O emissions
37 than had been occurring under native vegetation, in the absence of fertilisation (**Figure 2.12**) (Meurer et al.
38 2016; van Lent et al. 2015) (*medium evidence, high agreement*). Conversion of native vegetation to fertilised
39 systems typically leads to increased N₂O emissions over time, with the rate of emission often being a
40 function of nitrogen fertilisation rates, but this response can be moderated by soil characteristics and water
41 availability (*medium evidence, high agreement*) (van Lent et al. 2015; Meurer et al. 2016). Restoration of
42 agroecosystems to natural vegetation, over the period of one to two decades does not lead to recovery of N₂O
43 emissions to the levels of the original vegetation (McDaniel et al. 2019). To conclude, findings since AR5
44 increasingly highlight the limits of linear N₂O emission factors, particularly from field to regional scales,
45 with emissions rising nonlinearly at high nitrogen application rates (*high confidence*). Emissions from
46 unfertilised systems often increase and then decline over time with typically lower emissions than was the
47 case under native vegetation (*high confidence*).

Figure 2.12 Effect of time since conversion on N_2O fluxes in unfertilised (black circles) and fertilised (white circles) tropical croplands (left frame) and in unfertilised tropical pastures (right frame). Average N_2O flux and 95% confidence intervals are given for upland forests (black inverted triangle) and low canopy forests (white inverted triangle), for comparison. The solid lines represent the trends for unfertilised and fertilised cases. Data source: (van Lent et al. 2015).

While soil emissions are the predominant source in agriculture, other sources are important or their importance is only just emerging. Biomass burning is responsible for approximately $0.7 \text{ Tg N}_2\text{O-N yr}^{-1}$ ($0.5\text{--}1.7 \text{ Tg N}_2\text{O-N yr}^{-1}$) or 11% of total gross anthropogenic emissions due to the release of N_2O from the oxidation of organic nitrogen in biomass (van der Werf et al. 2013). This source includes crop residue burning, forest fires, household cook stoves, and prescribed savannah, pasture and cropland burning. Aquaculture is currently not accounted for in most assessments or compilations. While it is currently responsible for less than $0.1 \text{ Tg N}_2\text{O-N yr}^{-1}$, is one of the fastest growing sources of anthropogenic N_2O emissions (Williams and Crutzen 2010; Bouwman et al. 2013) (*limited evidence, high agreement*). Finally, increased nitrogen deposition from terrestrial sources is leading to greater indirect N_2O emissions, particularly since 1980 (*moderate evidence, high agreement*). (Tian et al. 2018, 2016). In marine systems, deposition is estimated to have increased the oceanic N_2O source by $0.2 \text{ Tg N}_2\text{O-N yr}^{-1}$ or 3% of total gross anthropogenic emissions (Suntharalingam et al. 2012).

Box 2.2: Methodologies for estimating national to global scale anthropogenic land carbon fluxes

Bookkeeping/accounting models (Houghton et al. 2012b; Hansis et al. 2015; Houghton and Nassikas 2017) calculate changes in biomass and soils that result from changes in land activity using data on biomass density and rates of growth/decomposition, typically from ground-based inventory data collection (field measurements of carbon in trees and soils). The approach includes only those changes directly caused by major categories of land-use change and management. The models do not explicitly include the indirect effects to changing environmental conditions, although some effects are implicit in biomass, growth rates and decay rates used. Thus, the models may overestimate past fluxes. The bookkeeping models include fluxes from peatland burning based on GFED estimates (Global Fire Emissions Database, (Randerson et al. 2015).)

Dynamic Global Vegetation Models (DGVMs) simulate ecological processes, such as photosynthesis, respiration, allocation, growth, decomposition etc., driven by environmental conditions (climate variability, climate change, CO_2 , nitrogen concentrations). Models vary with respect to the processes included, with many since AR5 now including forest management, fire, N, and other management (Sitch et al. 2005; Le Quéré et al. 2018). Models are forced with increasing atmospheric CO_2 and changing climate, and run with and without “land use change” (land cover and forest harvest) to differentiate the anthropogenic effects from

1 the indirect effects of climate and CO₂ - the “land sink”. Thus, indirect effects are explicitly included. This
2 approach also includes a “lost atmospheric sink capacity”, or the carbon uptake due to environmental effects
3 on forests that does not happen once the forests are removed (Pongratz et al. 2010).
4

5 **Integrated Assessment Models (IAMs)** use story-lines to construct alternative future scenarios of GHG
6 emissions and atmospheric concentrations within a global socio-economic framework, including projections
7 of AFOLU based on assumptions of, for example, crop yields, population growth, bioenergy use (See Cross-
8 Chapter Box 1: Scenarios, Chapter 1). Some models include simplified DGVMs, which may include climate
9 and CO₂ effects, while others use AFOLU emissions from other sources.
10

11 **Earth system models (ESMs)** couple DGVMs, surface hydrology and energy exchange models with a
12 atmosphere, ocean, and sea ice models, enabling exploration of feedbacks between climate change and the
13 carbon cycle (e.g., warming effects increase soil and plant respiration and lead to higher atmospheric CO₂
14 concentrations, which in turn promote plant growth) (Friedlingstein et al. 2014). They sometimes include
15 numerical experiments with and without land-use change to diagnose the anthropogenic AFOLU flux
16 (Lawrence et al. 2016).
17

18 **Satellite data** can be used as a proxy for plant activity (e.g. greenness) and to map land cover, vegetation
19 fires and biomass density. Algorithms, models and independent data are used to calculate fluxes of CO₂ from
20 satellite data, although calculating the net carbon flux is difficult because of the lack of information on the
21 respiratory flux. Some active satellite sensors (LiDAR) are able to measure three-dimensional structure in
22 woody vegetation, which is closely related to biomass density (Zarin et al. 2016a; Baccini et al. 2012;
23 Saatchi et al. 2011). Together with land-cover change data, these estimates of biomass density can be used to
24 provide observational-based estimates of fluxes due to changes in forest area (e.g., (Tyukavina et al. 2015;
25 Harris et al. 2015; Baccini et al. 2012) or degradation (Baccini et al. 2017). Satellite estimates of biomass
26 vary considerably (Mitchard et al. 2013; Saatchi et al. 2015; Avitabile et al. 2016); data are available only for
27 recent decades; methods generally assume that all losses of carbon are immediately released to the
28 atmosphere; and changes in soil carbon are generally ignored. The approach implicitly includes indirect and
29 natural disturbance effects as well as direct anthropogenic effects.
30

31 **Atmospheric Inversions** use observations of atmospheric concentrations with a model of atmospheric
32 transport, based on data for wind speed and direction, to calculate implied emissions (Gatti et al. 2014; Liu et
33 al. 2017a; van der Laan-Luijkx et al. 2017). Since AR5 there has been an increase in availability of
34 concentration data from flux tower networks and satellites, enabling better global coverage at finer spatial
35 scales and some national estimates (e.g. in the UK inverse techniques are used together with national GHG
36 inventories). A combination of concentrations of different gases and isotopes enables the separation of fossil,
37 ocean and land fluxes. However, inversions give only the net flux of CO₂ from land; they cannot separate
38 natural and anthropogenic fluxes.
39

40 **Micrometeorological flux measurements:** Data on CO₂ concentrations and air movements recorded on
41 instrumented towers enable calculation of CO₂ flux at the ecosystem scale. Global and regional Flux
42 Networks (FluxNet (Global), AsiaFlux, Ameriflux (North America), ICOS (EU), NEON (USA), and others)
43 contribute to a global flux data base, which is used to verify the results of modelling, inventory and remote
44 sensing studies.
45

46 **FAOSTAT:** The United Nations Food and Agricultural Organization has produced country level estimates
47 of greenhouse gas emissions (Tubiello et al. 2013) from agriculture (1961–2016) and land use (1990–2016)
48 using a globally consistent methodological approach based largely on IPCC Tier 1 methods of the 2006
49 IPCC Guidelines (FAO 2015b). FAO emissions estimates were used as one of the three database inputs into
50 the AR5 WGIII AFOLU chapter. Non-CO₂ emissions from agriculture are estimated directly from national
51 statistics of activity data reported by countries to FAO. CO₂ emissions from land use and land-use change are
52 computed mostly at Tier 1, albeit at fine geospatial scales to capture effects from peatland degradation and
53 biomass fires (Rossi et al. 2016). Emissions from forest land and deforestation are based on the IPCC carbon
54 stock change method, thus constituting a Tier 3 estimate relying on country statistics of carbon stocks and
55 forest area collected through the FAO FRA. The carbon flux is estimated assuming instantaneous emissions
56 in the year of forest area loss, and changes in carbon stocks within extant forests, but does not distinguish

1 “managed” and “unmanaged” forest areas, albeit it treats separately emissions from primary, secondary and
 2 planted forest (Federici et al. 2015).
 3

4 **Country Reporting of GHG Inventories (GHGIs):** All Parties to the UNFCCC are required to report
 5 national GHG Inventories (GHGIs) of anthropogenic emissions and removals. Reporting requirements are
 6 differentiated between developed and developing countries. Because of the difficulty of separating direct
 7 anthropogenic fluxes from indirect or natural fluxes, the (IPCC 2003) adopted the “managed land” concept
 8 as a proxy to facilitate GHGI reporting. All GHG fluxes on “managed land” are defined as anthropogenic,
 9 with each country applying their own definition of “managed land” (i.e. “where human interventions and
 10 practices have been applied to perform production, ecological or social functions” (IPCC 2006)). Fluxes may
 11 be determined on the basis of changes in carbon stocks (e.g., from forest inventories) or by activity data (e.g.
 12 area of land cover change management activity multiplied by emission factors or with modelled fluxes).
 13 Depending on the specific methods used, GHGIs include all direct anthropogenic effects and may include the
 14 indirect anthropogenic effects of environmental change (generally sinks) and natural effects (see Section
 15 2.3.1.2). GHG fluxes from “unmanaged land” are not reported in GHGIs because they are assumed to be
 16 non-anthropogenic. The reported estimates may then be filtered through agreed “accounting rules” - i.e. what
 17 countries actually count towards their mitigation targets (Cowie AL et al. 2007; Lee, D. and Sanz 2017). The
 18 accounting aims to better quantify the additional mitigation actions by, for example, factoring out the impact
 19 of natural disturbances and forest age-related dynamics (Canadell et al. 2007; Grassi et al. 2018).
 20

25 **Box 2.3: CO₂ fertilisation and enhanced terrestrial uptake of carbon**

26
 27 All Dynamic Global Vegetation Models (DGVMs) and Earth System Models (ESMs) represent the CO₂
 28 fertilisation effect ((Le Quéré et al. 2017; Hoffman et al. 2014). There is *high confidence* that elevated CO₂
 29 results in increased short-term CO₂ uptake per unit leaf area (Swann et al. 2016; Field et al. 1995; Donohue
 30 et al. 2013);. However, whether this increased CO₂ uptake at the leaf level translates into increased growth
 31 for the whole plant differs among plant species and environments because growth is constrained by whole-
 32 plant resource allocation, nutrient limitation (e.g., nitrogen (N), phosphorus (P), potassium (K) and soil water
 33 and light limitations (Körner 2006; Peñuelas et al. 2017; Friend et al. 2014a). Interactions between plants and
 34 soil microbes, further modulate the degree of nutrient limitation on CO₂ fertilisation (Terrer et al. 2017).
 35

36 At the ecosystems level, enhanced CO₂ uptake at decadal or longer time scales depends on changes in plant
 37 community composition and ecosystem respiration, as well disturbance and natural plant mortality (De
 38 Kauwe et al., 2016; Farrior et al., 2015; Keenan et al., 2017; Sulman et al, 2019). The results of FACE
 39 experiments (free-air carbon dioxide enrichment) over two decades are highly variable because of these
 40 factors (Norby et al. 2010; Körner 2015; Feng et al. 2015; Paschalis et al. 2017; Terrer et al. 2017; Du et al.
 41 2019b). Under higher atmospheric CO₂ concentrations, the ratio of CO₂ uptake to water loss (water use
 42 efficiency, WUE), increases and enhances drought tolerance of plants (*high confidence*) (Berry et al., 2010;
 43 Ainsworth & Rogers, 2007).
 44

45 Long-term CO₂ and water vapour flux measurements show that WUE in temperate and boreal forests of the
 46 Northern Hemisphere has increased more than predicted by photosynthetic theory and models over the past
 47 two decades (*high confidence*) (Keenan et al. 2013; Laguë and Swann 2016b). New theories have emerged
 48 on how CO₂ uptake by trees is related to water loss and to the risk of damaging xylem (water conducting
 49 tissues) in the trunk and branches (Wolf et al. 2016a; Anderegg et al. 2018a). Tree ring studies of stable
 50 carbon and oxygen isotopes also detected increased WUE in recent decades (Battipaglia et al. 2013; Silva
 51 and Anand 2013; van der Sleen et al. 2014). Yet, tree ring studies often fail to show acceleration of tree
 52 growth rates in support of CO₂ fertilisation, even when they show increased WUE (van der Sleen et al.
 53 2014). The International Tree Ring Data Bank (ITRDB) indicated that only about 20% of the sites in the
 54 database showed increasing trends in tree growth that cannot be explained by climate variability, nitrogen
 55 deposition, elevation, or latitude. Thus there is *limited evidence (low agreement)* among observations of
 56 enhanced tree growth due to CO₂ fertilisation of forests during the 20th century (Gedalof and Berg 2010).

1
2 In grasslands, although it is possible for CO₂ fertilisation to alleviate the impacts of drought and heat stress
3 on net carbon uptake (Roy et al. 2016b), there is *low confidence* about its projected magnitude. Because of
4 its effect on water use efficiency, CO₂ fertilisation is expected to be pronounced in semi-arid habitats; and
5 because of different metabolic pathways, C₃ plants are expected to be more sensitive to elevated CO₂
6 concentrations than C₄ grasses (Donohue et al. 2013; Morgan et al. 2011; Derner et al. 2003). Neither of
7 these expectations was observed over a 12-year study of elevated CO₂ in a grassland system: enhanced
8 growth was not observed during dry summers, and growth of C₄ grasses was unexpectedly stimulated, while
9 growth of C₃ grasses was not (Reich et al. 2014, 2018).

10
11 There is *medium confidence* that CO₂ fertilisation effects have increased water use efficiency in crops and
12 thus reduced agricultural water use per unit of crop produced (Deryng et al. 2016b; Nazemi and Wheeler
13 2015; Elliott et al. 2014) . This effect could lead to near-term continued greening of agricultural areas.
14 However, current assessments of these effects are based on limited observations, mostly from the temperate
15 zone (Deryng et al. 2016a).

16
17 One line of evidence for CO₂ fertilisation is the increasing land sink (“the residual land sink” in AR5) over
18 the last 50 years as the atmospheric CO₂ concentration has increased (Los 2013; Sitch et al. 2015b; Campbell
19 et al. 2017; Keenan and Riley 2018). A combined analysis of atmospheric inverse analyses, ecosystem
20 models, and forest inventory data concluded that 60% of the recent terrestrial carbon sink can be directly
21 attributed to increasing atmospheric CO₂ (Schimel et al. 2015). A global analysis using a “reconstructed
22 vegetation index” (RVI) for the period 1901–2006 from MODIS satellite-derived NDVI (Normalised
23 Vegetation Difference Index) showed that CO₂ fertilisation contributed at least 40% of the observed increase
24 in the land carbon sink (Los 2013). Without CO₂ fertilisation ESMs are unable to simulate the increasing
25 land sink and the observed atmospheric CO₂ concentration growth rate since the middle of the 20th century
26 (Shevliakova et al. 2013). There are other mechanisms that could explain enhanced land C uptake such as
27 increased regional forest and shrub cover (see Cross-Chapter Box 2: Implications of large-scale conversion
28 from non-forest to forest land, Chapter 1);(Chen et al. 2019), and, at higher latitudes, increasing temperatures
29 and longer growing seasons (Zhu et al. 2016).

30
31 In summary, there is *low confidence* about the magnitude of the CO₂ effect and other factors that may
32 explain at least a portion of the land sink (e.g., nitrogen deposition, increased growing season, reduced
33 burning, erosion and re-deposition or organic sediments, and aerosol-induced cooling). Increases in
34 atmospheric CO₂ result in increased water use efficiency and increase leaf-level photosynthesis (*high*
35 *confidence*). The extent to which CO₂ fertilisation results in plant- or ecosystem-level carbon accumulation is
36 highly variable and affected by other environmental constraints (*high confidence*). Even in ecosystems where
37 CO₂ fertilisation has been detected in recent decades, those effects are found to weaken as a result of
38 physiological acclimation, soil nutrient limitation, and other constraints on growth (Friend et al., 2014;
39 Körner, 2006; Peñuelas et al., 2017).

40 41 42 **2.4 Emissions and impacts of short-lived climate forcers (SLCF) from land**

43
44 While the rising atmospheric concentration of GHGs is the largest driver of anthropogenic changes in
45 climate, the levels of short-lived climate forcers (SLCF) can significantly modulate regional climate by
46 altering radiation exchanges and hydrological cycle and impact ecosystems (Boucher et al. 2013; Rogelj et
47 al. 2014; Kok et al. 2018) (*high confidence*). This section assesses the current state of knowledge with
48 respect to past and future emissions of the three major SLCFs and their precursors: mineral dust,
49 carbonaceous aerosols (Black Carbon and Organic Carbon), and Biogenic volatile organic compounds
50 (BVOCs). The chapter also reports on implications of changes in their emissions for climate. Aerosols
51 particles with diameters between about 0.010 µm to about 20 µm are recognised as SLCFs, a term that refers
52 to their short atmospheric lifetime (a few days). BVOCs are important precursors of ozone and organic
53 carbon (OC), both important climate forcing agents with short atmospheric lifetimes.

54
55 While the AR5 did not assess land aerosols emissions in depth, their findings stated that although progress in
56 quantifying regional emissions of anthropogenic and natural land aerosols has been made, considerable

1 uncertainty still remains about their historical trends, their inter-annual and decadal variability and about any
2 changes in the future (Calvo et al. 2013; Klimont et al. 2017). Some new and improved understanding of
3 processes controlling emissions and atmospheric processing has been developed since AR5, for example, a
4 better understanding of the climatic role of Black Carbon (BC) as well as the understanding of the role of
5 BVOCs in formation of secondary organic aerosols (SOA).

6
7 Depending on the chemical composition and size, aerosols can absorb or scatter sunlight and thus directly
8 affect the amount of absorbed and scattered radiation (Fuzzi et al. 2015a; Nousiainen 2011; de Sá et al. 2019)
9 Aerosols affect clouds formation and development, and thus can also influence precipitation patterns and
10 amounts (Sun et al. 2015). In addition, deposition of aerosols—especially black carbon—on snow and ice
11 surfaces can reduce albedo and increase warming as a self-reinforcing feedback. Aerosols deposition also
12 change biogeochemical cycling in critical terrestrial ecosystems with deposition of nutrients such as nitrogen
13 and phosphorus (Andreae et al. 2002). Primary land aerosols are emitted directly into the atmosphere due to
14 natural or anthropogenic processes and include mineral aerosols (or dust), volcanic dust, soot from
15 combustion, organic aerosols from industry, vehicles or biomass burning, bioaerosols from forested regions,
16 and others. Secondary organic aerosols (SOA) are particulates that are formed in the atmosphere by gas-to-
17 particles conversion processes from gaseous precursors, such as BVOCs, and account for a large fraction of
18 fine mode (particles less than 2.5µm) aerosol mass (Hodzic et al. 2016; Manish et al. 2017). Land use change
19 can affect the climate through changed emissions of SLCFs such as aerosols, ozone precursors and methane.

20
21 Aerosols from air pollution will decline in the coming years as a means for improving urban and regional air,
22 but their removal will lead to additional warming (Boucher et al. 2013), with important regional variability,
23 and partially offsetting projected mitigation effects for two to three decades in 1.5°C consistent pathways
24 (IPCC 2018) (*high confidence*). It is important to emphasise that changes in emissions can either be due to
25 external forcing or through a feedback in the climate system (Box 2.1:). For instance, enhanced dust
26 emissions due to reduced vegetation could be a forcing if overgrazing is the cause of larger dust emission, or
27 a feedback if dryer climate is the cause. This distinction is important in terms of mitigation measures to be
28 implemented.

29 30 **2.4.1 Mineral dust**

31
32 One of the most abundant atmospheric aerosols emitted into the atmosphere is mineral dust, a “natural”
33 aerosol that is produced by wind strong enough to initiate the emissions process of sandblasting. Mineral
34 dust is preferentially emitted from dry and unvegetated soils in topographic depressions where deep layer of
35 alluvium have been accumulated (Prospero et al. 2002). Dust is also emitted from disturbed soils by human
36 activities with a 25% contribution to global emission, based on satellite-based estimate (Ginoux et al. 2012).
37 Dust is then transported over long distances across continents and oceans. Dust cycle, which consists of
38 mineral dust emission, transport, deposition and stabilisation, have multiple interactions with many climate
39 processes and biogeochemical cycles.

40 41 **2.4.1.1 Mineral dust as a short-lived climate forcer from land**

42 Depending on the dust mineralogy, mixing state, and size, dust particles can absorb or scatter shortwave and
43 long-wave radiation. Dust particles serve as cloud condensation nuclei and ice nuclei. They can influence the
44 microphysical properties of clouds, their lifetime and precipitation rate (Kok et al. 2018). New and improved
45 understanding of processes controlling emissions and transport of dust, its regional patterns and variability as
46 well as its chemical composition has been developed since AR5.

47
48 While satellites remain the primary source of information to locate dust sources and atmospheric burden, in-
49 situ data remains critical to constrain optical and mineralogical properties of the dust (Di Biagio et al. 2017;
50 Rocha-Lima et al. 2018). Dust particles are composed of minerals, including iron oxides which strongly
51 absorb shortwave radiation and provide nutrient for marine ecosystems. Other mineral such as feldspar is an
52 efficient ice nuclei (Harrison et al. 2016). Dust mineralogy depending on the native soils, global databases
53 were developed to characterise mineralogical composition of soils for use in the weather and climate models
54 (Journet et al. 2014; Perlwitz et al. 2015). New field campaigns as well as new analysis from prior campaign
55 have produced insights into role of dust in western Africa in climate system, for example, for dust
56 (Veselovskii et al. 2016), long-ranged transport of dust across the Atlantic (Groß et al. 2015), and the

1 characterisation of aerosol particles and their ability to act as ice and cloud condensation nuclei (Price et al.
2 2018). Size distribution at emission is another key parameter controlling dust interactions with radiation.
3 Most models use now the parametrisation of Kok (2011) based on the theory of brittle material. It was shown
4 that most models underestimate the size of global dust cycle (Kok 2011) has been underestimated.
5 Characterisation of spatial and temporal distribution of dust emissions is essential for weather prediction and
6 climate projections (*high confidence*). Although there is a growing confidence in characterising the
7 seasonality and peak of dust emissions (i.e., spring-summer, (Wang et al. 2015)) and how the meteorological
8 and soil conditions control dust sources, an understanding of long-term future dust dynamics, inter-annual
9 dust variability and how they will affect future climate still requires substantial work. Dust is also important
10 at high latitude, where it has impacts on snow covered surface albedo and weather (Bullard et al. 2016).

11 **2.4.1.2 Effects of past climate change on dust emissions, and feedbacks**

12 Limited number of model-based studies found that dust emissions increased significantly since late 19th
13 century: by 25% from preindustrial to present day (e.g., from 729 Tg yr⁻¹ to 912 Tg yr⁻¹) with ~50% increase
14 driven by climate change and ~40% by land use cover change such as conversion of natural land to
15 agriculture (Stanelle et al. 2014) (*low confidence*). These changes resulted in a clear sky radiative forcing at
16 the top of the atmosphere of -0.14 W m⁻² (Stanelle et al. 2014). The authors found that, in North Africa most
17 dust is of natural origin with a recent 15% increase in dust emissions attributed to climate change; in North
18 America two thirds of dust emissions take place on agricultural lands and both climate change and land use
19 change jointly drive the increase; between pre-industrial and present-day the overall effect of changes in dust
20 is -0.14 W m⁻² cooling of clear sky net radiative forcing on top of the atmosphere, with -0.05 W m⁻² from land
21 use and -0.083 W m⁻² from changes in climate.

22
23
24 The comparison of observations for vertically integrated mass of atmospheric dust mass per unit area (i.e.
25 Dust Mass Path or DMP) obtained from the remotely sensed data and the DMP from CMIP5 models reveal
26 that model-simulate range of DMP was much lower than the estimates from (Evan et al. 2014). ESM
27 typically do not reproduce inter-annual and longer time scales variability seen in observations (Evan et al.
28 2016). Analyses of the CMIP5 models (Evan 2018; Evan et al. 2014)) reveal that all climate models
29 systematically under-estimate dust emissions, amount of dust in the atmosphere and its inter-annual
30 variability (*medium confidence*).

31
32 One commonly suggested reason for the lack of dust variability in climate models is the models' inability to
33 simulate the effects of land surface changes on dust emission (Stanelle et al. 2014). Models which account
34 for changes in land surface show more agreement with the satellite observations both in terms of Aerosol
35 Optical Depth and DMP (Kok et al. 2014). New prognostic dust emissions models now able to account for
36 both changes in surface winds and vegetation characteristics (e.g., leaf area index and stem area index) and
37 soil water, ice, and snow cover (Evans et al. 2016). As a result, new modelling studies (e.g. Evans et al.
38 2016) indicate that in regions where soil and vegetation respond strongly to ENSO events, such as in
39 Australia, inclusion of dynamic vegetation characteristics into dust emission parameterisations improves
40 comparisons between the modelled and observed relationship long-term climate variability (e.g., ENSO) and
41 dust levels (Evans et al. 2016). Thus, there has been progress in incorporating effects of vegetation, soil
42 moisture, surface wind and vegetation on dust emission source functions but the number of studies
43 demonstrating such improvement remains small (*limited evidence, medium agreement*).

44 **2.4.1.3 Future changes of dust emissions**

45
46
47 There is no agreement about direction of future changes in dust emissions. Atmospheric dust loading is
48 projected to increase over the southern edge of the Sahara in association with surface wind and precipitation
49 changes (Pu and Ginoux, 2018), while Evan et al. (2016) project a decline in African dust emissions. Dust
50 Optical Depth (DOD) is also projected to increase over the central Arabian Peninsula in all seasons and to
51 decrease over northern China from MAM to SON (Pu and Ginoux 2018). Climate models project rising
52 drought risks over the southwestern and central US. in the twenty-first century. The projected drier regions
53 largely overlay the major dust sources in the US. However, whether dust activity in the US will increase in
54 the future is not clear, due to the large uncertainty in dust modelling (Pu and Ginoux 2017). Future trends of
55 dust emissions will depend on changes in precipitation patterns and atmospheric circulation (*limited*
56 *evidence, high agreement*). However, implication of changes in human activities, including mitigation (e.g.

1 bioenergy production) and adaption (e.g. irrigation) are not characterised in the current literature.

2 3 4 **2.4.2 Carbonaceous Aerosols**

5
6 Carbonaceous aerosols are one of the most abundant components of aerosol particles in continental areas of
7 the atmosphere and a key land-atmosphere component (Contini et al. 2018). They can make up to 60-80% of
8 PM_{2.5} (Particulate matter with size less than 2.5 µm) in urban and remote atmosphere (Tsigaridis et al.
9 2014a; Kulmala et al. 2011). It comprises an organic fraction (Organic Carbon - OC) and a refractory light
10 absorbing component, generally referred as Elemental Carbon (EC), from which Black Carbon (BC) is the
11 optically active absorption component of EC (Gilardoni et al. 2011; Bond et al. 2013).

12 13 **2.4.2.1 Carbonaceous aerosol precursors of short-lived climate forcers from land**

14 OC is a major component of aerosol mass concentration, and it originates from different anthropogenic
15 (combustion processes) and natural (from natural biogenic emissions) sources (Robinson et al. 2007). A
16 large fraction of OC in the atmosphere has a secondary origin, as it can be formed in the atmosphere through
17 condensation to the aerosol phase of low vapour pressure gaseous compounds emitted as primary pollutants
18 or formed in the atmosphere. This component is called Secondary Organic Aerosol (SOA) (Hodzic et al.
19 2016). A third component of the optically active aerosols is the so-called brown carbon (BrC), an organic
20 material that shows enhanced solar radiation absorption at short wavelengths (Wang et al. 2016b; Laskin et
21 al. 2015; Liu et al. 2016a; Bond et al. 2013; Saturno et al. 2018).

22
23 OC and EC have distinctly different optical properties, with OC being important for the scattering properties
24 of aerosols and EC is central for the absorption component (Rizzo et al. 2013; Tsigaridis et al. 2014a; Fuzzi
25 et al. 2015a). While organic carbon is reflective and scatter solar radiation, it has a cooling effect on climate.
26 On the other side, BC and BrC absorbs solar radiation and they have a warming effect in the climate system.
27 (Bond et al. 2013).

28
29 Organic carbon is also characterised by a high solubility with a high fraction of water-soluble organic
30 compounds (WSOC) and it is one of the main drivers of the oxidative potential of atmospheric particles. This
31 makes particles loaded with oxidised OC an efficient CCN in most of the conditions (Pöhlker et al. 2016;
32 Thalman et al. 2017; Schmale et al. 2018).

33
34 Biomass burning is a major global source of carbonaceous aerosols (Bowman et al. 2011b; Harrison et al.
35 2010; Reddington et al. 2016; Artaxo et al. 2013). As knowledge of past fire dynamics improved through
36 new satellite observations, new fire proxies' datasets (Marlon et al. 2013; van Marle et al. 2017), and
37 process-based models (Hantson et al. 2016), a new historic biomass burning emissions dataset starting in
38 1750 has been developed (Van Marle et al. 2017a) (see Cross-Chapter Box 3: Fire and Climate Change, in
39 this chapter). Revised versions of OC biomass burning emissions (Van Marle et al. 2017a) show in general
40 reduced trends compared to the emissions derived by (Lamarque et al. 2010) for CMIP5. CMIP6 global
41 emissions pathways (Gidden et al. 2018; Hoesly et al. 2018) estimate global BC emissions in 2015 at 9.8 Mt
42 BC yr⁻¹, while global OC emissions are 35 Mt OC yr⁻¹.

43
44 Land use change is critically important for carbonaceous aerosols, since biomass burning emissions consist
45 mostly of organic aerosol, and the undisturbed forest is also a large source of organic aerosols (Artaxo et al.
46 2013). Additionally, urban aerosols are also mostly carbonaceous, because of the source composition (traffic,
47 combustion, industry, etc.) (Fuzzi et al. 2015b). Burning of fossil fuel, biomass burning emissions and SOA
48 from natural BVOC emissions are the main global sources of carbonaceous aerosols. Any change in each of
49 these components influence directly the radiative forcing (Contini et al. 2018; Boucher et al. 2013; Bond et
50 al. 2013).

51
52 One important component of carbonaceous aerosols is the primary biological aerosol particles (PBAP), also
53 called bioaerosols, that correspond to a significant fraction of aerosols in forested areas (Fröhlich-Nowoisky
54 et al. 2016; Pöschl and Shiraiwa 2015). They are emitted directly by the vegetation as part of the biological
55 processes (Huffman et al. 2012). Airborne bacteria, fungal spores, pollen, archaea, algae, and other
56 bioparticles are essential for the reproduction and spread of organisms across various terrestrial ecosystems.

1 They can serve as nuclei for cloud droplets, ice crystals, and precipitation, thus influencing the hydrological
2 cycle and climate (Whitehead et al. 2016; Scott et al. 2015; Pöschl et al. 2010).

3 4 **2.4.2.2 Effects of past climate change on carbonaceous aerosols emissions, and feedbacks**

5 Annual global emission estimates of BC range from 7.2-7.5 Tg yr⁻¹ using bottom-up inventories (Bond et al.
6 2013; Klimont et al. 2017) up to 17.8 ± 5.6 Tg yr⁻¹ using a fully coupled climate-aerosol-urban model
7 constrained by aerosol measurements (Cohen and Wang 2014), with considerably higher BC emissions for
8 Eastern Europe, Southern East Asia, and Southeast Asia mostly due to higher anthropogenic BC emissions
9 estimates. A significant source of BC, the net trend in global burned area from 2000 to 2012 was a modest
10 decrease of 4.3 Mha yr⁻¹ (-1.2% yr⁻¹).

11
12 Carbonaceous aerosols are important in urban areas as well as pristine continental regions, since they can be
13 responsible for 50-85% of PM_{2.5} (Contini et al. 2018; Klimont et al. 2017). In boreal and tropical forests,
14 carbonaceous aerosols originate from BVOC oxidation (Section 2.4.3). The largest global source of BC
15 aerosols is open burning of forests, savannah and agricultural lands with emissions of about 2,700 Gg yr⁻¹
16 in the year 2000 (Bond et al. 2013).

17
18 ESMS most likely underestimate globally averaged EC emissions (Bond et al. 2013; Cohen and Wang 2014),
19 although recent emission inventories have included an upwards adjustment in these numbers (Hoesly et al.
20 2018). Vertical EC profiles have also been shown to be poorly constrained (Samset et al. 2014a), with a
21 general tendency of too much EC at high altitudes. Models differ strongly in the magnitude and importance
22 of the coating-enhancement of ambient EC absorption (Boucher et al. 2016) (Gustafsson and Ramanathan
23 2016), in their estimated lifetime of these particles, as well as in dry and wet removal efficiency (Mahmood
24 et al. 2016) (*limited evidence, medium agreement*).

25
26 The equilibrium in emissions and concentrations between the scattering properties of organic aerosol versus
27 the absorption component of BC is a key ingredient in the future climatic projections of aerosol effects
28 (*limited evidence, high agreement*). The uncertainties in net climate forcing from BC rich sources are
29 substantial, largely due to lack of knowledge about cloud interactions with both black carbon and co-emitted
30 organic carbon. A strong positive forcing of about 1.1 W m⁻² was calculated by (Bond et al. 2013), but this
31 forcing is balanced by a negative forcing of -1.45 W m⁻², and shows clearly a need to work on the co-
32 emission issue for carbonaceous aerosols. The forcing will also depend on the aerosol-cloud interactions,
33 where carbonaceous aerosol can be coated and change their CCN capability. It is difficult to estimate the
34 changes in any of these components in a future climate, but this will influence strongly the radiative forcing
35 (Contini et al. 2018; Boucher et al. 2013; Bond et al. 2013) (*high confidence*).

36
37 De Coninck et al. (2018) reported studies estimating a lower global temperature effect from BC mitigation
38 (e.g., Samset et al. 2014b; Boucher et al. 2016), although commonly used models do not capture properly
39 observed effects of BC and co-emissions on climate (e.g., (Bond et al. 2013). Regionally, the warming
40 effects can be substantially larger, for example, in the Arctic (Sand et al. 2015) and high mountain regions
41 near industrialised areas or areas with heavy biomass burning impacts (Ming et al. 2013) (*high confidence*).

42 43 **2.4.2.3 Future changes of carbonaceous aerosol emissions**

44 Due to the short atmospheric lifetime of carbonaceous aerosols in the atmosphere, of the order of a few days,
45 most studies dealing with the future concentration levels have a regional character (Cholakian et al. 2018;
46 Fiore et al. 2012). The studies agree that the uncertainties in changes in emissions of aerosols and their
47 precursors are generally higher than those connected to climate change itself. Confidence in future changes
48 in carbonaceous aerosol concentration projections is limited by the reliability of natural and anthropogenic
49 emissions (including wildfires, largely caused by human activity) of primary aerosol as well as that of the
50 precursors. The Aerosol Chemistry Model Intercomparison Project (AerChemMIP) is endorsed by the
51 Coupled-Model Intercomparison Project 6 (CMIP6) and is designed to quantify the climate impacts of
52 aerosols and chemically- reactive gases (Lamarque et al. 2013). These simulations calculated future
53 responses to SLCF emissions for the RCP scenarios in terms of concentration changes and radiative forcing.
54 Carbonaceous aerosol emissions are expected to increase in the near future due to possible increases in open
55 biomass burning (forest, savannah, and agricultural fires) emissions, and increase in SOA from oxidation of
56 BVOCs (Tsigaridis et al. 2014b; Van Marle et al. 2017b; Giglio et al. 2013) (*medium confidence*).

1
2 More robust knowledge has been produced since the conclusions reported in AR5 (Boucher et al. 2013) and
3 all lines of evidence now agree on a small effect on carbonaceous aerosol global burden due to climate
4 change (*medium confidence*). The regional effects, however, are predicted to be much higher (Westervelt et
5 al. 2015). With respect to possible changes in the chemical composition of PM as a result of future climate
6 change only a few sparse data are available in the literature and the results are, as yet, inconclusive. The co-
7 benefits of reducing aerosol emissions due to air quality issues will play an important role in future
8 carbonaceous aerosol emissions (Gonçalves et al. 2018; Shindell et al. 2017) (*high confidence*).
9

10 **2.4.3 Biogenic Volatile Organic Compounds (BVOCs)**

11
12 Biogenic volatile organic compounds (BVOCs) are emitted in large amounts by forests (Guenther et al.
13 2012). They include isoprene, terpenes, alkanes, alkenes, alcohols, esters, carbonyls and acids (Peñuelas and
14 Staudt 2010; Guenther et al. 1995, 2012). Their emissions represent a carbon loss to the ecosystem, which
15 can represent up to 10% of the carbon fixed by photosynthesis under stressful conditions (Bracho-Nunez et
16 al. 2011). The global average emission for vegetated surfaces is $0.7 \text{ g C m}^{-2} \text{ yr}^{-1}$ but can exceed 100 g C m^{-2}
17 yr^{-1} in some tropical ecosystems (Peñuelas and Llusà 2003).
18

19 **2.4.3.1 BVOC precursors of short-lived climate forcers from Land**

20 BVOCs are rapidly oxidised in the atmosphere to form less volatile compounds that can condense and form
21 secondary organic aerosol (SOA). In boreal and tropical forests, carbonaceous aerosols originate from
22 BVOC oxidation, of which isoprene and terpenes are the most important precursors (Claeys et al. 2004; Hu
23 et al. 2015; De Sá et al. 2017; de Sá et al. 2018; Liu et al. 2016b, see following sub-section). BVOCs are the
24 most important precursors of SOA. This transformation process of BVOCs affects the aerosol size
25 distribution both by contributing to new particle formation and to the growth of larger pre-existing particles.
26 SOA affect the scattering of radiation by the particles themselves (direct aerosol effect), but also change the
27 amount of cloud condensation nuclei (CCN) and the lifetime and optical properties of clouds (indirect
28 aerosol effect).
29

30 High amounts of SOA are observed over forest areas, in particular in boreal and tropical regions where they
31 have been found to mostly originate from BVOC emissions (Manish et al. 2017). In particular, isoprene
32 epoxydiol-derived SOA (IEPOX-SOA) is being identified in recent studies in North America and
33 Amazonian forest as a major component in the oxidation of isoprene (Allan et al. 2014; Schulz et al. 2018;
34 De Sá et al. 2017). In tropical regions BVOC can be convected up to the upper atmosphere, where their
35 volatility is reduced and where they become SOA. In some cases those particles are even transported back to
36 the lower atmosphere (Schulz et al. 2018; Wang et al. 2016a; Andreae et al. 2018). In the upper troposphere
37 in the Amazon, SOA are important CCN and are responsible for the vigorous hydrological cycle (Pöhlker et
38 al. 2018). This strong link between BVOC emissions by plants and hydrological cycle has been discussed in
39 a number of studies (Fuentes et al. 2000; Schmale et al. 2018; Pöhlker et al. 2018, 2016).
40

41 Changing BVOC emissions also affect the oxidant concentrations in the atmosphere. Their impact on the
42 concentration of ozone depends on the NO_x concentrations. In polluted regions, high BVOC emissions lead
43 to increased production of ozone, followed by the formation of more OH and a reduction in the methane
44 lifetime. In more pristine regions (NO_x-limited), increasing BVOC emissions instead lead to decreasing OH
45 and ozone concentrations, resulting in a longer methane lifetime. The net effect of BVOCs then can change
46 over time if NO_x emissions are changing.
47

48 BVOCs' possible climate effects have received little attention because it was thought that their short lifetime
49 would preclude them from having any significant direct influence on climate (Unger 2014a; Sporre et al.
50 2018). Higher temperatures and increased CO₂ concentrations are (separately) expected to increase the
51 emissions of BVOCs (Jardine et al. 2011, 2015; Fuentes et al. 2016). This has been proposed to initiate
52 negative climate feedback mechanisms through increased formation of SOA (Arneth et al. 2010; Kulmala
53 2004; Unger et al. 2017). More SOA can make the clouds more reflective, which can provide a cooling.
54 Furthermore, the increase in SOA formation has also been proposed to lead to increased aerosol scattering,
55 resulting in an increase in diffuse radiation. This could boost gross primary production (GPP) and further
56 increase BVOC emissions (Kulmala et al. 2014; Cirino et al. 2014; Sena et al. 2016; Schafer et al. 2002;

Ometto et al. 2005; Oliveira et al. 2007). These important feedbacks are starting to emerge (Sporre et al. 2018; Kulmala 2004; Arneth et al. 2017b). However, there is evidence that this influence might be significant at different spatial scales, from local to global, through aerosol formation and through direct and indirect greenhouse effects (*limited evidence, medium agreement*). Most tropical forest BVOC are primarily emitted from foliage of trees but soil microbes can also be a major source of some compounds including sesquiterpenes (Bourtsoukidis et al. 2018).

2.4.3.2 *Historical changes of BVOCs and contribution to climate change*

Climate warming over the past 30 years, together with the longer growing season experienced in boreal and temperate environments, have increased BVOC global emissions by since the preindustrial times (*limited evidence, medium agreement*) (Peñuelas 2009; Sanderson et al. 2003; Pacifico et al. 2012). This was opposed by lower BVOC emissions caused by the historical conversion of natural vegetation and forests to cropland (*limited evidence, medium agreement*) (Unger 2013, 2014a; Fu and Liao 2014). The consequences of historical anthropogenic land cover change were a decrease in the global formation of SOA (-13 %, Scott et al. 2017) and tropospheric burden (-13 %, Heald and Geddes 2016). This has resulted in a positive radiative forcing (and thus warming) from 1850 to 2000 of 0.017 W m^{-2} (Heald and Geddes 2016), 0.025 (Scott et al. 2017) and 0.09 W m^{-2} (Unger 2014b) through the direct aerosol effect. In present-day conditions, global SOA production from all sources spans between 13 and 121 Tg yr^{-1} (Tsigaridis et al. 2014a). The indirect aerosol effect (change in cloud condensation nuclei), resulting from land use induced changes in BVOC emissions, adds an additional positive radiative forcing of 0.008 W m^{-2} (Scott et al. 2017). More studies with different model setups are needed to fully assess this indirect aerosol effect associated with land use change from the preindustrial to present. CMIP6 global emissions pathways (Hoesly et al. 2018; Gidden et al. 2018) estimates global VOCs emissions in 2015 at $230 \text{ Mt VOC yr}^{-1}$. They also estimated that from 2000 to 2015, emissions were up from 200 to $230 \text{ Mt VOC yr}^{-1}$.

There is (*limited evidence, medium agreement*) that historical changes in BVOC emissions have also impacted tropospheric ozone. At most surface locations where land use has changed, the NO_x concentrations are sufficiently high for the decrease in BVOC emissions to lead to decreasing ozone concentrations (Scott et al. 2017). However, in more pristine regions (with low NO_x concentrations), the imposed conversion to agriculture has increased ozone through decreased BVOC emissions and their subsequent decrease in OH (Scott et al. 2017; Heald and Geddes 2016). In parallel, the enhanced soil NO_x emissions from agricultural land, can increase the ozone concentrations in NO_x limited regions (Heald and Geddes 2016).

Another impact of historical decrease in BVOC emissions is the reduction in the atmospheric lifetime of methane (*limited evidence, medium agreement*), which results in a negative radiative forcing that ranges from -0.007 W m^{-2} (Scott et al. 2017) to -0.07 W m^{-2} (Unger 2014b). However, the knowledge of to which degree BVOC emissions impact oxidant concentrations, in particular OH (and thus methane concentrations), is still limited and therefore these numbers are very uncertain (Heald and Spracklen 2015; Scott et al. 2017). The effect of land use change on BVOC emissions are highly heterogeneous (Rosenkranz et al. 2015) and though the global values of forcing described above are small, the local or regional values can be higher and even of opposite sign than the global values.

2.4.3.3 *Future changes of BVOCs*

Studies suggest that increasing temperature will change BVOC emissions through change in species composition and rate of BVOC productions. A further 2°C to 3°C rise in the mean global temperature, could increase BVOC global emissions by an additional 30–45% (Peñuelas and Llusà 2003). In two modelling studies, the impact on climate from rising BVOC emissions have been found to become even larger with decreasing anthropogenic aerosol emissions (Kulmala et al. 2013; Sporre et al. 2018). A negative feedback on temperature, arising from the BVOC-induced increase in the first indirect aerosol effect have been estimated by two studies to be in the order of $-0.01 \text{ W m}^{-2} \text{ K}$ (Scott et al. 2018b; Paasonen et al. 2013). Enhanced aerosol scattering from increasing BVOC emissions has been estimated to contribute with a global gain in BVOC emissions of 7% (Rap et al. 2018). In a warming planet, BVOC emissions are expected to increase but magnitude is unknown and will depend on future land use change, in addition to climate (*limited evidence, medium agreement*).

There is a very limited number of studies investigating the climate impacts of BVOCs using future land use

scenarios (Ashworth et al. 2012; Pacifico et al. 2012). Scott et al. (2018a) found that a future deforestation according to the land use scenario in RCP8.5 leads to a 4% decrease in BVOC emissions at the end of the century. This resulted in a direct aerosol forcing of $+0.006 \text{ W m}^{-2}$ (decreased reflection by particles in the atmosphere) and a first indirect aerosol forcing of -0.001 W m^{-2} (change in the amount of CCN). Studies not including future land use scenarios but investigating the climate feedbacks leading to increasing future BVOC emissions, have found a direct aerosol effect of -0.06 W m^{-2} (Sporre et al. 2018) and an indirect aerosol effect of -0.45 W m^{-2} (Makkonen et al. 2012; Sporre et al. 2018). The stronger aerosol effects from the feedback compared to the land use are, at least partly, explained by a much larger change in the BVOC emissions.

A positive climate feedback could happen in a future scenario with increasing BVOC emissions, where higher ozone and methane concentrations could lead to an enhanced warming which could further increase BVOC emissions (Arneeth et al. 2010). This possible feedback is mediated by NO_x levels. One recent study including dynamic vegetation, land use change, CO₂ and climate change found no increase or even a slight decrease in global BVOC emissions at the end of the century (Hantson et al. 2017). There is a lack of understanding concerning the processes governing the BVOC emissions, the oxidation processes in the atmosphere, the role of the BVOC oxidation products in new particle formation and particle growth, as well as general uncertainties in aerosol-cloud interactions. There is a need for continued research into these processes but the current knowledge indicates that changing BVOC emissions need to be taken into consideration when assessing the future climate and how land use will affect it. In summary, the magnitude and sign of net effect of BVOC emissions on the radiation budget and surface temperature is highly uncertain.

2.5 Land impacts on climate and weather through biophysical and GHGs effects

The focus of this section is summarised **Figure 2.13**. We report on what we know regarding the influence land has on climate via biophysical and biogeochemical exchanges. Biogeochemical effects herein only refer to changes in net emissions of CO₂ from land. The influence of land on atmospheric composition is discussed in Section 2.3.

All sections discuss impacts of land on global and regional climate, and climate extremes, whenever the information is available. Section 2.5.1 presents effects of historical and future land use scenarios; section 2.5.2 is devoted to impacts of specific anthropogenic land uses such as forestation, deforestation, irrigation, crop and forest management; section 2.5.3 focuses on how climate driven land changes feedback on climate and section 2.5.4 puts forward that land use changes in one region can affect another region.

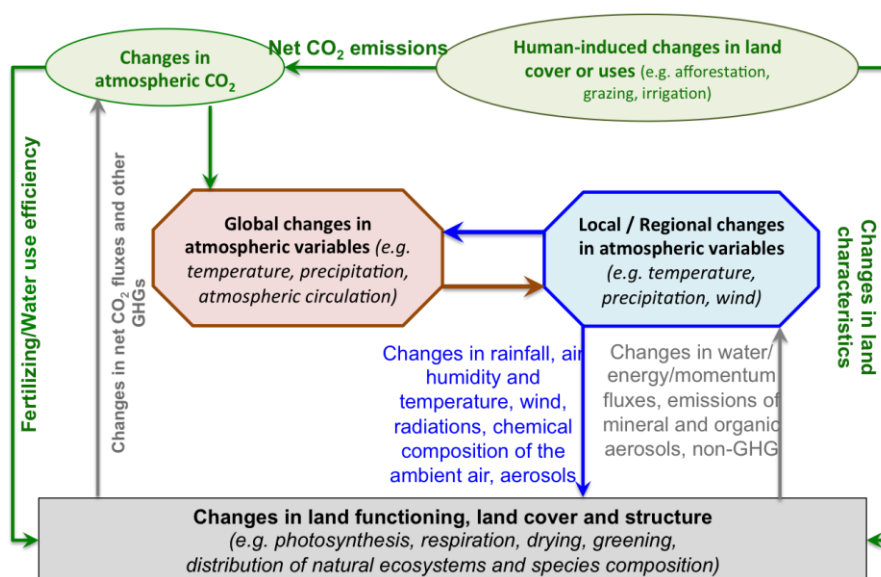

Figure 2.13 Global, local and regional climate changes are the focus of this section. They are examined

through changes in climate states (e.g., changes in air temperature and humidity, rainfall, radiation) as well as through changes in atmospheric dynamics (e.g., circulation patterns). Changes in land that influence climate are either climate- or Human- driven. Green arrows and boxes refer to what we consider herein as imposed changes (forcings). Grey box and arrows refer to responses of land to forcings (green and blue boxes) and feedbacks on those initial forcings. Red and blue boxes and arrows refer respectively to global and local/regional climate changes and their subsequent changes on land

2.5.1 Impacts of historical and future anthropogenic land cover changes

The studies reported below focus essentially on modelling experiments, as there is no direct observation of how historical land use changes have affected the atmospheric dynamics and physics at the global and regional scales. Moreover, the climate modelling experiments only assess the impacts of anthropogenic land cover changes (e.g. deforestation, urbanisation) and neglect the effects of changes in land management (e.g. irrigation, use of fertilisers, choice of species varieties among managed forests or crops). Because of this restricted accounting for land use changes we will use the term land cover changes in the following sub-sections (2.5.1.1 and 2.5.1.2).

Each section starts by describing changes at the global scale, and at the regional scale and ends with what we know about the impacts of those scenarios on extreme weather events, whenever the information is available.

2.5.1.1 Impacts of global historical land cover changes on climate

2.5.1.1.1 At the global level

The contribution of anthropogenic land cover changes to the net global warming throughout the 20th century has been derived from few model-based estimates that account simultaneously for biogeochemical and biophysical effects of land on climate (Table 2.4). The simulated net change in mean global annual surface air temperature, averaged over all the simulations, is a small warming of $0.078 \pm 0.093^\circ\text{C}$, ranging from small cooling simulated by two models (-0.05°C and -0.02°C respectively in (Brovkin et al. 2004) and (Simmons and Matthews 2016), to larger warming simulated by three models ($>+0.14^\circ\text{C}$ (Shevliakova et al. 2013; Pongratz et al. 2010; Matthews et al. 2004). When starting from the Holocene period (He et al. 2014) has estimated an even larger net warming effect of anthropogenic land cover changes ($+0.72^\circ\text{C}$).

Table 2.4 Change in mean global annual surface air temperature resulting from anthropogenic land cover change over the historical period. This historical period varies from one simulation to another (middle column).

Reference of the study	Time period	Mean global annual change in surface air temperature ($^\circ\text{C}$)
(Simmons and Matthews 2016)	1750-2000	-0.02
(Shevliakova et al. 2013)	1861-2005	+0.17
(Pongratz et al. 2010)	1900-2000	+0.14
(Matthews et al. 2004)	1700-2000	+0.15
(Brovkin et al. 2004)	1850-2000	-0.05
Mean \pm standard deviation		0.078 ± 0.093

This net small warming signal results from the competing effects of biophysical cooling (*medium confidence*) and biogeochemical warming (*very high confidence*; Figure 2.14²). The global biophysical cooling alone has been estimated by a larger range of climate models and is $-0.10 \pm 0.14^\circ\text{C}$; it ranges from -0.57°C to $+0.06^\circ\text{C}$ (e.g. (Zhang et al. 2013a; Hua and Chen 2013; Jones et al. 2013b; Simmons and Matthews 2016), Table A2.1). This cooling is essentially dominated by increases in surface albedo: historical land cover changes have generally led to a dominant brightening of land as discussed in AR5 (Myhre et al. 2013). Reduced incoming long-wave radiation at the surface from reduced evapotranspiration and thus less water vapour in the atmosphere has also been reported as a potential contributor to this cooling (Claussen et al. 2001a). The cooling is however dampened by decreases in turbulent fluxes leading to decreased loss of

² FOOTNOTE: The detailed list of all values used to construct this figure is provided in Table A2.1 in the Appendix at the end of the Chapter

1 heat and water vapour from the land through convective processes. Those non-radiative processes are indeed
2 well-known to often oppose the albedo-induced surface temperature changes (e.g., (Davin and de Noblet-
3 Ducoudre 2010; Boisier et al. 2012)).

4
5 Historical land cover changes have contributed to the increase in atmospheric CO₂ content (Section 2.3) and
6 thus to global warming (biogeochemical effect, *very high confidence*). The global mean biogeochemical
7 warming has been calculated from observation-based estimates (+0.25±0.10°C; e.g. (Li et al. 2017a;
8 Avitabile et al. 2016; Carvalhais et al. 2014; Le Quéré et al. 2015)), or estimated from dynamic global
9 vegetation models (+0.24±0.12°C; e.g. (Peng et al. 2017; Arneth et al. 2017a; Pugh et al. 2015; Hansis et al.
10 2015)) and global climate models (+0.20±0.05°C; (Pongratz et al. 2010; Brovkin et al. 2004; Matthews et al.
11 2004; Simmons and Matthews 2016)).

12
13 The magnitude of these simulated biogeochemical effects may however be underestimated as they do not
14 account for a number of processes such as land management, nitrogen/phosphorus cycles, changes in the
15 emissions of CH₄, N₂O and non-GHG emissions from land (Ward et al. 2014; Arneth et al. 2017b; Cleveland
16 et al. 2015; Pongratz et al. 2018). Two studies have accounted for those compounds and found a global net
17 positive radiative forcing in response to historical anthropogenic land cover changes, indicating a net surface
18 warming (Mahowald et al. 2017; Ward et al. 2014). However, first the estimated biophysical radiative
19 forcing in those studies only accounts for changes in albedo and not for changes in turbulent fluxes.
20 Secondly, the combined estimates also depend on other several key modelling estimates such as climate
21 sensitivity, CO₂ fertilisation caused by land use emissions, possible synergistic effects, validity of radiative
22 forcing concept for land forcing. The comparison with the other above-mentioned modelling studies is thus
23 difficult.

24
25 In addition, most of those estimates do not account for the evolution of natural vegetation in unmanaged
26 areas, while observations and numerical studies have reported a greening of the land in boreal regions
27 resulting from both extended growing season and poleward migration of tree lines (Lloyd et al. 2003; Lucht
28 et al. 1995), Section 2.2). This greening enhances global warming via a reduction of surface albedo (winter
29 darkening of the land through the snow-albedo feedbacks, e.g. (Forzieri et al. 2017)). At the same time
30 cooling occurs due to increased evapotranspiration during the growing season, along with enhanced
31 photosynthesis, i.e. increased CO₂ sink (Qian et al. 2010). When feedbacks from the poleward migration of
32 treeline is accounted for together with the biophysical effects of historical anthropogenic land cover change,
33 the biophysical annual cooling (about -0.20°C to -0.22°C on land, -0.06°C globally) is significantly
34 dampened by the warming (about +0.13°C) resulting from the movements of natural vegetation (Strengers et
35 al. 2010). Accounting simultaneously for both anthropogenic and natural land cover changes reduces the
36 cooling impacts of historical land cover change in this specific study.
37

1
 2 **Figure 2.14** Changes in mean global annual surface air temperature (°C) in response to historical and
 3 **future anthropogenic land cover changes** as estimated from a range of studies (see Table A2.1 in the
 4 **Appendix for detailed information**). Temperature changes resulting from biophysical processes (e.g.
 5 **changes in physical land surface characteristics such as albedo, evapotranspiration, and roughness**
 6 **length) are illustrated using blue symbols**; temperature changes resulting from biogeochemical processes
 7 **(e.g. changes in atmospheric CO₂ composition) use red symbols**. Future changes are shown for three
 8 **distinct scenarios: RCP8.5, RCP4.5 & RCP2.6**. The markers ‘filled circle’, ‘filled cross’, and ‘filled
 9 **triangle down**’ represent estimates from respectively **global climate models, dynamic global vegetation**
 10 **models (DGVMs), and observations**. When the number of estimate is sufficiently large, box plots are
 11 **overlaid; they show the ensemble minimum, first quartile (25th percentile), median, third quartile (75th**
 12 **percentile), and the ensemble maximum**. Scatter points beyond the box plot are the outliers. Details
 13 **about how temperature change is estimated from DGVMs and observations is provided in Appendix**.
 14 **Numbers on the right hand-side give the mean and the range of simulated mean global annual warming**
 15 **from various climate models**.

16
 17 **2.5.1.1.2 At the regional level**

18 The global and annual estimates reported above mask out very contrasted regional and seasonal differences.
 19 Biogeochemical effects of anthropogenic land cover change on temperature follow the spatial patterns of
 20 GHG-driven climate change with stronger warming over land than ocean, and stronger warming in northern
 21 high latitudes than in the tropics and equatorial regions (Arctic amplification). Biophysical effects on the
 22 contrary are much stronger where land cover has been modified than in their surroundings (see 2.5.4 for a
 23 discussion on non-local effects). Very contrasted regional temperature changes can thus result depending on
 24 whether biophysical processes dampen or exacerbate biogeochemical impacts.
 25

Figure 2.15 compares, for seven climate models, the biophysical effects of historical anthropogenic land cover change in North America and Eurasia (essentially cooling) to the regional warming resulting from the increased atmospheric CO₂ content since pre-industrial times ((De Noblet-Ducoudré et al. 2012); comparing 1973–2002 to 1871–1900). It shows a dominant biophysical cooling effect of changes in land cover, at all seasons, as large as the regional footprint of anthropogenic global warming. Averaged over all agricultural areas of the world (Pongratz et al. 2010) reported a 20th century biophysical cooling of -0.10°C, and (Strengers et al. 2010) reported a land induced cooling as large as -1.5°C in western Russia and eastern China between 1871 and 2007. There is thus *medium confidence* that anthropogenic land cover change has dampened warming in many regions of the world over the historical period.

Very few studies have explored the effects of historical land cover changes on seasonal climate. There are however evidences that the seasonal magnitude and sign of those effects at the regional level are strongly related to soil-moisture/evapotranspiration and snow regimes, particularly in temperate and boreal latitudes (Teuling et al. 2010; Pitman and de Noblet-Ducoudré 2012; Alkama and Cescatti 2016). Quesada et al. (2017a) showed that atmospheric circulation changes can be significantly strengthened in winter for tropical and temperate regions. However, the lack of studies underlines the need for a more systematic assessment of seasonal, regional and other than mean temperature metrics in the future.

Figure 2.15 Simulated changes in mean surface air temperature (°C) between the pre-industrial period (1870–1900) and present-day (1972–2002) for all seasons and for a) North America and b) Eurasia (De Noblet-Ducoudré et al. 2012). Light grey boxes are the changes simulated in response to increased atmospheric GHG content between both time periods and subsequent changes in sea-surface temperature and sea-ice extent (SST/CO₂); the CO₂ changes accounted for include emissions from all sources including land use. Dark grey boxes are the changes simulated in response to the biophysical effects of historical land cover changes. The box-and-whisker plots have been drawn using results from seven climate models and ensembles of ten simulations per model and time period. The bottom and top of the each grey box are the 25th and 75th percentiles, and the horizontal line within each box is the 50th percentile (the median). The whiskers (straight lines) indicate the ensemble maximum and minimum values. Seasons are respectively December-January-February (DJF), March-April-May (MAM), June-July-August (JJA) and September-October-November (SON). North America and Eurasia are extended regions where land use changes are the largest between the two time periods considered (their contours can be found in Figure 1 of (De Noblet-Ducoudré et al. 2012)).

2.5.1.1.3 Effects on extremes

The effect of historical deforestation on extreme temperature trends is intertwined with the effect of other climate forcings thus making it difficult to quantify based on observations. Based on results from four climate models, the impact of historical anthropogenic land cover change on temperature and precipitation extremes was found to be locally as important as changes arising from increases in atmospheric CO₂ and sea-surface temperatures, but with a lack of model agreement on the sign of changes (Pitman et al. 2012). In some regions the impact of land cover change masks or amplifies the effect of increased CO₂ on extremes (Avila et al. 2012; Christidis et al. 2013). Using an observational constraint for the local biophysical effect of land cover change applied to a set of CMIP5 climate models, (Lejeune et al. 2018) found that historical deforestation increased extreme hot temperatures in northern mid-latitudes. The results also indicate a stronger impact on the warmest temperatures compared to mean temperatures. Findell et al. (2017) reached similar conclusions, although using only a single climate model. Importantly, the climate models involved in

1 these three studies did not consider the effect of management changes which have been shown to be
 2 important, as discussed Section 2.5.2.

3
 4 Based on the studies discussed above there is yet *limited evidence* but *high agreement* that land cover change
 5 affects local temperature extremes more than mean values. Observational studies assessing the role of land
 6 cover on temperature extremes are still very limited (Zaitchik et al. 2006; Renaud and Rebetez 2008), but
 7 suggest that trees dampen seasonal and diurnal temperature variations at all latitudes and even more so in
 8 temperate regions compared to short vegetation (Chen et al. 2018; Duveiller et al. 2018b; Li et al. 2015a; Lee
 9 et al. 2011). Furthermore, trees also locally dampen the amplitude of heat extremes (Renaud and Rebetez
 10 2008; Zaitchik et al. 2006) although this result depends on the forest type, coniferous trees providing less
 11 cooling effect than broadleaf trees (Renaud et al. 2011; Renaud and Rebetez 2008).

12 13 **2.5.1.2 Impacts of future global land cover changes on climate**

14 **2.5.1.2.1 At the global level**

15 The most extreme emissions scenario (RCP8.5) that has been developed for the last coordinated modelling
 16 intercomparison of climate models (CMIP5) is the one that has received the most attention in the literature
 17 with respect to how projected future anthropogenic land cover changes (Hurtt et al. 2011) will affect the very
 18 large simulated global warming.

19
 20 Seven model-based studies have examined both the biophysical and biogeochemical effects of anthropogenic
 21 changes in land-cover, as projected in RCP8.5, on future climate change (Table 2.5 ; (Simmons and
 22 Matthews 2016; Davies-Barnard et al. 2014; Boysen et al. 2014)). They all agree on a biogeochemical
 23 warming, ranging from +0.04°C to +0.35°C, in response to land cover change. Two models predict an
 24 additional biophysical warming, while the others agree on a biophysical cooling that dampens (or overrules)
 25 the biogeochemical warming. Using a wider range of global climate models, the biogeochemical warming
 26 (*high confidence*) is +0.20±0.15°C whereas it is +0.28±0.11°C when estimated from dynamic global
 27 vegetation models (Pugh et al. 2015; Stocker et al. 2014). This biogeochemical warming is compensated for
 28 by a biophysical cooling (*medium confidence*) of -0.10±0.14°C (Quesada et al. 2017a; Davies-Barnard et al.
 29 2015; Boysen et al. 2014). The estimates of temperature changes resulting from anthropogenic land cover
 30 changes alone remain very small compared to the projected mean warming of +3.7°C by the end of the 21st
 31 century (ranging from 2.6 to 4.8°C depending on the model and compared to 1986-2005; Figure 2.14).

32
 33 **Table 2.5 Change in mean global annual surface air temperature resulting from**
 34 **anthropogenic land cover changes projected for the future, according to three different**
 35 **scenarios: RCP8.5, RCP4.5 and RCP2.6. Temperature change resulting from biophysical**
 36 **and biogeochemical effects of land cover change are examined.**

Reference of the study	Time period	Mean global annual change in surface air temperature (°C)		
		Biophysical / Biogeochemical		
		RCP2.6	RCP4.5	RCP8.5
(Simmons and Matthews 2016)	2000-2100	-0.35 / +0.42	-0.29 / + 0.37	-0.34 / + 0.35
(Davies-Barnard et al. 2014)	2005-2100	-0.01 / +0.04	+0.14 / -0.08	-0.015 / +0.04
				+0.04 / +0.08
				0 / +0.05
(Boysen et al. 2014)	2005-2100			+0.08 / +0.06
				-0.20 / +0.13
				-0.06 / +0.33

37
 38 Two other projected land cover change scenarios have been examined (RCP4.5 and RCP2.6; Table 2.5 ;
 39 Figure 2.14) but only one climate modelling experiment has been carried out for each, to estimate the
 40 biophysical impacts on climate of those changes (Davies-Barnard et al. 2015). For RCP2.6, earth system and
 41 dynamic global vegetation models agree on a systematic biogeochemical warming resulting from the
 42 imposed land cover changes, ranging from +0.03 to +0.28°C (Brovkin et al. 2013a), which is significant
 43 compared to the projected mean climate warming of +1°C by the end of the 21st century (ranging from 0.3 to
 44 1.7°C depending on the models, compared to 1986-2005). A very small biophysical cooling is expected from
 45 the one estimate. For RCP4.5 biophysical warming is expected from only one estimate, and results from a

1 projected large forestation in the temperate and high latitudes. There is no agreement on the sign of the
2 biogeochemical effect: there are as many studies predicting cooling as warming, whichever the method to
3 compute those effects (earth system models or dynamic global vegetation models).
4

5 Previous scenarios (Special Report on Emission Scenarios (SRES), results of climate studies using those
6 scenarios were reported in AR4) displayed larger land use changes than the more recent ones (RCP, AR5).
7 There is *low confidence* from some of those previous scenarios (SRES A2 and B1) of a small warming effect
8 (+0.2 to +0.3°C) of anthropogenic land cover change on mean global climate, this being dominated by the
9 release of CO₂ in the atmosphere from land conversions (Sitch et al. 2005). This additional warming remains
10 quite small when compared to the one resulting from the combined anthropogenic influences [+1.7°C for
11 SRES B1 and +2.7°C for SRES A2]. A global biophysical cooling of -0.14°C is estimated in response to the
12 extreme land cover change projected in SRES A2, a value that far exceeds the impacts of historical land use
13 changes (-0.05°C) calculated using the same climate model (Davin et al. 2007). The authors derived a
14 biophysical climatic sensitivity to land use change of about -0.3°C W.m⁻² for their model, whereas a warming
15 of about 1°C W.m⁻² is obtained in response to changes in atmospheric CO₂ concentration.
16

17 Those studies generally do not report on changes in atmospheric variables other than surface air temperature,
18 thereby limiting our ability to assess the effects of anthropogenic land cover changes on regional climate
19 Sitch et al. (2005). However, reported small reductions in rainfall via changes in biophysical properties of
20 the land, following the massive tropical deforestation in SRES A2 (+0.5 and +0.25 mm day⁻¹ respectively in
21 the Amazon and Central Africa). They also report opposite changes, that is increased rainfall of about 0.25
22 mm day⁻¹ across the entire tropics and subtropics, triggered by biogeochemical effects of this same
23 deforestation.
24

25 **2.5.1.2.2 At the regional level**

26 In regions that will undergo land cover changes, dampening of the future anthropogenic warming can be as
27 large as -26% while enhancement is always smaller than 9% within RCP8.5 by the end of the 21st century
28 (Boysen et al. 2014). Voltaire (2006) show that, by 2050 and following the SRES B2 scenario, the
29 contribution of land cover changes to the total temperature change can be as large as 15% in many boreal
30 regions, and as large as 40% in south western tropical Africa. Feddema et al. (2005) simulate large decreases
31 in the diurnal temperature range in the future (2050 and 2100 in SRES B1 and A2) following tropical
32 deforestation in both scenarios. In the Amazon for example the diurnal temperature range is lowered by
33 2.5°C due to increases in minimum temperature while little change is obtained for the maximum value.

34 There is thus *medium evidence* that future anthropogenic land cover change will have a significant effect on
35 regional temperature via biophysical effects in many regions of the world. There is however *no agreement*
36 on whether warming will be dampened or enhanced and there is *no agreement* on the sign of the contribution
37 across regions.
38

39 There are very few studies that go beyond analysing the changes in mean surface air temperature. Some
40 studies attempted to look at global changes in rainfall and found no significant influence of future land cover
41 changes (Brovkin et al. 2013a; Sitch et al. 2005; Feddema et al. 2005). Quesada et al. (2017a,b) however
42 carried out a systematic multi-model analysis of the response of a number of atmospheric, radiative and
43 hydrological variables (e.g. rainfall, sea level pressure, geopotential height, wind speed, soil-moisture,
44 turbulent heat fluxes, shortwave and longwave radiation, cloudiness) to RCP8.5 land cover scenario. In
45 particular, they found a significant reduction of rainfall in 6 out of 8 monsoon regions studied (Figure 2.16)
46 of about 1.9% to 3% (which means more than -0.5mm day⁻¹ in some areas) in response to future
47 anthropogenic land cover changes. Including those changes in global climate models reduces the projected
48 increase in rainfall by about 9% to 41% in those same regions, when all anthropogenic forcings are
49 accounted for (30% in the Global Monsoon region as defined by (Wang and Ding 2008)). In addition, they
50 found a shortening of the monsoon season of one to four days. They conclude that the projected future
51 increase in monsoon rains may be overestimated by those models that do not yet include biophysical effects
52 of land cover changes. Overall, the regional hydrological cycle was found to be substantially reduced and
53 wind speed significantly strengthened in response to regional deforestation within the tropics, with
54 magnitude comparable to projected changes with all forcings (Quesada et al. 2017b).
55

Figure 2.16 Changes in monsoon rainfall in RCP8.5 scenario resulting from projected changes in anthropogenic land cover, in eight monsoonal regions (%), grey bars). Differences are calculated between the end of the 21st century (2071–2100) and the end of the 20th century (1976–2005); percent change is calculated with reference to 1976–2005. Blue bars refer to the relative contribution of land cover changes (in %) to future rainfall projections: it is the ratio between the change in rainfall responding to land cover changes and the one responding to all anthropogenic changes (Quesada et al. 2017b). Negative values mean that changes in land cover have an opposite effect (dampening) on rainfall compared to the effects of all anthropogenic changes. Monsoon regions have been defined following (Yim et al. 2014). The changes have been simulated by five climate models (Brovkin et al. 2013, symbols). Results are shown for December-January-February for southern hemisphere regions, and for June-July-August for northern hemisphere regions. Statistical significance is given by green tick marks and circles: one, two, and three green tick marks are displayed for the regions where at least 80%, 75%, and 80th confidence level, respectively; green circles are added when the regional values are also significant at 90th confidence level. Note that future land cover change impacts on South American monsoon are neither significant nor robust among models, along with very small future projected changes in South American monsoon rainfall.

2.5.1.2.3 Effects on extremes

Results from a set of climate models have shown that the impact of future anthropogenic land cover change on extreme temperatures can be of similar magnitude as the changes arising from half a degree global mean annual surface temperature change (Hirsch et al. 2018). However, this study also found a lack of agreement between models with respect to the magnitude and sign of changes, thus making land cover change a factor of uncertainty in future climate projections.

2.5.2 Impacts of specific land use changes

2.5.2.1 Impacts of deforestation and forestation

Deforestation or forestation³, wherever it occurs, triggers simultaneously warming and cooling of the surface and of the atmosphere via changes in its various characteristics (Pitman 2003; Strengers et al. 2010; Bonan 2008b). Following deforestation, warming results from a) the release of CO₂ and other GHG in the atmosphere (biogeochemical impact) and subsequent increase in incoming infrared radiation at surface (greenhouse effect), b) a decreased in the total loss of energy through turbulent fluxes (latent and sensible

³ FOOTNOTE: The term « forestation » is used herein as this chapter does not distinguish between afforestation and reforestation. In model-based studies, simulations with and without trees are compared; in observation-based estimates, sites with and without trees are compared.

1 heat fluxes) resulting from reduced surface roughness, c) an increased incoming solar radiation following
2 reduced cloudiness that often (but not always) accompanies the decreased total evapotranspiration. Cooling
3 occurs in response to d) increased surface albedo that reduces the amount of absorbed solar radiation, e)
4 reduced incoming infrared radiation triggered by the decreased evapotranspiration and subsequent decrease
5 in atmospheric water vapour. Points b-c-d-e are referred to as biophysical effects. Deforestation and
6 forestation also alter rainfall and winds (horizontal as well as vertical as will be further discussed below).
7

8 The literature that discusses the effects of forestation on climate is more limited than for deforestation, but
9 they reveal a similar climatic response with opposite sign as further discussed below. For each latitudinal
10 band (tropical, temperate and boreal) how very large scale deforestation or forestation impacts global mean
11 climate is examined, followed by examination of the large-scale changes in the specific latitudinal band and
12 end up with more regionally focused analysis. Large scale idealised deforestation or forestation experiments
13 are often carried out with global or regional climate models as they allow to understand and measure how
14 sensitive climate is to very large changes in land cover (similar to the instant doubling of CO₂ in climate
15 models to calculate the climatic sensitivity to GHGs). Details of the model-based studies discussed below
16 can be found in Table A2.2 in the Appendix.
17

18 2.5.2.1.1 *Global and regional impacts of deforestation/forestation in tropical regions*

19 A pan-tropical deforestation would lead to the net release of CO₂ from land and thus to mean global annual
20 warming, with model-based estimates of biogeochemical effects ranging from +0.19 to +1.06°C, with a
21 mean value of +0.53±0.32°C (Ganopolski et al. 2001; Snyder et al. 2004; Devaraju et al. 2015a; Longobardi
22 et al. 2016; Perugini et al. 2017). There is however *no agreement* between models on the magnitude and sign
23 of the biophysical effect of such changes at the global scale (the range spans from -0.5°C to +0.7°C with a
24 mean value of +0.1±0.27°C; Figure 2.17 ; e.g. (Devaraju et al. 2015c; Snyder 2010; Longobardi et al.
25 2016a)). This is the result of many compensation effects in action: increased surface albedo following
26 deforestation, decreased atmospheric water vapour content due to less tropical evapotranspiration, decreased
27 loss of energy from tropical land in the form of latent and sensible heat fluxes.
28

29 There is however *high confidence* that such large land cover change would lead to a mean biophysical
30 warming when averaged over the deforested land. A mean warming of +0.61±0.48°C is found over the entire
31 tropics. Reversely, biophysical regional cooling and global warming is expected from forestation (Wang et
32 al. 2014b; Bathiany et al. 2010a).
33

34 Large-scale deforestation (whether pan-tropical or imposed at the sub-continent level, e.g. the Amazon)
35 results in significant mean rainfall decrease (Lawrence and Vandecar 2015; Lejeune et al. 2015; Perugini et
36 al. 2017). In their review (Perugini et al. 2017) reported an average simulated decrease of -288 ± 75 mm yr⁻¹
37 (95%-confidence interval). Inversely large-scale forestation increases tropical rainfall by 41 ± 21 mm yr⁻¹.
38 The magnitude of the change in precipitation strongly depends on the type of land cover conversion. For
39 instance, conversion of tropical forest to bare soil causes larger reductions in regional precipitation than
40 conversion to pasture (respectively -470 ± 60 mm yr⁻¹ and -220 ± 100 mm yr⁻¹). Biogeochemical effects in
41 response to pan-tropical deforestation, particularly CO₂ release, are generally not taken into account in those
42 studies but could intensify the hydrological cycle and thus precipitation (Kendra Gotangco Castillo and
43 Gurney 2013).
44

 11

12 Specific model-based deforestation studies have been carried out for Africa (Hagos et al. 2014; Boone et al.
 13 2016; Xue et al. 2016; Nogherotto et al. 2013; Hartley et al. 2016; Klein et al. 2017; Abiodun et al. 2012),
 14 southern America (Butt et al. 2011; Wu et al. 2017; Spracklen and Garcia-Carreras 2015; Lejeune et al.
 15 2015), South-East Asia (Ma et al. 2013b; Werth and Avissar 2005; Mabuchi et al. 2005; Tölle et al. 2017).
 16 All found decreases in evapotranspiration following deforestation (*high agreement*), resulting in surface
 17 warming despite the competing effect from increased surface albedo (*high agreement*). Changes in thermal
 18 gradients between deforested and adjacent regions, between land and ocean, affect horizontal surface winds
 19 (*high agreement*) and thus modify the areas where rainfalls as discussed in Section 2.5.4. An increase in the
 20 land-sea thermal contrast has been found in many studies as surface friction is reduced by deforestation, thus

1 increasing the monsoon flow in Africa and South America (Wu et al. 2017).

2
3 Observation-based estimates all agree that deforestation increases local land-surface and ambient air
4 temperatures in the tropics, while forestation has the reverse effect (*very high confidence*; (Prevedello et al.
5 2019; Schultz et al. 2017; Li et al. 2015b; Alkama and Cescatti 2016)). There is *very high confidence* that
6 forests are cooler than any shorter vegetation (crops, grasses, bare soil) during daytime due to larger
7 transpiration rates, and there is *high confidence* that the amplitude of the diurnal cycle is smaller in the
8 presence of forests.

9
10 Large-scale forestation scenarios of West Africa (Abiodun et al. 2012), eastern China (Ma et al. 2013a) or
11 Saharan and Australian deserts (Ornstein et al. 2009; Kemena et al. 2017) all concluded that regional surface
12 cooling is simulated wherever trees are grown (-2.5°C in the Sahel and -1°C in the Savanna area of West
13 Africa, up to -8°C in western Sahara, -1.21°C over land in eastern China) while cooling of the ambient air is
14 smaller (-0.16°C). In the case of Savanna forestation this decrease entirely compensates the GHG induced
15 future warming ($+1^{\circ}\text{C}$ following the SRES A1B scenario). West African countries thus have the potential to
16 reduce, or even totally cancel at some places, the GHG-induced warming in the deforested regions (Abiodun
17 et al. 2012). However, this is compensated by enhanced warming in adjacent countries (non-local effect).

18 19 **2.5.2.1.2 Global and regional impacts of deforestation/forestation in temperate regions**

20 As for the tropics, model-based experiments show that large-scale temperate deforestation would induce a
21 small mean global annual warming through the net release of CO_2 into the atmosphere (ranging from $+0.10$
22 to $+0.40^{\circ}\text{C}$ with a mean value of $+0.20 \pm 0.13^{\circ}\text{C}$, Figure 2.17), whereas there is less agreement on the sign of
23 the mean global annual temperature change resulting from biophysical processes: estimates range from -
24 0.5°C to $+0.18^{\circ}\text{C}$ with a mean value of $-0.13 \pm 0.22^{\circ}\text{C}$. There is also *very low agreement* on the mean annual
25 temperature change in the temperate zone ($-0.4 \pm 0.62^{\circ}\text{C}$; (Phillips et al. 2007; Snyder et al. 2004b;
26 Longobardi et al. 2016a; Devaraju et al. 2015a, 2018b)). There is *medium agreement* on a global and
27 latitudinal biophysical warming in response to forestation (Figure 2.17 ; (Laguë and Swann 2016a; Swann et
28 al. 2012a; Gibbard et al. 2005; Wang et al. 2014b)), but this is based on a smaller number of studies.

29
30 The lack of agreement at the annual scale among the climate models is however masking *rising agreement*
31 regarding seasonal impacts of deforestation at those latitudes. There is *high agreement* that temperate
32 deforestation leads to summer warming and winter cooling (Bright et al. 2017; Zhao and Jackson 2014;
33 Gálos et al. 2011, 2013; Wickham et al. 2013; Ahlswede and Thomas 2017; Anderson-Teixeira et al. 2012;
34 Anderson et al. 2011; Chen et al. 2012; Strandberg and Kjellström 2018). The winter cooling is driven by the
35 increased surface albedo, amplified by the snow-albedo feedback. In some models and when deforestation is
36 simulated for very large areas, the cooling is further amplified by high latitude changes in sea-ice and snow
37 extent (polar amplification). Summer warming occurs because the latent and sensible heat fluxes, that take
38 energy out of the surface, diminish with the smaller roughness length and lower evapotranspiration
39 efficiency of low vegetation as compared to tree canopies (Davin and de Noblet-Ducoudre 2010; Anav et al.
40 2010). Conversely, there is *high agreement* that forestation in North America or in Europe cools surface
41 climate during summer time, especially in regions where water availability can support large
42 evapotranspiration rates. In temperate regions with water deficits, the simulated change in evapotranspiration
43 following forestation will be insignificant while the decreased surface albedo will favour surface warming.

44
45 Observation-based estimates confirm the existence of a seasonal pattern of response to deforestation, with
46 colder winters anytime there is snow on the ground and anywhere soils are brighter than trees, and warmer
47 summers (Schultz et al. 2017; Wickham et al. 2014; Juang et al. 2007; Tang et al. 2018; Peng et al. 2014;
48 Zhang et al. 2014b; Prevedello et al. 2019; Li et al. 2015b; Alkama and Cescatti 2016). In contrast
49 forestation induces cooler summers wherever trees have access to sufficient soil moisture to transpire. The
50 magnitude of the cooling depends on the wetness of the area of concern (Wickham et al. 2013) as well as on
51 the original and targeted species and varieties implicated in the vegetation conversion (Peng et al. 2014;
52 Juang et al. 2007).

53
54 There is also *high confidence* from observation-based estimates that mean annual daytime temperatures are
55 warmer following deforestation, while night time temperatures are cooler (Schultz et al. 2017; Wickham et
56 al. 2014; Juang et al. 2007; Tang et al. 2018; Prevedello et al. 2019; Peng et al. 2014; Zhang et al. 2014b; Li

1 et al. 2015b; Alkama and Cescatti 2016). Deforestation then increases the amplitude of diurnal temperature
2 variations while forestation reduces it (*high confidence*). Two main reasons have been put forward to explain
3 why nights are warmer in forested areas: their larger capacity to store heat, and the existence of a nocturnal
4 temperature inversion bringing warmer air from aloft.
5

6 In addition to those seasonal and diurnal fluctuations, (Lejeune et al. 2018) found systematic warming of the
7 hottest summer days following historical deforestation in the northern mid-latitudes, and this echoes
8 (Strandberg and Kjellström 2018) who argue that the August 2003 and July 2010 heat-waves could have
9 been largely mitigated if Europe had been largely forested.
10

11 In a combined modelling of large-scale forestation of western Europe and climate change scenario (SRES
12 A2) (Gálos et al. 2013) found a relatively small dampening potential of additional forest on ambient air
13 temperature at the end of the 21st century when compared to the beginning (the cooling resulting from land
14 cover changes is -0.5°C whereas the GHG-induced warming exceeds 2.5°C). Influence on rainfall was
15 however much larger and significant. Projected annual rainfall decreases following warming were cancelled
16 in Germany and significantly reduced in both France and Ukraine through forestation. In addition forestation
17 also decreased the number of warming-induced dry days, but increased the number of extreme precipitation
18 events.
19

20 The net impact of forestation, combining both biophysical and biogeochemical effects, has been tested in the
21 warmer world predicted by RCP 8.5 scenario (Sonntag et al. 2016, 2018). The cooling effect from the
22 addition of 8 Mkm^2 of forests following the land use RCP 4.5 scenario was too small (-0.27°C annually) to
23 dampen the RCP 8.5 warming. It however reached about -1°C in some temperate regions and -2.5°C in
24 boreal ones. This is accompanied by a reduction in the number of extremely warm days.
25

26 **2.5.2.1.3 Global and regional impacts of deforestation/forestation in boreal regions**

27 Consistent with what we have previously discussed for temperate and tropical regions, large-scale boreal
28 deforestation induces a biogeochemical warming of $+0.11 \pm 0.09^{\circ}\text{C}$ (Figure 2.17). But contrary to those other
29 latitudinal bands, the biophysical effect is a consistent cooling across all models ($-0.55 \pm 0.29^{\circ}\text{C}$ when
30 averaged globally). It is also significantly larger than the biogeochemical warming (e.g. (Dass et al. 2013;
31 Longobardi et al. 2016a; Devaraju et al. 2015a; Bathiany et al. 2010a; Devaraju et al. 2018b)). It is driven by
32 the increased albedo, enhanced by the snow-albedo feedback as well as by an increase in sea-ice extent in the
33 Arctic. Over the boreal lands, the cooling is as large as $-1.8 \pm 1.2^{\circ}\text{C}$. This mean annual cooling however
34 masks out a seasonal contrast as discussed in (Strandberg and Kjellström 2018) and (Gao et al. 2014): during
35 summer time, following the removal of forest, the decreased evapotranspiration results in a significant
36 summer warming that outweighs the effect of an increased albedo effect.
37

38 The same observation-based estimates as discussed in the previous sub-section show similar patterns as for
39 the temperate latitudes: seasonal and daily contrasts. (Schultz et al. 2017) however found that mean annual
40 nighttime changes are as large as daytime ones in those regions (mean annual nocturnal cooling $-1.4 \pm 0.10^{\circ}\text{C}$,
41 balanced by mean annual daytime warming of $1.4 \pm 0.04^{\circ}\text{C}$). This contrasts with both temperate and tropical
42 regions where daytime changes are always larger than nighttime ones.
43

44 Arora and Montenegro (2011) combined large-scale forestation and climate change scenario (SRES A2):
45 forestation of either 50% or 100% of the total agricultural area was gradually prescribed between years 2011
46 and 2060 everywhere. In addition, boreal, temperate and tropical forestation have been tested separately.
47 Both biophysical and biogeochemical effects were accounted for. The net simulated impact of forestation
48 was a cooling varying from -0.04°C to -0.45°C , depending on the location and magnitude of the additional
49 forest cover. It was, however, quite marginal compared to the large global warming resulting from
50 anthropogenic GHG emissions ($+3^{\circ}\text{C}$ at the end of the 21st century). In their experiment, forestation in
51 boreal regions led to biophysical warming and biogeochemical cooling that compensated each other, whereas
52 forestation in the tropics led to both biophysical and biogeochemical cooling. The authors concluded that
53 tropical forestation is three times more effective in cooling down climate than are boreal or temperate
54 forestation.
55

2.5.2.1.4 Conclusion

In conclusion, planting trees will always result in capturing more atmospheric CO₂ and thus in mean annual cooling of the globe (*very high confidence*). At the regional level however the magnitude and sign of the local temperature change depends on a) where forestation occurs, b) its magnitude, c) the level of warming under which the land cover change is applied and d) the land conversion type. This is because the background climatic conditions (e.g., precipitation and snow regimes, mean annual temperature) within which the land cover changes occur vary across regions (Pitman et al. 2011; Montenegro et al. 2009; Juang et al. 2007; Wickham et al. 2014; Hagos et al. 2014; Voltaire 2006; Feddema et al. 2005; Strandberg and Kjellström 2018). In addition there is *high confidence* that estimates of the influence of any land cover or land use change on surface temperature from the sole consideration of the albedo and the CO₂ effects is incorrect as changes in turbulent fluxes (i.e., latent and sensible heat fluxes) are large contributors to local temperature change (Bright et al. 2017).

There is *high confidence* that in boreal and temperate latitudes the presence of forest cools temperature in warmer locations and seasons provided that the soil is not dry, whereas it warms temperature in colder locations and seasons provided the soil is brighter than trees or covered with snow. In the humid tropics forestation increases evapotranspiration year round and thus decreases temperature (*high confidence*). In tropical areas with a strong seasonality of rainfall, forestation will also increase evapotranspiration year round unless the soil becomes too dry. In all regions there is *medium confidence* that the diurnal temperature range decreases with increasing forest cover, with potentially reduced extreme values of temperature

Although there is not enough literature yet that rigorously compares both biophysical and biogeochemical effects of realistic scenarios of forestation, there is *high confidence* that, at the local scale (that is where the forest change occurs) biophysical effects on surface temperature are far more important than the effects resulting from the changes in emitted CO₂.

What is lacking in the literature as of today is an estimate of the impacts natural disturbances in forests will have on local climates and on the build-up of atmospheric CO₂. (O'Halloran et al. 2012) for example illustrated with many examples that changes in albedo following disturbances can result in radiative forcing changes opposite to and as large as the ones resulting from the associated changes in the net release of CO₂ by land. The resulting climate effects depend on the duration of the perturbation and of the following recovery of vegetation.

2.5.2.2 Impacts of changes in land management

There have been little changes in net cropland area over the past 50 years (at the global scale) compared to continuous changes in land management (Erb et al. 2017). Similarly, in Europe change in forest management was a very significant anthropogenic land change. Management affects water, energy and GHG fluxes exchanged between the land and the atmosphere, and thus temperature and rainfall, sometimes to the same extent as changes in land cover do as discussed in (Luyssaert et al. 2014b).

The effects of irrigation, which is a practice that has been substantially studied, and one attempt to manage solar radiation via increases in cropland albedo (geoengineering the land) is assessed, along with discussion of recent findings on the effects of forest management on local climate, although there is not enough literature yet on this topic to carry out a real assessment. The effects of urbanisation on climate are assessed in a specific cross-chapter box within this chapter (Cross-Chapter Box 4 : Climate change and urbanisation, in this chapter).

There are a number of other practices that exist, some of them being reported in Section 2.6 and chapter 6 whose importance for climate mitigation has been examined. There is however not enough literature available for assessing their biophysical effect on climate. Few papers are generally found per agricultural practice, e.g., (Jeong et al. 2014b) for double cropping, (Bagley et al. 2017) for the timing of the growing season, and (Erb et al. 2017) for a review of ten management practices.

Similarly there are very few studies that have examined how choosing species varieties and harvesting strategies in forest management impacts climate through biophysical effects, and how those effects compare to the consequences of the chosen strategies on the net CO₂ sink of the managed forest. The modelling

1 studies highlight the existence of competing effects between e.g. the capacity of certain species to store more
2 carbon than others (thus inducing cooling) while at the same time reducing the total evapotranspiration loss
3 and absorbing more solar radiation via lower albedo (thus inducing warming) (Naudts et al. 2016a; Luysaert
4 et al. 2018).

6 2.5.2.2.1 *Irrigation*

7 There is substantial literature on the effects of irrigation on local, regional and global climate as this is a
8 major land management. There is *very high confidence* that irrigation increases total evapotranspiration,
9 increases the total amount of water vapour in the atmosphere, and decreases mean surface daytime
10 temperature within the irrigated area and during the time of irrigation (Bonfils and Lobell 2007; Alter et al.
11 2015; Chen and Jeong 2018; Christy et al. 2006; Im and Eltahir 2014; Im et al. 2014; Mueller et al. 2015).
12 Decreases in maximum daytime temperature can locally be as large as -3°C to -8°C (Cook et al. 2015; Han
13 and Yang 2013; Huber et al. 2014; Alter et al. 2015; Im et al. 2014). Estimates of the contribution of
14 irrigation to past historical trends in ambient air temperature vary between -0.07°C and $-0.014^{\circ}\text{C}/\text{decade}$ in
15 Northern China (Han and Yang 2013; Chen and Jeong 2018) while being quite larger in California (-0.14°C
16 to $-0.25^{\circ}\text{C}/\text{decade}$; (Bonfils and Lobell 2007)). Surface cooling results from increased energy being taken up
17 from the land via larger evapotranspiration rates. In addition, there is growing evidence from modelling
18 studies that such cooling can locally mitigate the effect of heatwaves (Thiery et al. 2017; Mueller et al.
19 2015).

21 There is *no agreement* on changes in nighttime temperatures as discussed in (Chen and Jeong 2018) who
22 summarised the findings from observations in many regions of the World (India, China, North America and
23 eastern Africa; Figure 2.18). Where nighttime warming is found (Chen and Jeong 2018; Christy et al. 2006),
24 two explanations are put forward: the first is an increase in incoming long-wave radiation in response to
25 increased atmospheric water vapour content (greenhouse effect); the second is an increased storage of heat in
26 the soil during daytime, because of the larger heat capacity of a moister soil, heat that is then released to the
27 atmosphere at night.

29 There is *robust evidence* from modelling studies that implementing irrigation enhances rainfall although
30 there is *very low confidence* on where this increase occurs. When irrigation occurs in Sahelian Africa, during
31 the monsoon period, rainfall is decreased over the irrigated areas (*high agreement*) and increases south-west
32 if the crops are located in western Africa (Alter et al. 2015) and east / north-east when crops are located
33 further East in Sudan (Im and Eltahir 2014; Im et al. 2014) The cooler irrigated surfaces in the Sahel,
34 because of their greater evapotranspiration, inhibits convection and creates an anomalous descending motion
35 over crops that suppresses rainfall but influences the circulation of monsoon winds. Irrigation in India occurs
36 prior to the start of the monsoon season and the resulting land cooling decreases the land-sea temperature
37 contrast. This can delay the onset of the Indian monsoon and decrease its intensity (Niyogi et al. 2010;
38 Guimberteau et al. 2012). Results from (De Vrese et al. 2016a) modelling study suggest that part of the
39 excess rainfall triggered by Indian irrigation falls westward, in the horn of Africa. The theory behind those
40 local and downwind changes in rainfall support the findings from the models but we do not yet have
41 sufficient literature to robustly assess the magnitude and exact location of the expected changes driven by
42 irrigation.

1
2 **Figure 2.18** Global map of areas equipped for irrigation (colours), expressed as a percentage of total area, or
3 irrigation fraction (Siebert et al. 2013). Numbered boxes show regions where irrigation causes cooling (down
4 arrow) of surface mean (Tmean), maximum (Tmax) or minimum (Tmin) temperature, or else no significant
5 effect (right arrow) or where the effect is uncertain (question mark), based on observational studies as
6 reviewed in (Chen and Jeong 2018). Tmax refers to the warmest daily temperature while Tmin to the coldest
7 one which generally occurs at night. References are (Alter et al. 2015; Han and Yang 2013; Roy et al. 2007;
8 Shi et al. 2013; Bonfils and Lobell 2007; Lobell et al. 2008; Lobell and Bonfils 2008; Christy et al. 2006;
9 Mahmood et al. 2006; Mueller et al. 2015)

11 2.5.2.2.2 Cropland albedo

12 Various methods have been proposed to increase surface albedo in cropland and thus reduce locally surface
13 temperature (*high confidence*): choose ‘brighter’ crop varieties (Ridgwell et al. 2009; Crook et al. 2015;
14 Hirsch et al. 2017; Singarayer et al. 2009; Singarayer and Davies-Barnard 2012), abandon tillage (Lobell et
15 al. 2006; Davin et al. 2014), include cover crops into the rotation in areas where soils are darker than
16 vegetation (Carrer et al. 2018; Kaye and Quemada 2017) or use greenhouses (as in (Campra et al. 2008), see
17 (Seneviratne et al. 2018) for a review).

18 Whatever the solution chosen, the induced reduction in absorbed solar radiation cools the land, more
19 specifically during the hottest summer days ((Davin et al. 2014; Wilhelm et al. 2015); *low confidence*)
20 (Figure 2.19). Changes in temperature are essentially local and seasonal (limited to crop growth season) or
21 sub-seasonal (when resulting from inclusion of cover crop or tillage suppression). Such management action
22 on incoming solar radiation thus holds the potential to counteract warming in cultivated areas during crop
23 growing season.

24 Introducing cover crops into a rotation can also have a warming effect in areas where vegetation has a darker
25 albedo than soil, or in winter during snow periods if the cover crops or their residues are tall enough to
26 overtop the snow cover (Kaye and Quemada 2017; Lombardozzi et al. 2018). In addition evapotranspiration
27 greater than that of bare soil during this transitional period reduces soil temperature (Ceschia et al. 2017).
28 Such management strategy can have another substantial mitigation effect as it allows to store carbon in the
29 soil and to reduce both direct and indirect N₂O emissions (Basche et al. 2014; Kaye and Quemada 2017), in
30 particular if fertilisation of the subsequent crop is reduced (Constantin et al. 2010, 2011). The use of cover
31 crops thus improves substantially the GHG budget of croplands (Kaye and Quemada 2017; Tribouillois et al.
32 2018). More discussion on the role of the management practices for mitigation can be found in section 2.6
33 and chapter 6.

34 Only a handful of modelling studies have looked at effects other than changes in atmospheric temperature in
35 response to increased cropland albedo. (Seneviratne et al. 2018) have found significant changes in rainfall
36 following an idealised increase in cropland albedo, especially within the Asian monsoon regions. The
37 benefits of cooler temperature on production, resulting from increased albedo, is cancelled by decreases in
38 rainfall that are harmful for crop productivity. The rarity of a concomitant evaluation of albedo management
39 impact on crop productivity prevents us from providing a robust assessment of this practice in terms of both
40 climate mitigation and food security.

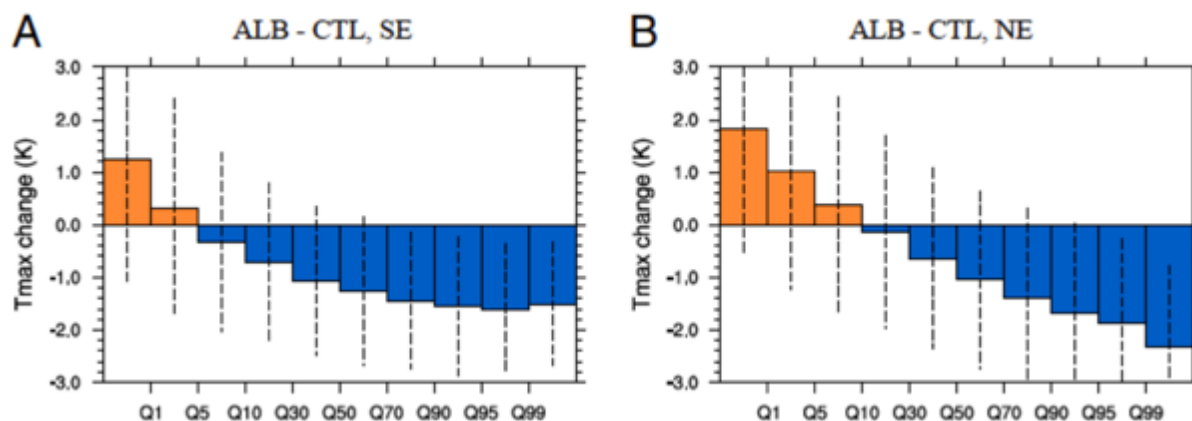

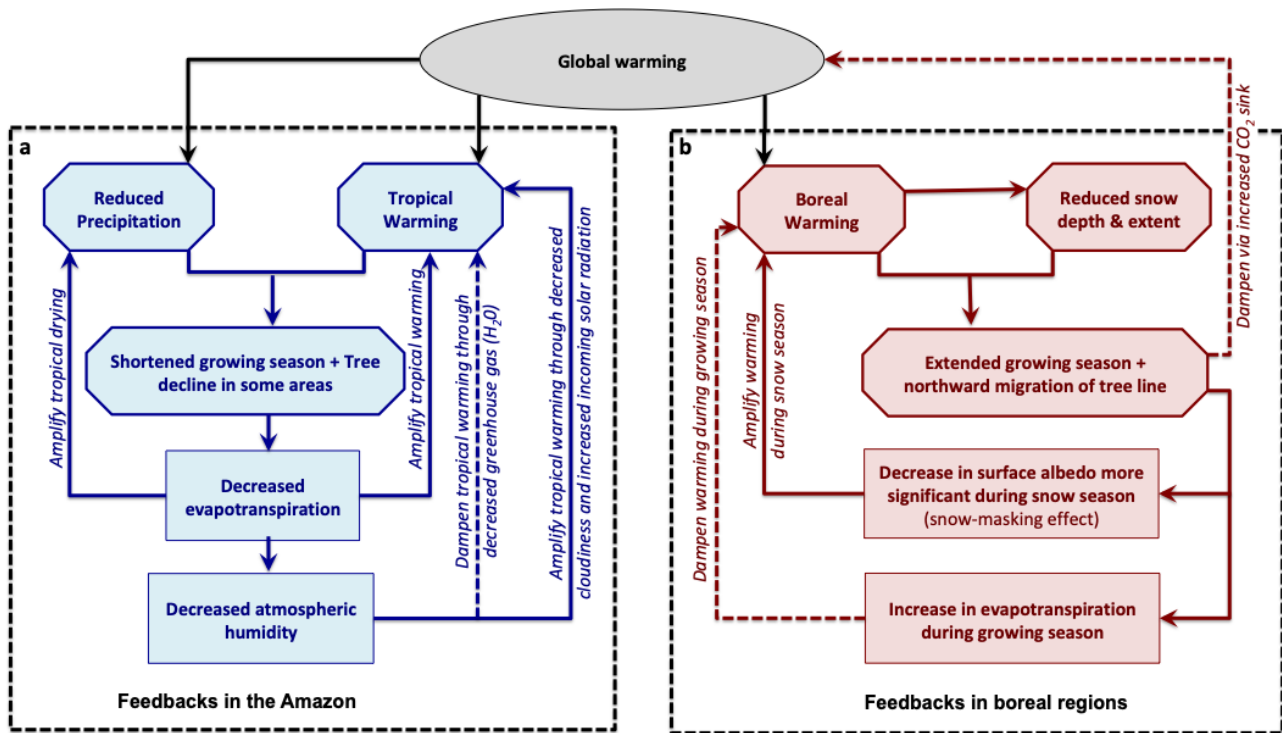

Figure 2.19 Change in summer (July-August) daily maximum temperature ($^{\circ}\text{C}$) resulting from increased surface albedo in unploughed versus ploughed land, in (A) Southern and (B) Northern Europe, during the period 1986–2009. Changes are simulated for different quantiles of the daily maximum temperature distribution, where Q1 represents the coolest 1% and Q99 the warmest 1% of summer days. Only grid cells with more than 60% of their area in cropland are included. The dashed bars represent the standard deviation calculated across all days and grid points. SE refers to southern Europe (below 45°N) and NE to northern Europe (above 45°N)

2.5.3 Amplifying / dampening climate changes via land responses

Section 2.1 and Box 2.1: illustrates the various mechanisms through which land can affect the atmosphere and thereby climate and weather. Section 2.2 illustrates the many impacts climate changes have on the functioning of land ecosystems. Section 2.3 discusses the effects future climatic conditions on the capacity of the land to absorb anthropogenic CO_2 , which then controls the sign of the feedback to the initial global warming. Sections 2.5.1 and 2.5.2 show effects of changes in anthropogenic land cover or land management on climate variables or processes. Land has thus the potential to dampen or amplify the GHG-induced global climate warming or can be used as a tool to mitigate regional climatic consequences of global warming such as extreme weather events, in addition to increasing the capacity of land to absorb CO_2 (Figure 2.20).

Land-to-climate feedbacks are difficult to assess with global or regional climate models as both types of models generally omit a large number of processes. Among these are 1) the response of vegetation to climate change in terms of growth, productivity, and geographical distribution, 2) the dynamics of major disturbances such as fires, 3) the nutrients dynamics, and 4) the dynamics and effects of short-lived chemical tracers such as biogenic volatile organic compounds (Section 2.4). Therefore, only those processes that are fully accounted for in climate models are considered here.

Figure 2.21 Schematic illustration of the processes through which the effects of global warming in the a) Amazon (left panel, blue boxes and arrows) and b) boreal regions (right panel, red boxes and arrows) feedback on the regional climate change. In boreal regions the sign of the feedbacks depends on the season, although annually global warming is further enhanced in those regions. Dashed lines illustrate negative feedbacks while solid lines indicate positive feedbacks. References supporting this figure can be found in the text.

In the tropics climate change will cause both greening and browning (see Section 2.2). Where global warming provokes decrease in rainfall, the induced decrease in biomass production leads to increased local warming (Port et al. 2012; Wu et al. 2016; Yu et al. 2016; *high confidence*). The reverse is true where warming generates increases in rainfall and thus greening. As an example, (Port et al. 2012) simulated decreases in tree cover and shortened growing season in the Amazon, despite the CO₂ fertilisation effects, in response to both future tropical warming and reduced precipitation (Figure 2.21, left panel). This browning of the land decreases both evapotranspiration and atmospheric humidity. The warming driven by the drop in evapotranspiration is enhanced via decreases in cloudiness that increases incoming solar radiation, and is dampened by reduced water vapour greenhouse radiation.

There is *very low confidence* on how feedbacks affect rainfall in the tropics where vegetation changes may occur, as the sign of the change in precipitation depends on where the greening occurs and on the season (as discussed in Section 2.5.2). There is however *high confidence* that increased vegetation growth in the southern Sahel increases African monsoon rains (Yu et al. 2016; Port et al. 2012; Wu et al. 2016). Confidence on the direction of such feedbacks is also based on a significant number of paleoclimate studies that analysed how vegetation dynamics helped maintain a northward position of the African monsoon during the Holocene time period (9 to 6 kyr BP) (de Noblet-Ducoudré et al. 2000; Rachmayani et al. 2015).

2.5.3.2 Feedbacks to climate from high-latitude land-surface changes

In high latitudes, snow albedo and permafrost carbon feedbacks are the most well-known and most important surface-related climate feedbacks because of their large-scale impacts.

In response to ongoing and projected decrease in seasonal snow cover (Derksen and Brown 2012; Brutel-Vuilmet et al. 2013) warming is and will continue to be enhanced in boreal regions (*high confidence*; Brutel-Vuilmet et al. 2013; Perket et al. 2014; Thackeray and Fletcher 2015; Mudryk et al. 2017). One reason for this is the large reflectivity (albedo) the snow exerts on shortwave radiative forcing: the all-sky global land snow shortwave radiative effect is evaluated to be around $-2.5 \pm 0.5 \text{ W m}^{-2}$ (Flanner et al. 2011; Singh et al. 2015). In the Southern Hemisphere, perennial snow on the Antarctic is the dominant contribution, while in the Northern Hemisphere, this is essentially attributable to seasonal snow with a smaller contribution from

1 snow on glaciated areas. Another reason is the sensitivity of snow cover to temperature: (Mudryk et al. 2017)
2 recently showed that in the high latitudes, climate models tend to correctly represent this sensitivity, while in
3 mid-latitude and alpine regions, the simulated snow cover sensitivity to temperature variations tends to be
4 biased low. In total, the global snow albedo feedback is about $0.1 \text{ W m}^{-2} \text{ K}^{-1}$, which amounts to about 7% of
5 the strength of the globally dominant water vapour feedback (e.g., (Thackeray and Fletcher 2015)). While
6 climate models do represent this feedback, a persistent spread in the modelled feedback strength has been
7 noticed (Qu and Hall 2014) and, on average, the simulated snow albedo feedback strength tends to be
8 somewhat weaker than in reality (Flanner et al. 2011; Thackeray and Fletcher 2015) (*medium confidence*).
9 Various reasons for the spread and biases of the simulated snow albedo feedback have been identified,
10 notably inadequate representations of vegetation masking of snow in forested areas (Lorantý et al. 2014;
11 Wang et al. 2016c; Thackeray and Fletcher 2015).

12
13 The second most important potential feedback from land to climate relates to permafrost decay. There is *high*
14 *confidence* that, following permafrost decay from a warming climate, the resulting emissions of carbon
15 dioxide and/or methane (caused by the decomposition of organic matter in previously frozen soil) will
16 produce additional GHG-induced warming. There is however substantial uncertainty on the magnitude of
17 this feedback, although recent years have seen large progress in its quantification. Lack of agreement results
18 from several critical factors that carry large uncertainties. The most important are a) the size of the
19 permafrost carbon pool, b) its decomposability, c) the magnitude, timing and pathway of future high-latitude
20 climate change and d) the correct identification and model representation of the processes at play (Schuur et
21 al. 2015b). The most recent comprehensive estimates establish a total soil organic carbon storage in
22 permafrost of about $1500 \pm 200 \text{ Pg C}$ (Hugelius et al. 2014, 2013; Olefeldt et al. 2016), which is about 300
23 Pg C lower than previous estimates (*low confidence*). Important progress has been made in recent years at
24 incorporating permafrost-related processes in complex Earth System Models (e.g., (McGuire et al. 2018)),
25 but representations of some critical processes such as thermokarst formation are still in their infancy (Schuur
26 et al. 2015b). Recent model-based estimates of future permafrost carbon release (Koven et al. 2015; McGuire
27 et al. 2018) have converged on an important insight. Their results suggest that substantial net carbon release
28 of the coupled vegetation-permafrost system will probably not occur before about 2100 because carbon
29 uptake by increased vegetation growth will initially compensate for GHG releases from permafrost (*limited*
30 *evidence, high agreement*).

31 **2.5.3.3 Feedbacks related to changes in soil moisture resulting from global warming**

32 There is *medium evidence* but *high agreement* that soil moisture conditions influence the frequency and
33 magnitude of extremes such as drought and heat waves. Observational evidence indicates that dry soil
34 moisture conditions favour heat-waves, in particular in regions where evapotranspiration is limited by
35 moisture availability (Mueller and Seneviratne 2012; Quesada et al. 2012; Miralles et al. 2018; Geirinhas et
36 al. 2018; Miralles et al. 2014; Chiang et al. 2018; Dong and Crow 2019; Hirschi et al. 2014).

37
38
39 In future climate projections, soil moisture plays an important role in the projected amplification of extreme
40 heat-waves and drought in many regions of the world (*medium confidence*; (Seneviratne et al. 2013; Vogel et
41 al. 2017; Donat et al. 2018; Miralles et al. 2018)). In addition, the areas where soil moisture affects heat
42 extremes will not be located exactly where they are today. Changes in rainfall, temperature and thus
43 evapotranspiration will induce changes in soil moisture and therefore of where temperature and latent heat
44 flux will be negatively coupled (Seneviratne et al. 2006; Fischer et al. 2012). Quantitative estimates of the
45 actual role of soil moisture feedbacks are however very uncertain due to the *low confidence* in projected soil
46 moisture changes (IPCC 2013a), to weaknesses in the representation of soil moisture-atmosphere
47 interactions in climate models (Sippel et al. 2017; Ukkola et al. 2018; Donat et al. 2018; Miralles et al. 2018)
48 and to methodological uncertainties associated with the soil moisture prescription framework commonly
49 used to disentangle the effect of soil moisture on changes in temperature extremes (Hauser et al. 2017).

50
51 Where soil moisture is predicted to decrease in response to climate change in the subtropics and temperate
52 latitudes, this drying could be enhanced by the existence of soil moisture feedbacks (*low confidence* (Berg et
53 al. 2016)). The initial decrease in precipitation and increase in potential evapotranspiration and latent heat
54 flux, in response to global climate change, leads to decreased soil moisture at those latitudes and can
55 potentially amplify both. Such a feature is consistent with evidence that in a warmer climate land and
56 atmosphere will be more strongly coupled via both the water and the energy cycles (Dirmeyer et al. 2014;

Guo et al. 2006). This increased sensitivity of atmospheric response to land perturbations implies that changes in land uses and cover are expected, in the future, to have more impact on climate in the future than they do today.

Beyond temperature, it has been suggested that soil moisture feedbacks influence precipitation occurrence and intensity. But the importance and even the sign of this feedback is still largely uncertain and debated (Tuttle and Salvucci 2016; Yang et al. 2018; Froidevaux et al. 2014; Guillod et al. 2015).

2.5.4 Non-local and downwind effects resulting from changes in land cover

Changes in land cover or land management do not just have local consequences but also affect adjacent or more remote areas. Those non-local impacts may occur in three different ways.

(1) Any action on land that affects photosynthesis and respiration has an impact on the atmospheric CO₂ content as this GHG is well mixed in the atmosphere. This change in turn affects the downwelling long-wave radiation everywhere on the planet and contributes to global climate change. This is more thoroughly discussed in Section 2.6 where various land-based mitigation solutions are examined. Local land use changes thus have the potential to affect global climate via changes in atmospheric CO₂.

(2) Any change in land cover or land management may impact local surface air temperature and moisture and thus sea-level pressure. Thermal, moisture and surface pressure gradients between the area of change and neighbouring areas are then modified and affect the amount of heat, water vapour and pollutants flowing out (downwind) of the area (e.g. Ma et al. 2013b; McLeod et al. 2017; Abiodun et al. 2012; Keys 2012).

Forests for example provide water vapour to the atmosphere which supports terrestrial precipitation downwind (Ellison et al. 2017a; Layton and Ellison 2016; Spracklen et al. 2012, 2018). Within a few days water vapour can travel several hundreds of kilometres before being condensed into rain and potentially being transpired again (Makarieva et al. 2009). This cascading moisture recycling (succession of evapotranspiration, water vapour transport and condensation-rainfall) has been observed in south America (Spracklen et al. 2018; Zemp et al. 2014; Staal et al. 2018; Spracklen et al. 2012). Deforestation can thus potentially decrease rainfall downwind, while combining 'small-scale' forestation and irrigation in the semi-arid region is susceptible to boost the precipitation-recycling mechanism with better vegetation growth downwind (Figure 2.22; (Ellison et al. 2017a; Layton and Ellison 2016)).

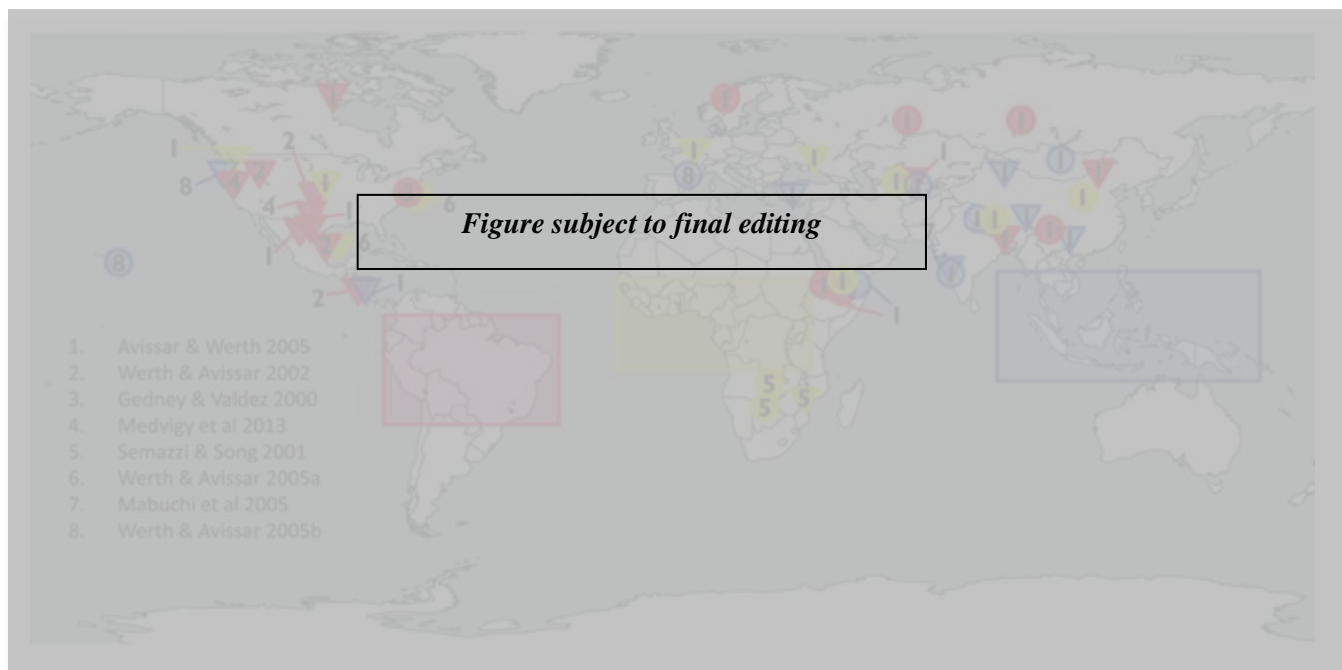

Figure 2.22 Schematic illustration of how combined forestation and irrigation can influence downwind precipitation on mountainous areas (here in Los Angeles, California area), favour vegetation growth and feeds back to the forested area via increased runoff (Layton and Ellison 2016). Areas of forests plantation and irrigation are located on the left panel, whereas consequent downwind effects and feedbacks are illustrated in the middle and right panels.

(3) Many studies using global climate models have reported that the climatic changes resulting from changes in land are not limited to the lower part of the atmosphere but can reach the upper levels via changes in large scale ascent (convection) or descent (subsidence) of air. This coupling to the upper atmosphere triggers perturbations in large-scale atmospheric transport (of heat, energy and water) and subsequent changes in temperature and rainfall in regions located quite far away from the original perturbation (Figure 2.23, Laguë and Swann 2016; Feddema et al. 2005, badger & dirmeyer 2016, Garcia 2016, Stark 2015, Devaraju 2018, Quesada et al. (2017a)).

De Vrese et al. (2016) for example, using a global climate model, found that irrigation in India could affect

1 regions as remote as eastern Africa through changes in the atmospheric transport of water vapour. At the
 2 onset of boreal spring (February to March) evapotranspiration is already large over irrigated crops and the
 3 resulting excess moisture in the atmosphere is transported south-westward by the low-level winds. This
 4 results in increases in precipitation as large as 1mm d⁻¹ in the horn of Africa. Such finding implies that if
 5 irrigation is to decrease in India, rainfall can decrease in eastern Africa where the consequences of drought
 6 are already disastrous.
 7

8
 9
 10 **Figure 2.23 Extra-tropical effects on precipitation due to deforestation in each of the three major tropical**
 11 **regions. Increasing (circles) and decreasing (triangles) precipitation result from complete deforestation of either**
 12 **Amazonia (red), Africa (yellow), or Southeast Asia (blue) as reviewed by (Lawrence and Vandecar 2015). Boxes**
 13 **indicate the area in which tropical forest was removed in each region. Numbers refer to the study from which**
 14 **the data were derived. Cited papers are the following (Avissar and Werth 2005; Gedney and Valdes 2000;**
 15 **Semazzi and Song 2001; Werth 2002; Mabuchi et al. 2005; Werth 2005)**
 16

17 Changes in sea-surface temperature have also been simulated in response to large-scale vegetation changes
 18 (Cowling et al. 2009; Davin and de Noblet-Ducoudre 2010; Wang et al. 2014b, Notaro Liu 2007).
 19 Most of those modelling studies have been carried out with land cover changes that are extremely large and
 20 often exaggerated with respect to reality. The existence of such teleconnections can thus be biased as
 21 discussed in Lorenz et al. (2016).
 22

23 In conclusion, there is *high confidence* that any action on land (for example to dampen global warming
 24 effects), wherever they occur, will not only have effects on local climate but also generate atmospheric
 25 changes in neighbouring regions, and potentially as far as few hundreds of kilometres downwind. More
 26 remote teleconnections, thousands of kilometres away from the initial perturbation, are impossible to observe
 27 and have only been reported by modelling studies using extreme land cover changes. There is *very low*
 28 *confidence* that detectable changes due to such long-range processes can occur.

Cities extent, population, and expected growth

Despite only covering 0.4-0.9% of the global land surface (Esch et al. 2017; Zhou et al. 2015), over half the world's population live in towns and cities (United Nations 2017) generating around three-quarters of the global total carbon emissions from energy use (Creutzig et al. 2015b; Intergovernmental Panel on Climate Change 2014). Urban food consumption is a large source of these anthropogenic greenhouse gas emissions (Goldstein et al. 2017). In developed countries, per capita emissions are larger in small cities than bigger ones, while the opposite is found in developing countries (Gudipudi et al. 2019). Climate change is expected to increase the energy demand of people living in urban areas (Santamouris et al. 2015; Wenz et al. 2017).

In addition to being a driver of emissions, urbanisation contributes to forest degradation, converts neighbouring agricultural, forested, or otherwise undeveloped land to urban use, altering natural or semi-natural ecosystems both within and outside of urban areas (Du and Huang 2017). It has been identified as a major driver of land degradation as illustrated in Chapters 3, 4 and 5. Highly productive lands are experiencing the highest rate of conversion to urbanised landscapes (Nizeyimana et al. 2001; Pandey et al. 2018), affecting food security. Loss of agricultural land, and increased pollution and waste are some of key challenges arising from urbanisation and urban growth (Chen 2007). The proportion of urban population is predicted to reach ~70% by the middle of the century (United Nations 2017) with growth especially taking place in the developing world (Angel et al. 2011; Dahiya 2012). Urban sprawl is projected to consume 1.8–2.4% and 5% of the current cultivated land by 2030 and 2050 respectively (Pradhan et al. 2014; Brend'Amour et al. 2016) driven by both general population increase and migration from rural areas (Adger et al. 2015; Seto et al. 2011; Geddes et al. 2012). New city dwellers in developing countries will require land for housing to be converted from non-urban to urban land (Barbero-Sierra et al. 2013), indicating future degradation. These growing urban areas will experience direct and indirect climate change impacts, such as sea level rise and storm surges (Boettle et al. 2016; Revi et al. 2014), increasing soil salinity, and landslides from precipitation extremes. Furthermore, poorly planned urbanisation can increase people's risk to climate hazards as informal settlements and poorly built infrastructure are often the most exposed to hazards from fire, flooding, and landslides (Adger et al. 2015; Geddes et al. 2012; Revi et al. 2014). Currently, avoiding land degradation and maintaining/enhancing ecosystem services are rarely considered in planning processes (Kuang et al. 2017).

Climate change, urban heat island and threats specific to urban populations

Cities alter the local atmospheric conditions as well as those of the surrounding areas (Wang et al. 2016b; Zhong et al. 2017). There is *high confidence* that urbanisation increases mean annual surface air temperature in cities and in their surroundings, with increases ranging from 0.19°C to 2.60°C (Cross Chapter Box 4 Figure 1) (Torres-Valcárcel et al. 2015; Li et al. 2018a; Doan et al. 2016). This phenomenon is referred to as the urban heat island (UHI) effect (Oke et al. 2017; Bader et al. 2018). The magnitude and diurnal amplitude of the UHI varies from one city to another and depends on the local background climate (Wienert and Kuttler 2005; Zhao et al. 2014; Ward et al. 2016). There is nevertheless *high confidence* that urbanisation affects night time temperatures more substantially than daytime ones (Argüeso et al. 2014; Alghamdi and Moore 2015; Alizadeh-Choobari et al. 2016; Fujibe 2009; Hausfather et al. 2013; Liao et al. 2017; Sachindra et al. 2016; Camilloni and Barrucand 2012; Wang et al. 2017a; Hamdi 2010; Arsiso et al. 2018; Elagib 2011; Lokoshchenko 2017; Robaa 2013). In addition there is *high confidence* that the UHI effect makes heatwaves more intense in cities by 1.22°C to 4°C, particularly at night (Li and Bou-Zeid 2013; Li et al. 2017b; Hamdi et al. 2016; Founda and Santamouris 2017; Wang et al. 2017a). As there is a well-established relationship between extremely high temperatures and morbidity, mortality (Watts et al. 2015) and labour productivity (Costa et al. 2016), expected increase in extreme heat events with future climate change will worsen the conditions in cities.

Cross Chapter Box 4, Figure 1: Change in annual mean surface air temperature resulting from urbanisation (°C). Colour and size of the circles refer to the magnitude of the change. This map has been compiled using the following studies: (Kim et al. 2016; Sun et al. 2016; Chen et al. 2016a; Founda et al. 2015; Rafael et al. 2017; Hinkel and Nelson 2007; Chrysanthou et al. 2014; Dou et al. 2014; Zhou et al. 2016, 2017; Polydoros et al. 2018; Li et al. 2018a; Bader et al. 2018; Alizadeh-Choobari et al. 2016; Fujibe 2009; Lokoshchenko 2017; Torres-Valcárcel et al. 2015; Doan et al. 2016; Elagib 2011; Liao et al. 2017).

Individual city case studies show that precipitation mean and extremes are increased over and downwind of urban areas, especially in the afternoon and early evening when convective rise of the atmosphere is the strongest (*medium confidence*). The case studies covered: different inland and coastal US cities (M. et al. 2014; McLeod et al. 2017; Ganeshan and Murtugudde 2015); Dutch coastal cities (Daniels et al. 2016); Hamburg (Schlünzen et al. 2010); Shanghai (Liang and Ding 2017); Beijing (Dou et al. 2014); and Jakarta and Kuala Lumpur (Lorenz et al. 2016). Increased aerosol concentrations however can interrupt the precipitation formation process and thereby reduce heavy rainfall (Daniels et al. 2016; Zhong et al. 2017). Urban areas also experience altered water cycle in other aspects, the evaporative demand for plants in cities are increased by as much as 10% (Zipper et al. 2017) while high proportion of paving in cities mean that surface runoff of water is high (Hamdi et al. 2011; Pataki et al. 2011). In addition, water retention is lower in degraded, sealed soils beneath urban surfaces compared to intact soils. Increased surface water runoff, especially when and where the rainfall intensity is likely to intensify (IPCC 2013b), leads to a greater likelihood of flooding in urban areas without implementation of adaptation measures (Shade and Kremer 2019; Wang et al. 2013; Environmental Protection Agency 2015).

Urbanisation alters the stock size of soil organic carbon (SOC) and its stability. The conversion of vegetated land to urban land results in a loss of carbon stored in plants, while stresses associated with the urban environment (e.g., heat, limited water availability and pollution) reduce plant growth and survival in cities (Xu et al. 2016b). Overall, carbon densities or stocks decrease from natural land areas to the urban core along the rural-urban gradient (Tao et al. 2015; Zhang et al. 2015). For example the Seoul Forest Park, an urban park, shows a tenfold difference in SOC stocks across its land cover types (Bae and Ryu 2015). In Changchun in Northeast China, however, SOC density is higher in recreational forests within urban areas compared to a production forest (Zhang et al. 2015).

Urban air pollution as an environmental risk increases with climate change. Increased air temperatures can lead to reduced air quality by enhancing the formation of photochemical oxidants and increasing the concentration of air pollutants such as ozone, with corresponding threats to human health (Sharma et al. 2013). The occurrence of bronchial asthma and allergic respiratory diseases is increasing worldwide, and urban residents are experiencing poor air quality conditions more frequently than rural residents (D'Amato et al. 2010). Excess morbidity and mortality related to extremely poor air quality are found in many cities

1 worldwide (Harlan and Ruddell 2011). Some emissions that lead to reduced air quality are also contributors
2 to climate change (Shindell et al. 2018; de Coninck et al. 2018).

4 **Urban response options for climate change, desertification, land degradation and food security**

5 Urban green infrastructure (UGI; see glossary) has been proposed as a solution to mitigate climate change
6 directly through carbon sequestration (Davies et al. 2011; Edmondson et al. 2014). However, compared to
7 overall carbon emissions from cities, its mitigation effects are likely to be small (*medium confidence*). UGI
8 nevertheless has an important role in adapting cities to climate change (Demuzere et al. 2014; Sussams et al.
9 2015; Martin et al. 2016; Gill et al. 2007; Revi et al. 2014). Adaptation through UGIs is achieved through,
10 for example: (i) reduction in air temperature (Cavan et al. 2014; Di Leo et al. 2016; Feyisa et al. 2014; Zölch
11 et al. 2016; Li et al. 2019) which can help improve human health and comfort (e.g. (Brown and Nicholls
12 2015; Klemm et al. 2015)); (ii) reduction in the energy demands of buildings through the use of green roofs
13 and walls (e.g.(Coma et al. 2017)); (iii) reduction in surface water runoff and flood risk (Zeleňáková et al.
14 2017). Given that UGI necessarily involves the retention and management of non-sealed surfaces, co-
15 benefits for land degradation will also be apparent (Murata and Kawai 2018; Scalenghe and Marsan 2009)
16 (*limited evidence, high agreement*).

17
18 Urban agriculture is one aspect of UGI that has the potential to both meet some of the food needs of cities
19 and reduce land degradation pressures in rural areas (*low confidence*; e.g. Wilhelm and Smith 2018). Urban
20 agriculture has many forms, such as backyard gardening, allotments, plants on roof-tops or balconies, urban-
21 fringe/peri-urban agriculture, hydroponics, aquaponics, livestock grazing in open spaces and vertical farming
22 (Gerster-Bentaya 2013) (see also Section 5.6.5).

23
24 Consuming locally produced food and enhancing the efficiency of food processing and transportation can
25 minimise food losses, contribute to food security, and in some circumstances reduce GHG emissions (Brodt
26 et al. 2013; Michalský and Hooda 2015; Tobarra et al. 2018) (see also Section 5.5.2.3). Furthermore, urban
27 agriculture has the potential to counteract the separation of urban populations from food production. This
28 separation is one driver of the transition towards more homogeneous, high protein diets, which are associated
29 with increased greenhouse gas emissions (Goldstein et al. 2017; Moragues-Faus and Marceau 2018;
30 Magarini and Calori 2015). Barriers to the uptake of urban agriculture as a climate change mitigation option
31 include the need for efficient distribution systems to ensure lowered carbon emissions (Newman et al. 2012)
32 and the concern that urban agriculture may harbour pathogenic diseases, or that its products be contaminated
33 by soil or air pollution (Hamilton et al. 2014; Ercilla-Montserrat et al. 2018).

35 **In summary**

36 Climate change is already affecting the health and energy demand of large numbers of people living in urban
37 areas (*high confidence*; see also Section 2.2). Future changes to both climate and urbanisation will enhance
38 warming in cities and their surroundings, especially during heat waves (*high confidence*). Urban and peri-
39 urban agriculture, and more generally the implementation of urban green infrastructure, can contribute to
40 climate change mitigation (*medium confidence*) as well as to adaptation (*high confidence*), including co-
41 benefits for food security and reduced soil-water-air pollution.

2.6 Climate consequences of response options

Response options can affect climate mitigation and adaptation simultaneously, therefore this Special Report on Climate Change and Land (SRCCL) discusses land-based response options in an integrated way (Chapter 1). In this chapter we assess response options that have an effect on climate. A description of the full set of response options across the SRCCL can be found in Chapter 6, including the interplay between mitigation, adaptation, desertification, land degradation, food security and other co-benefits and trade-offs. Response options specific to desertification, degradation and food security are described in more detail in Chapters 3, 4 and 5.

Some response options lead to land use change and can compete with other land uses, including other response options, while others may free-up land that can be used for further mitigation/adaptation by reducing demand for land or products e.g. agricultural intensification, diet shifts, and reduction of waste (*high confidence*).

Some response options result in a net removal of GHGs from the atmosphere and storage in living or dead organic material, or in geological stores (IPCC SR15). Such options are frequently referred to in the literature as carbon dioxide removal (CDR), Greenhouse Gas Removal (GGR) or negative emissions technologies (NETs). CDR options are assessed alongside emissions reduction options. Although they have a land footprint, solar and wind farms are not assessed here as they affect greenhouse gas flux in the energy industrial sectors with minimal effect in the land sector, but the impact of solar farms on agricultural land competition is dealt with in Chapter 7.

A number of different types of scenario approach exist for estimating climate contribution of land-based response options (see Cross-Chapter Box 1: Scenarios, Chapter 1). Mitigation potentials have been estimated for single and sometimes multiple response options using stylised “bottom-up” scenarios. Response options are not mutually exclusive (e.g., management of soil carbon and cropland management). Different options interact with each other; they may have additive effects or compete with each other for land or other resources, thus these potentials cannot necessarily be added up. The interplay between different land-based mitigation options, as well as with mitigation options in other sectors (such as energy or transport), in contributing to specific mitigation pathways has been assessed using Integrated Assessment Models, see Section 2.7.2. These include interactions with wider socioeconomic conditions (see Cross-Chapter Box 1: Scenarios, Chapter 1) and other sustainability goals (see chapter 6).

2.6.1 Climate impacts of individual response options

Since AR5, there have been many new estimates of the climate impacts of single or multiple response options, summarised in Figure 2.24 and discussed in sub-sections below. Recently published syntheses of mitigation potential of land-based response options (e.g. Hawken 2017a; Smith et al. 2016b; Griscom et al. 2017a; Minx et al. 2018; Fuss et al. 2018b; Nemet et al. 2018) are also included in Figure 2.24. The wide range in mitigation estimates reflects differences in methodologies that may not be directly comparable, and estimates cannot be necessarily be added if they were calculated independently as they may be competing for land and other resources.

Some studies assess a “technical mitigation potential” - the amount possible with current technologies. Some include resource constraints (e.g., limits to yields, limits to natural forest conversion) to assess a “sustainable potential”. Some assess an “economic potential” mitigation at different carbon prices. Few include social and political constraints (e.g. behaviour change, enabling conditions, see Chapter 7), the biophysical climate effects (Section 2.5), or the impacts of future climate change (Section 2.3). Carbon stored in biomass and soils may be at risk of future climate change (see Section 2.2), natural disturbances such as wildfire (see Cross-Chapter Box 3: Fire and Climate Change, in this chapter) and future changes in land use or management changes that result in a net loss of carbon (Gren and Aklilu 2016).

15 2.6.1.1 Land management in agriculture

16 Reducing non-CO₂ emissions from agriculture through cropland nutrient management, enteric fermentation,
 17 manure management, rice cultivation and fertiliser production has a total mitigation potential of 0.30–3.38
 18 GtCO₂-eq yr⁻¹ (*medium confidence*) (combined sub-category measures in **Figure 2.24**, details below) with a
 19 further 0.25–6.78 GtCO₂-eq yr⁻¹ from soil carbon management (Section 2.6.1.3). Other literature that looks at
 20 broader categories finds mitigation potential of 1.4–2.3 GtCO₂-eq yr⁻¹ from improved cropland management
 21 (Smith et al. 2008, 2014; Pradhan et al., 2013); 1.4–1.8 GtCO₂-eq yr⁻¹ from improved grazing land
 22 management (Conant et al. 2017; Herrero et al. 2016; Smith et al. 2008, 2014) and 0.2–2.4 GtCO₂-eq yr⁻¹
 23 from improved livestock management (Smith et al. 2008, 2014; Herrero et al. 2016, FAO 2007). A detailed
 24 discussion of the mitigation potential of agricultural response options and their co-benefits are provided in
 25 Chapter 5, Section 5.5. and 5.6).

26
 27 The three main measures to reduce enteric fermentation include improved animal diets (higher quality, more
 28 digestible livestock feed), supplements and additives (reduce methane by changing the microbiology of the
 29 rumen), and animal management and breeding (improve husbandry practices and genetics) – and applying
 30 these measures can mitigate 0.12–1.18 GtCO₂-eq yr⁻¹ (*medium confidence*) (Hristov et al. 2013; Dickie et al.
 31 2014; Herrero et al. 2016; Griscom et al. 2017). However, these measures may have limitations such as need
 32 of crop-based feed (Pradhan et al. 2013) and associated ecological costs and toxicity and animal welfare
 33 issues related to food additives (Llonch et al. 2017). Measures to manage manure include anaerobic digestion
 34 for energy use, composting as a nutrient source, reducing storage time, and changing livestock diets, and
 35 have a potential of 0.01–0.26 GtCO₂-eq yr⁻¹ (Herrero et al. 2016a; Dickie et al. 2014).

36
 37 On croplands, there is a mitigation potential of 0.03–0.71 GtCO₂-eq yr⁻¹ for cropland nutrient management
 38 (fertiliser application) (*medium confidence*) (Griscom et al. 2017a; Hawken 2017; Paustian et al. 2016;
 39 Dickie et al. 2014; Beach et al. 2015). Reducing emissions from rice production through improved water
 40 management (periodic draining of flooded fields to reduce methane emissions from anaerobic
 41 decomposition), and straw residue management (apply in dry conditions instead of on flooded fields, avoid
 42 burning to reduce methane and nitrous oxide emissions) has the potential to mitigate up to 60% of emissions
 43 (Hussain et al. 2015), or 0.08–0.87 GtCO₂-eq yr⁻¹ (*medium confidence*) (Griscom et al. 2017a; Hawken
 44 2017; Paustian et al. 2016; Hussain et al. 2015; Dickie et al. 2014; Beach et al. 2015). Further, sustainable
 45 intensification through the integration of crop and livestock systems can increase productivity, decrease
 46 emission intensity and act as a climate adaptation option (see chapter 5.5.1.4).

47
 48 Agroforestry is a land management system that combines woody biomass (e.g., trees or shrubs) with crops
 49 and/or livestock). The mitigation potential from agroforestry ranges between 0.08 to 5.7 GtCO₂ yr⁻¹, (*medium*
 50 *confidence*) (Griscom et al. 2017c; Dickie et al. 2014; Zomer et al. 2016; Hawken 2017). The high estimate
 51 is from an optimum scenario combining four agroforestry solutions (silvopasture, tree intercropping,
 52 multistrata agroforestry and tropical staple trees) of Hawken (2017a). Zomer et al. (2016) reported that the
 53 trees in agroforestry landscapes had increased carbon stock by 7.33 GtCO₂ between 2000 and 2010, or 0.7
 54 GtCO₂ yr⁻¹. For more details see Chapter 5, Section 5.5.1.3.

56 2.6.1.2 Land management in forests

57 The mitigation potential for reducing and/or halting deforestation and degradation ranges from 0.4 to 5.8

1 GtCO₂ yr⁻¹ (*high confidence*) (Griscom et al. 2017a; Hawken 2017; Busch and Engelmann 2017; Baccini et
2 al. 2017; Zarin et al. 2016b; Federici et al. 2015; Carter et al. 2015; Houghton et al. 2015; Smith et al. 2013a;
3 Houghton and Nassikas 2018). The higher figure represents a complete halting of land use conversion in
4 forests and peatlands (i.e. assuming recent rates of carbon loss are saved each year). Separate estimates of
5 degradation only range from 1.0-2.18 GtCO₂ yr⁻¹. Reduced deforestation and forest degradation include
6 conservation of existing carbon pools in vegetation and soil through protection in reserves, controlling
7 disturbances such as fire and pest outbreaks, and changing management practices. Differences in estimates
8 stem from varying land cover definitions, time periods assessed, and carbon pools included (most higher
9 estimates include belowground, dead wood, litter, soil, and peat carbon). When deforestation and
10 degradation are halted, it may take many decades to fully recover the biomass initially present in native
11 ecosystems (Meli et al. 2017, See also Chapter 4.8.3).

12
13 Afforestation/Reforestation (A/R) and forest restoration can increase carbon sequestration in both vegetation
14 and soils by 0.5–10.1 GtCO₂ yr⁻¹ (*medium confidence*) (Fuss et al. 2018; Griscom et al. 2017a; Hawken
15 2017; Kreidenweis et al. 2016; Li et al. 2016; Huang et al. 2017; Sonntag et al. 2016; Lenton 2014; McLaren
16 2012; Lenton 2010; Erb et al. 2018a; Dooley and Kartha 2018; Yan et al. 2017; Houghton et al. 2015;
17 Houghton and Nassikas 2018). Afforestation is the conversion to forest of land that historically has not
18 contained forests. Reforestation is the conversion to forest of land that has previously contained forests but
19 that has been converted to some other use. Forest restoration refers to practices aimed at regaining ecological
20 integrity in a deforested or degraded forest landscape. The lower estimate represents the lowest range from
21 an earth system model (Yan et al. 2017) and of sustainable global negative emissions potential (Fuss et al.
22 2018), and the higher estimate reforests all areas where forests are the native cover type, constrained by food
23 security and biodiversity considerations (Griscom et al. 2017a). It takes time for full carbon removal to be
24 achieved as the forest grows. Removal occurs at faster rates in young to medium aged forests and declines
25 thereafter such that older forest stands have smaller carbon removals but larger stocks with net uptake of
26 carbon slowing as forests reach maturity (Yao et al. 2018; Poorter et al. 2016; Tang et al. 2014). The land
27 intensity of afforestation and reforestation has been estimated at 0.0029 km² tC⁻¹ yr⁻¹ (Smith et al. 2016a).
28 Boysen et al. (2017) estimated that to sequester about 100 GtC by 2100 would require 13 Mkm² of
29 abandoned cropland and pastures. See also Chapter 4.8.3.

30
31 Forest management has the potential to mitigate 0.4-2.1 GtCO₂-eq yr⁻¹ (*medium confidence*) (Sasaki et al.
32 2016; Griscom et al. 2017; Sasaki et al. 2012). Forest management can alter productivity, turnover rates,
33 harvest rates carbon in soil, and carbon in wood products (Erb et al. 2017; Campioli et al. 2015; Birdsey and
34 Pan 2015; Erb et al. 2016; Noormets et al. 2015; Wäldchen et al. 2013; Malhi et al. 2015; Quesada et al.
35 2018; Nabuurs et al. 2017; Bosello et al. 2009) (see also Chapter 4, Section 4.8.4). Fertilisation may enhance
36 productivity but would increase N₂O emissions. Preserving and enhancing carbon stocks in forests has
37 immediate climate benefits but the sink can saturate and is vulnerable to future climate change (Seidl et al.
38 2017). Wood can be harvested and used for bioenergy substituting for fossil fuels (with or without carbon
39 capture and storage) (Section 2.6.1.5), for long-lived products such as timber (see below), to be buried as
40 biochar (Section 2.6.1.1) or to be used in the wider bioeconomy, enabling areas of land to be used
41 continuously for mitigation. This leads to initial carbon loss and lower carbon stocks but with each harvest
42 cycle, the carbon loss (debt) can be paid back and after a parity time, result in net savings (Laganière et al.
43 2017; Bernier and Paré 2013; Mitchell et al. 2012; Haberl et al. 2012; Haberl 2013; Ter-Mikaelian et al.
44 2015; Macintosh et al. 2015). The trade-off between maximising forest C stocks and maximising substitution
45 is highly dependent on the counterfactual assumption (no-use vs. extrapolation of current management),
46 initial forest conditions and site-specific contexts such as regrowth rates and, the displacement factors and
47 efficiency of substitution, and relative differences in emissions released during extraction, transport and
48 processing of the biomass- or fossil-based resources as well as assumptions about emission associated with
49 the product or energy source that is substituted (Grassi et al. 2018b; Nabuurs et al. 2017; Pingoud et al. 2018;
50 Smyth et al. 2017a; Luysaert et al. 2018; Valade et al. 2017; York 2012; Ter-Mikaelian et al. 2014; Naudts
51 et al. 2016b; Mitchell et al. 2012; Haberl et al. 2012; Macintosh et al. 2015; Laganière et al. 2017; Haberl
52 2013). This leads to uncertainty about optimum mitigation strategies in managed forests, while high carbon
53 ecosystems such as primary forests would have large initial carbon losses and long pay-back times and thus
54 protection of stocks would be more optimal (Lemprière et al. 2013; Kurz et al. 2016; Keith et al. 2014). See
55 also 4.8.4.

1 Global mitigation potential from increasing the demand of wood products to replace construction materials
2 range from 0.25–1 GtCO₂-eq yr⁻¹ (McLaren 2012; Miner 2010) (*medium confidence*), the uncertainty is
3 determined in part by consideration of the factors described above, and is sensitive to the displacement
4 factor, or the substitution benefit in CO₂, when wood is used instead of another material, which may vary in
5 the future as other sectors reduce emissions, as well as market factors (Sathre and O'Connor 2010; Nabuurs
6 et al. 2018; Iordan et al. 2018; Braun et al. 2016; Gustavsson et al. 2017; Peñaloza et al. 2018; Soimakallio et
7 al. 2016; Grassi et al. 2018b). Using harvested carbon in long-lived products (e.g., for construction) can
8 represent a store that can sometimes be from decades to over a century while the wood can also substitute for
9 intensive building materials, avoiding emissions from the production of concrete and steel (Sathre and
10 O'Connor 2010; Smyth et al. 2017b; Nabuurs et al. 2007; Lemprière et al. 2013). The harvest of carbon and
11 storage in products affects the net carbon balance of the forest sector, with the aim of sustainable forest
12 management strategies being to optimise carbon stocks and use of harvested products to generate sustained
13 mitigation benefits (Nabuurs et al. 2007).

14
15 Biophysical effects of forest response options are variable depending on the location and scale of activity
16 (Section 2.6). Reduced deforestation or afforestation in the tropics contributes to climate mitigation through
17 both biogeochemical and biophysical effects. It also maintains rainfall recycling to some extent. In contrast,
18 in higher latitude boreal areas observational and modelling studies show that afforestation and reforestation
19 lead to local and global warming effects, particularly in snow covered regions in the winter as the albedo is
20 lower for forests than bare snow (Bathiany et al. 2010a; Dass et al. 2013; Devaraju et al. 2018b; Ganopolski
21 et al. 2001b; Snyder et al. 2004a; West et al. 2011; Arora and Montenegro 2011) (Section 2.6). Management,
22 e.g. thinning practices in forestry, could increase the albedo in regions where albedo decreases with age. The
23 length of rotation cycles in forestry affects tree height and thus roughness, and through the removal of leaf
24 mass, harvest reduces evapotranspiration (Erb et al. 2017) which could lead to increased fire susceptibility in
25 the tropics. In temperate and boreal sites, biophysical forest management effects on surface temperature were
26 shown to be of similar magnitude than changes in land cover (Luyssaert et al. 2014b). These biophysical
27 effects could be of a magnitude to overcompensate biogeochemical effects, e.g. the sink strength of
28 regrowing forests after past depletions (Luyssaert et al. 2018; Naudts et al. 2016b), but many parameters and
29 assumptions on counterfactual influence the account (Anderson et al. 2011; Li et al. 2015b; Bright et al.
30 2015).

31
32 Forest cover also affects climate through reactive gases and aerosols with *limited evidence* and *medium*
33 *agreement* that the decrease in the emissions of BVOC resulting from the historical conversion of forests to
34 cropland has, resulted in a positive radiative forcing through direct and indirect aerosol effects, a negative
35 radiative forcing through the reduction in the atmospheric lifetime of methane it has increased an decreased
36 ozone concentrations in different regions (see Section 2.4).

37 38 39 **2.6.1.3 Land management of soils**

40 The global mitigation potential for increasing soil organic matter stocks in mineral soils is estimated to be in
41 the range of 0.4–8.64 GtCO₂ yr⁻¹ (*high confidence*) though the full literature range is wider with high
42 uncertainty related to some practices (Fuss et al. 2018; Sommer and Bossio 2014; Lal 2010; Lal et al. 2004;
43 Conant et al. 2017; Dickie et al. 2014; Frank et al. 2017a; Griscom et al. 2017c; Herrero et al. 2015, 2016b;
44 McLaren 2012; Paustian et al. 2016; Poeplau and Don 2015; Powlson et al. 2014b; Smith et al. 2016d;
45 Zomer et al. 2017). Some studies have separate potentials for soil carbon sequestration in croplands (0.25-
46 6.78 GtCO₂ yr⁻¹) (Griscom et al. 2017a; Hawken 2017; Frank et al. 2017a; Paustian et al. 2016; Herrero et al.
47 2016a; Henderson et al. 2015b; Dickie et al. 2014; Conant et al. 2017; Lal 2010) and soil carbon
48 sequestration in grazing lands (0.13-2.56 GtCO₂ yr⁻¹) (Griscom et al. 2017a; Hawken 2017; Frank et al.
49 2017a; Paustian et al. 2016; Powlson et al. 2014a; McLaren 2012; Zomer et al. 2017; Smith et al. 2015;
50 Sommer and Bossio 2014; Lal 2010). The potential for soil carbon sequestration and storage varies
51 considerably, depending on prior and current land management approaches, soil type, resource availability,
52 environmental conditions, microbial composition and nutrient availability among others (Hassink and
53 Whitmore 1997; Smith and Dukes 2013; Palm et al. 2014; Lal 2013; Six et al. 2002; Feng et al. 2013). Soils
54 are a finite carbon sink and sequestration rates may decline to negligible levels over as little as a couple of
55 decades as soils reach carbon saturation (West et al. 2004; Smith and Dukes 2013). The sink is at risk of
56 reversibility, in particular due to increased soil respiration under higher temperatures (section 2.3)

1
2 Land management practices to increase carbon interact with agricultural and fire management practices (see
3 Cross-chapter box 3: Fire and Climate Change, and Chapter 5) and include improved rotations with deeper
4 rooting cultivars, addition of organic materials, and agroforestry (Lal 2011; Smith et al. 2008; Lorenz and
5 Pitman 2014; Lal 2013; Vermeulen et al. 2012a; de Rouw et al. 2010). Adoption of green manure cover
6 crops, while increasing cropping frequency or diversity, helps sequester SOC (Poepflau and Don 2015;
7 Mazzoncini et al. 2011; Luo et al. 2010). Studies of the long-term SOC sequestration potential of
8 conservation agriculture, i.e. the simultaneous adoption of minimum tillage, (cover) crop residue retention
9 and associated soil surface coverage, and crop rotations, includes results that are both positive (Powlson et
10 al. 2016; Zhang et al. 2014) and inconclusive (Cheesman et al. 2016; Palm et al. 2014; Govaerts et al. 2009).

11
12 The efficacy of reduced and zero-till practices is highly context-specific; many studies demonstrate increased
13 carbon storage (e.g. Paustian et al., 2000; Six et al., 2004; van Kessel et al., 2013), while others show the
14 opposite effect (Sisti et al. 2004; Álvaro-Fuentes et al. 2008; Christopher et al. 2009). On the other hand,
15 deep ploughing can contribute to SOC sequestration by burying soil organic matter in the subsoil where it
16 decomposes slowly (Alcántara et al. 2016). Meta-analyses (Haddaway et al. 2017; Luo et al. 2010; Meurer
17 et al. 2018) also show a mix of positive and negative responses, and the lack of robust comparisons of soils
18 on an equivalent mass basis continues to be a problem for credible estimates (Wendt and Hauser 2013;
19 Powlson et al. 2011; Powlson et al. 2014).

20
21 Soil carbon management interacts with N₂O (Paustian et al. 2016). For example, (Li et al. 2005) estimate that
22 the management strategies required to increase C sequestration (reduced tillage, crop residue, and manure
23 recycling) would increase N₂O emissions significantly, offsetting 75–310% of the C sequestered in terms of
24 CO₂ equivalence, while other practices such as cover crops can reduce N₂O emissions (Kaye and Quemada
25 2017).

26
27 The management of soil erosion could avoid a net emissions of 1.36– 3.67 GtCO₂ yr⁻¹ and create a sink of
28 0.44–3.67 GtCO₂ yr⁻¹ (*low confidence*) (Jacinthe and Lal 2001; Lal et al. 2004; Stallard 1998; Smith et al.
29 2001; Van Oost et al. 2007). The overall impact of erosion control on mitigation is context-specific and
30 uncertain at the global level, uncertain and the final fate of eroded material is still debated (Hoffmann et al.,
31 2013).

32
33 Biochar is produced by thermal decomposition of biomass in the absence of oxygen (pyrolysis) into a stable,
34 long-lived product like charcoal that is relatively resistant to decomposition (Lehmann et al. 2015) and which
35 can stabilise organic matter added to soil (Han Weng et al. 2017). Although charcoal has been used
36 traditionally by many cultures as a soil amendment, “modern biochar”, produced in facilities that control
37 emissions, is not widely used. The range of global potential of biochar is 0.03-6.6 GtCO₂-eq yr⁻¹ by 2050
38 including energy substitution, with 0.03-4.9 GtCO₂ yr⁻¹ for CDR only (*medium confidence*) (Griscom et al.
39 2017a; Hawken 2017; Paustian et al. 2016; Fuss et al. 2018; Lenton 2014, 2010; Powell and Lenton 2012a;
40 Woolf et al. 2010; Pratt and Moran 2010; Smith 2016; Roberts et al. 2010). An analysis in which biomass
41 supply constraints were applied to protect against food insecurity, loss of habitat and land degradation,
42 estimated *technical potential* abatement of 3.7–6.6 GtCO₂-eq yr⁻¹ (including 2.6–4.6 GtCO₂ yr⁻¹ carbon
43 stabilisation) (Woolf et al. 2010). Fuss et al. (2018) propose a range of 0.5–2 GtCO₂-eq yr⁻¹ as
44 the *sustainable potential* for negative emissions through biochar. (Griscom et al. 2017b) suggest a potential
45 of 1.0 GtCO₂ yr⁻¹ based on available residues. Biochar can provide additional climate change mitigation
46 benefits by decreasing nitrous oxide (N₂O) emissions from soil and reducing nitrogen fertiliser requirements
47 in agricultural soils (Borchard et al. 2019). Application of biochar to cultivated soils can darken the surface
48 and reduce its mitigation potential via decreases in surface albedo, but the magnitude of this effect depends
49 on soil moisture content, biochar application method and type of land use (*low confidence*) (Verheijen et al.
50 2013; Bozzi et al. 2015). Biochar is discussed in more detail in Chapter 4, Section 4.9.5.

51 52 **2.6.1.4 Land management in other ecosystems**

53 Protection and restoration of wetlands, peatlands and coastal habitats reduces net carbon loss (primarily from
54 sediment/soils) and provides continued or enhanced natural CO₂ removal (Chapter 4, section 4.9.4).
55 Reducing annual emissions from peatland conversion, draining and burning could mitigate 0.45-1.22 GtCO₂-
56 eq yr⁻¹ up to 2050 (*medium confidence*) (Hooijer et al. 2010; Griscom et al. 2017; Hawken 2017) and

1 peatland restoration 0.15 to 0.81 (*low confidence*) (Couwenberg et al. 2010; Griscom et al. 2017b). The
2 upper end from Griscom et al. (2017) represents a maximum sustainable potential (accounting for
3 biodiversity and food security safeguards) for rewetting and biomass enhancement. Wetland drainage and
4 rewetting was included as a flux category under the second commitment Period of the Kyoto protocol, with
5 significant management knowledge gained over the last decade (IPCC 2013c). However, there are high
6 uncertainties as to the carbon storage and flux rates, in particular the balance between CH₄ sources and CO₂
7 sinks (Spencer et al. 2016). Peatlands are sensitive to climate change which may increase carbon uptake by
8 vegetation and carbon emissions due to respiration, with the balance being regionally dependent (*high*
9 *confidence*). There is *low confidence* about the future peatland sink globally. Some peatlands have been
10 found to be resilient to climate change (Minayeva and Sirin 2012), but the combination of land use change
11 and climate change may make them vulnerable to fire (Sirin et al. 2011). While models show mixed results
12 for the future sink (Spahni et al. 2013; Chaudhary et al. 2017; Ise et al. 2008), a study that used extensive
13 historical data sets to project change under future warming scenarios found that the currently global peatland
14 sink could increase slightly until 2100 and decline thereafter (Gallego-Sala et al. 2018).

15
16 Reducing the conversion of coastal wetlands (mangroves, seagrass and marshes) could reduce emissions by
17 0.11–2.25 GtCO₂-eq yr⁻¹ by 2050 (*medium confidence*) (Pendleton et al. 2012; Griscom et al. 2017a; Howard
18 et al. 2017; Hawken 2017). Mangrove restoration can mitigate the release of 0.07 GtCO₂ yr⁻¹ through
19 rewetting (Crooks et al. 2011) and take up 0.02–0.84 GtCO₂ yr⁻¹ from biomass and soil enhancement
20 (Griscom et al. 2017b) (*medium confidence*). The ongoing benefits provided by mangroves as a natural
21 carbon sink can be nationally-important for Small Island Developing States (SIDS) and other countries with
22 extensive coastlines, based on estimates of high carbon sequestration rates per unit area (McLeod et al. 2011;
23 Duarte et al. 2013; Duarte 2017; Taillardat et al. 2018). There is only *medium confidence* in the effectiveness
24 of enhanced carbon uptake using mangroves, due to the many uncertainties regarding the response of
25 mangroves to future climate change (Jennerjahn et al. 2017); dynamic changes in distributions (Kelleway et
26 al. 2017) and other local-scale factors affecting long-term sequestration and climatic benefits (e.g., methane
27 release; Dutta et al. 2017). The climate mitigation potential of coastal vegetated habitats (mangrove forests,
28 tidal marshes and seagrasses) is considered in Chapter 5 of the IPCC Special Report on the Ocean,
29 Cryosphere and Climate Change (SROCC), in a wider ‘blue carbon’ context.

30 31 32 **2.6.1.5 Bioenergy and bioenergy with carbon capture and storage (BECCS)**

33 An introduction and overview of bioenergy and BECCS can be found in the Cross-Chapter Boxes: Cross-
34 Chapter Box 12: Traditional biomass use, Chapter 7; Cross-Chapter Box 7: Bioenergy and BECCS in
35 mitigation scenarios, Chapter 6. CCS technologies are discussed in SR15. The discussion below refers to
36 modern bioenergy only, (e.g., liquid biofuels for transport and the use of solid biofuels in combined heat and
37 power plants).

38
39 The mitigation potential of bioenergy coupled with CCS, i.e., BECCS, is estimated to be between 0.4 and
40 11.3 GtCO₂ yr⁻¹ (*medium confidence*) based on studies that directly estimate mitigation for BECCS (not
41 bioenergy) in units of CO₂ (not EJ) (McLaren 2012; Lenton 2014; Fuss et al. 2018; Turner et al. 2018b;
42 Lenton 2010; Koornneef et al. 2012; Powell and Lenton 2012b). SR15 reported a potential of 1-85 GtCO₂ yr⁻¹
43 which they noted could be narrowed to a range of 0.5 to 5 GtCO₂ yr⁻¹ when taking account of sustainability
44 aims (Fuss et al. 2018). The upper end of the SR15 range is considered as a theoretical potential. Previously,
45 the IPCC Special Report on Renewable Energy Sources concluded the technical potential of biomass supply
46 for energy (without BECCS) could reach 100-300 EJ yr⁻¹ by 2050, which would be 2-15 GtCO₂ yr⁻¹ (using
47 conversion factors 1 EJ = 0.02-0.05 GtCO₂ yr⁻¹ emission reduction, SR15). A range of recent studies
48 including sustainability or economic constraints estimate that 50-244 EJ (1 to 12 GtCO₂ yr⁻¹ using
49 conversion factors above) of bioenergy could be produced on 0.1-13 Mkm² of land (Fuss et al. 2018; Chan
50 and Wu 2015; Schueler et al. 2016; Wu et al. 2013; Searle and Malins 2015; Wu et al. 2019; Heck et al.
51 2018; Fritz et al. 2013) SR15 SPM).

52
53 There is *high confidence* that the most important factors determining future biomass supply for energy are
54 land availability and land productivity (Berndes et al. 2013; Creutzig et al. 2015a; Woods et al. 2015;
55 Daioglou et al. 2019). Estimates of marginal/degraded lands currently considered available for bioenergy
56 range from 3.2 to 14.0 Mkm², depending on the adopted sustainability criteria, land class definitions, soil

1 conditions, land mapping method and environmental and economic considerations (Campbell et al. 2008;
2 Cai et al. 2011; Lewis and Kelly 2014).

3
4 Bioenergy production systems can lead to net emissions in the short term that can be “paid-back” over time,
5 with multiple harvest cycles and fossil fuel substitution, unlike fossil carbon emissions (Campbell et al.
6 2008; Cai et al. 2011; Lewis and Kelly 2014; De Oliveira Bordonal et al. 2015). Stabilising bioenergy crops
7 in previous high carbon forestland or peatland results in high emissions of carbon that may take from
8 decades to more than a century to be re-paid in terms of net CO₂ emission savings from replacing fossil
9 fuels, depending on previous forest carbon stock, bioenergy yields, and displacement efficiency (Elshout et
10 al. 2015; Harper et al. 2018; Daioglou et al. 2017). In the case of bioenergy from managed forests, the
11 magnitude and timing of the net mitigation benefits is controversial, as it varies with differences due to local
12 climate conditions, forest management practice, fossil fuel displacement efficiency and methodological
13 approaches (Hudiburg et al. 2011; Berndes et al. 2013; Guest et al. 2013; Lamers and Junginger 2013;
14 Cherubini et al. 2016; Cintas et al. 2017; Laurance et al. 2018; Valade et al. 2018; Baker et al. 2019).
15 Suitable bioenergy crops can be integrated in agricultural landscapes to reverse ecosystem carbon depletion
16 (Creutzig et al. 2015a; Robertson et al. 2017; Vaughan et al. 2018; Daioglou et al. 2017). Cultivation of short
17 rotation woody crops and perennial grasses on degraded land or cropland previously used for annual crops
18 typically accumulate carbon in soils due to their deep root systems (Don et al. 2012; Robertson et al. 2017).
19 The use of residues and organic waste as bioenergy feedstock can mitigate land use change pressures
20 associated with bioenergy deployment, but residues are limited and the removal of residues that would
21 otherwise be left on the soil could lead soil degradation (Chum et al. 2011; Liska et al. 2014; Monforti et al.
22 2015; Zhao et al. 2015; Daioglou et al. 2016).

23
24 The steps required to cultivate, harvest, transport, process and use biomass for energy generate emissions of
25 GHGs and other climate pollutants (Chum et al. 2011; Creutzig et al. 2015b; Staples et al. 2017; Daioglou et
26 al. 2019). Life-cycle GHG emissions of modern bioenergy alternatives are usually lower than those for fossil
27 fuels (*robust evidence, medium agreement*) (Chum et al. 2011; Creutzig et al. 2015b). The magnitude of
28 these emissions largely depends on location, (e.g. soil quality, climate), prior land use, feedstock used (e.g.,
29 residues, dedicated crops, algae), land use practice (e.g., soil management, fertiliser use), biomass transport
30 (distances and transport modes), the bioenergy conversion pathway and product (e.g., wood pellets, ethanol).
31 Use of conventional food and feed crops as a feedstock generally provides the highest bioenergy yields per
32 hectare, but also causes more GHG emissions per unit energy compared to agriculture residues, biomass
33 from managed forests, and lignocellulosic crops such as short-rotation coppice and perennial grasses (Chum
34 et al. 2011; Gerbrandt et al. 2016). This is due to the application of fertilisers and other inputs (Oates et al.
35 2016; Rowe et al. 2016; Lai et al. 2017; Robertson et al. 2017).

36
37 Bioenergy from dedicated crops are in some cases held responsible for GHG emissions resulting from
38 indirect land use change (iLUC), that is the bioenergy activity may lead to displacement of agricultural or
39 forest activities into other locations, driven by market-mediated effects. Other mitigation options may also
40 cause iLUC. At a global level of analysis, indirect effects are not relevant because all land-use emissions are
41 direct. iLUC emissions are potentially more significant for crop-based feedstocks such as corn, wheat and
42 soybean, than for advanced biofuels from lignocellulosic materials (Chum et al. 2011; Wicke et al. 2012;
43 Valin et al. 2015; Ahlgren and Di Lucia 2014). Estimates of emissions from iLUC are inherently uncertain,
44 are widely debated in the scientific community, and are highly dependent on modelling assumptions, such as
45 supply/demand elasticities, productivity estimates, incorporation or exclusion of emission credits for
46 coproducts, scale of biofuel deployment (Rajagopal and Plevin 2013; Finkbeiner 2014; Kim et al. 2014;
47 Zilberman 2017). In some cases, iLUC effects are estimated to result in emission reductions. For example,
48 market-mediated effects of bioenergy in North America showed potential for increased carbon stocks by
49 inducing conversion of pasture or marginal land to forestland (Cintas et al. 2017; Duden et al. 2017; Dale et
50 al. 2017; Baker et al. 2019). There is a wide range of variability in iLUC values for different types of
51 biofuels, from -75 to +55 g CO₂ MJ⁻¹ (Ahlgren and Di Lucia 2014; Valin et al. 2015; Plevin et al. 2015;
52 Taheripour and Tyner 2013; Bento and Klotz 2014). There is low confidence in attribution of emissions from
53 iLUC to bioenergy.

54
55 Bioenergy deployment can have large biophysical effects on regional climate, with the direction and
56 magnitude of the impact depending on the type of bioenergy crop, previous land use and seasonality (*limited*

1 *evidence, medium agreement*). A study of two alternative future bioenergy scenarios using 15 Mkm² of
2 intensively used managed land or conversion of natural areas showed a nearly neutral effect on surface
3 temperature at global levels (considering biophysical effects and CO₂ and N₂O fluxes from land but not
4 substitution effects), although there were significant seasonal and regional differences (Kicklighter et al.
5 2013). Modelling studies on biofuels in the US found the switch from annual crops to perennial bioenergy
6 plantations like Miscanthus in the US could lead to regional cooling due to increases in evapotranspiration
7 and albedo (Georgescu et al. 2011; Harding et al. 2016), with perennial bioenergy crop expansion over
8 suitable abandoned and degraded farmlands causing near-surface cooling up to 5°C during the growing
9 season (Wang et al. 2017b). Similarly, growing sugarcane on existing cropland in Brazil cools down the
10 local surface during daytime conditions up to -1°C, but warmer conditions occurs if sugar cane is deployed at
11 the expense of natural vegetation (Brazilian Cerrado) (Loarie et al. 2011). In general, bioenergy crops (as for
12 all crops) induce a cooling of ambient air during the growing season, but after harvest the decrease in
13 evapotranspiration can induce warming (Harding et al. 2016; Georgescu et al. 2013; Wang et al. 2017b).
14 Bioenergy crops were found to cause increased isoprene emissions in a scenario where 0.69 Mkm² of oil
15 palm for biodiesel in the tropics and 0.92 Mkm² of short rotation coppice (SRC) in the mid-latitudes were
16 planted, but effects on global climate were negligible (Ashworth et al. 2012).
17

18 **2.6.1.6 Enhanced weathering**

19 Weathering is the natural process of rock decomposition via chemical and physical processes in which CO₂
20 is removed from the atmosphere and converted to bicarbonates and/or carbonates (IPCC 2005). Formation of
21 calcium carbonates in the soil provides a permanent sink for mineralised organic carbon (Manning 2008;
22 Beerling et al. 2018). Mineral weathering can be enhanced through grinding up rock material to increase the
23 surface area, and distributing it over land to provide carbon removals of 0.5–4.0 GtCO₂ yr⁻¹ (*medium*
24 *confidence*) (Beerling et al. 2018; Lenton 2010; Smith et al. 2016a; Taylor et al. 2016). While the
25 geochemical potential is quite large, agreement on the technical potential is low due to a variety of unknown
26 parameters and of limits such as rates of mineral extraction, grinding, delivery, and challenges with scaling
27 and deployment.
28

29 **2.6.1.7 Demand management in the food sector (diet change, waste reduction)**

30 Demand-side management has the potential for climate change mitigation via reducing emissions from
31 production, switching to consumption of less emission intensive commodities, and making land available for
32 carbon dioxide removal (see Chapter 5 Section 5.5.2). Reducing food losses and waste increases the overall
33 efficiency of food value chains (less land and inputs needed) along the entire supply chain, and has the
34 potential to mitigate 0.8-4.5 GtCO₂-eq yr⁻¹ (*high confidence*) (Chapter 5 section 5.5.2.5, Bajželj et al. 2014;
35 Dickie et al 2014; Hawken 2017; Hiç et al. 2016).
36

37 Shifting to diets that are lower in emissions-intensive foods like beef delivers a mitigation potential of 0.7-
38 8.0 GtCO₂-eq yr⁻¹ (*high confidence*) (Bajželj et al. 2014; Dickie et al. 2014; Herrero et al. 2016; Hawken
39 2017; Springmann et al. 2016; Tilman and Clark 2014; Hedenus et al. 2014; Stehfest et al. 2009) with most
40 of the higher end estimates (> 6 GtCO₂-eq yr⁻¹) based on veganism, vegetarianism or very low ruminant meat
41 consumption) (see Chapter 5, Section 5.5.2). In addition to direct mitigation gains, decreasing meat
42 consumption, primarily of ruminants, and reducing wastes further reduces water use, soil degradation,
43 pressure on forests, land used for feed potentially freeing up land for mitigation (Tilman and Clark 2014)
44 (see chapters 5 and 6). Additionally, consumption of locally produced food, shortening the supply chain, can
45 in some cases minimise food loss, contribute to food security, and reduce GHG emissions associated with
46 energy consumption and food loss (see Chapter 5 Section 5.5.2.6).
47

48 **2.6.2 Integrated pathways for climate change mitigation**

49 Land-based response options have the potential to interact, resulting in additive effects (e.g., climate co-
50 benefits) or negating each other (e.g., through competition for land), they also interact with mitigation
51 options in other sectors (such as energy or transport), thus they need to be assessed collectively under
52 different climate mitigation targets and in combination with other sustainability goals (Popp et al. 2017;
53 Obersteiner et al. 2016; Humpenöder et al. 2018). Integrated Assessment Models (IAMs) with distinctive
54 land-use modules are the basis for the assessment of mitigation pathways as they combine insights from
55 various disciplines in a single framework and cover the largest sources of anthropogenic GHG emissions
56

1 from different sectors (see also SR15 Chapter 2 and technical Annex for more details). IAMs consider a
2 limited, but expanding, portfolio of land-based mitigation options. Furthermore, the inclusion and detail of a
3 specific mitigation measure differs across IAMs and studies (see also SR15 and Chapter 6). For example, the
4 IAM scenarios based on the Shared Socio-economic Pathways (SSPs) (Riahi et al. 2017)(see more details on
5 the SSPs in Cross-Chapter Box 1: Scenarios, Chapter 1) include possible trends in agriculture and land use
6 for five different socioeconomic futures, but cover a limited set of land-based mitigation options: dietary
7 changes, higher efficiency in food processing (especially in livestock production systems), reduction of food
8 waste, increasing agricultural productivity, methane reductions in rice paddies, livestock and grazing
9 management for reduced methane emissions from enteric fermentation, manure management, improvement
10 of N-efficiency, 1st generation biofuels, reduced deforestation, afforestation, 2nd generation bioenergy crops
11 and BECCS (Popp et al. 2017). However, many “natural climate solutions” (Griscom et al. 2017b), such as
12 forest management, rangeland management, soil carbon management or wetland management, are not
13 included in most of these scenarios. In addition, most IAMs neglect the biophysical effects of land-use such
14 as changes in albedo or evapotranspiration with few exceptions (Kreidenweis et al. 2016).

15
16 Mitigation pathways, based on IAMs, are typically designed to find the least cost pathway to achieve a pre-
17 defined climate target (Riahi et al. 2017). Such cost-optimal mitigation pathways, especially in RCP2.6
18 (broadly a 2°C target) and 1.9 scenarios (broadly a 1.5°C target), project GHG emissions to peak early in the
19 21st century, strict GHG emission reduction afterwards and, depending on the climate target, net carbon
20 dioxide removal (CDR) from the atmosphere in the second half of the century (see Chapter 2 of SR15,
21 (Tavoni et al. 2015; Riahi et al. 2017). In most of these pathways, land use is of great importance because of
22 its mitigation potential as discussed in section 2.7.1: these pathways are based on the assumptions that large-
23 scale afforestation and reforestation removes substantial amounts of CO₂ from the atmosphere; biomass
24 grown on cropland or from forestry residues can be used for energy generation or BECCS substituting fossil
25 fuel emissions and generating CDR; non-CO₂ emissions from agricultural production can be reduced, even
26 under improved agricultural management (Popp et al. 2017; Rogelj et al. 2018a; Van Vuuren et al. 2018,
27 Frank et al. 2018).

28
29 From the IAM scenarios available to this assessment, a set of feasible mitigation pathways has been
30 identified which is illustrative of the range of possible consequences on land use and GHG emissions
31 (presented in this chapter) and sustainable development (see Chapter 6). Thus, the IAM scenarios selected
32 here vary due to underlying socio-economic and policy assumptions, mitigation options considered, long-
33 term climate goal, the level of inclusion of other sustainability goals (such as land and water restrictions for
34 biodiversity conservation or food production), and models by which they are generated.

35
36 In the baseline case without climate change mitigation, global CO₂ emissions from land-use change decrease
37 over time in most scenarios due to agricultural intensification and decreases in demand for agricultural
38 commodities – some turning even negative by the end of the century due to abandonment of agricultural land
39 and associated carbon uptake through vegetation regrowth. Median global CO₂ emissions from land-use
40 change across 5 SSPs and 5 IAMs decrease throughout the 21st century: 3, 1.9 and -0.7 GtCO₂ yr⁻¹ in 2030,
41 2050 and 2100 respectively (Figure 2.25). In contrast, CH₄ and N₂O emissions from agricultural production
42 remain rather constant throughout the 21st century (CH₄: 214, 231.7 and 209.1 Mt CH₄ yr⁻¹ in 2030, 2050
43 and 2100 respectively; N₂O: 9.1, 10.1 and 10.3 Mt N₂O yr⁻¹ in 2030, 2050 and 2100 respectively).

44
45 In the mitigation cases (RCP4.5, RCP2.6 and RCP1.9), most of the scenarios indicate strong reductions in
46 CO₂ emissions due to i) reduced deforestation and ii) carbon uptake due to afforestation. However, CO₂
47 emissions from land use can occur in some mitigation scenarios as a result of weak land-use change
48 regulation (Fujimori et al. 2017; Calvin et al. 2017) or displacement effects into pasture land caused by high
49 bioenergy production combined with forest protection only (Popp et al. 2014). The level of carbon dioxide
50 removal globally (median value across SSPs and IAMs) increases with the stringency of the climate target
51 (RCP4.5, RCP2.6 and RCP1.9) for both afforestation (-1.3, -1.7 and -2.4 GtCO₂ yr⁻¹ in 2100) and BECCS (-
52 6.5, -11 and -14.9 GtCO₂ yr⁻¹ in 2100; see also Cross-Chapter Box 7: Bioenergy and BECCS in mitigation
53 scenarios, Chapter 6). In the mitigation cases (RCP4.5, RCP2.6 and RCP1.9), CH₄ and N₂O emissions are
54 remarkably lower compared to the baseline case (CH₄: 133.2, 108.4 and 73.5 Mt CH₄ yr⁻¹ in 2100; N₂O: 7.4,
55 6.1 and 4.5 Mt N₂O yr⁻¹ in 2100; see previous paragraph for CH₄ and N₂O emissions in the baseline case).
56 The reductions in the mitigation cases are mainly due to improved agricultural management such as

1 improved nitrogen fertiliser management, improved water management in rice production, improved manure
 2 management by for example covering of storages or adoption of biogas plants, better herd management and
 3 better quality of livestock through breeding and improved feeding practices. In addition, dietary shifts away
 4 from emission-intensive livestock products also lead to decreased CH₄ and N₂O emissions especially in
 5 RCP2.6 and RCP1.9 scenarios. However, high levels of bioenergy production can result in increased N₂O
 6 emissions due to nitrogen fertilisation of dedicated bioenergy crops.
 7

8

10 **Figure 2.25 Land-based global GHG emissions and removals in 2030, 2050 and 2100 for Baseline, RCP4.5,**
 11 **RCP2.6 and RCP1.9 based on the Shared Socioeconomic Pathways (SSP) (Popp et al. 2017; Rogelj et al.**
 12 **2018; Riahi et al. 2017). Data is from an update of the IAMC Scenario Explorer developed for the SR15**
 13 **(Huppmann et al. 2018; Rogelj et al. 2018). Boxplots (Tukey style) show median (horizontal line),**
 14 **interquartile range (IQR box) and the range of values within 1.5 x IQR at either end of the box (vertical**
 15 **lines) across 5 SSPs and across 5 IAMs. Outliers (red crosses) are values greater than 1.5 x IQR at either**
 16 **end of the box. The categories CO₂ Land, CH₄ Land and N₂O Land include GHG emissions from land-use**
 17 **change and agricultural land use (including emissions related to bioenergy production). In addition, the**
 18 **category CO₂ Land includes negative emissions due to afforestation. BECCS reflects the CO₂ emissions**
 19 **captured from bioenergy use and stored in geological deposits.**

20
21
22

23 Such high levels of carbon dioxide removal through mitigation options that require land conversion (BECCS
 24 and afforestation) shape the land system dramatically (Figure 2.26). Across the different RCPs, SSPs and
 25 IAMs median change of global forest area throughout the 21st century ranges from about -0.2 to +7.2 Mkm²
 26 between 2010 and 2100, and agricultural land used for 2nd generation bioenergy crop production ranges from

1 about 3.2–6.6 Mkm² in 2100 (Popp et al. 2017; Rogelj et al. 2018). Land requirements for bioenergy and
 2 afforestation for a RCP1.9 scenario are higher than for a RCP2.6 and especially a RCP4.5 mitigation
 3 scenario. As a consequence of the expansion of mainly land-demanding mitigation options, global pasture
 4 land is reduced in most mitigation scenarios much stronger compared to baseline scenarios (median
 5 reduction of 0, 2.6, 5.1 and 7.5 Mkm² between 2010 and 2100 in Baseline, RCP4.5, RCP2.6 and RCP1.9
 6 respectively). In addition, cropland for food and feed production decreases with the stringency of the climate
 7 target (+1.2, +0.2, -1.8 and -4 Mkm² in 2100 compared to 2010 in Baseline, RCP4.5, RCP2.6 and RCP1.9
 8 respectively). These reductions in agricultural land for food and feed production are facilitated by
 9 agricultural intensification on agricultural land and in livestock production systems (Popp et al. 2017) but
 10 also by changes in consumption patterns (Fujimori et al. 2017; Frank et al. 2017b). The pace of projected
 11 land-use change over the coming decades in ambitious mitigation scenarios goes well beyond historical
 12 changes in some instances (Turner et al. 2018c), see also SR15). This raises issues for societal acceptance,
 13 and distinct policy and governance for avoiding negative consequences for other sustainability goals
 14 (Humpenöder et al. 2018; Obersteiner et al. 2016; Calvin et al. 2014), see Chapter 6 and 7).
 15
 16

17
 18 **Figure 2.26** Global change of major land cover types by 2030, 2050 and 2100 relative to 2010 for Baseline,
 19 RCP4.5, RCP2.6 and RCP1.9 based on the Shared Socioeconomic Pathways (SSP) (Popp et al. 2017; Rogelj et
 20 al. 2018; Riahi et al. 2017). Data is from an update of the IAMC Scenario Explorer developed for the SR15
 21 (Huppmann et al. 2018; Rogelj et al. 2018). Boxplots (Tukey style) show median (horizontal line),
 22 interquartile range IQR (box) and the range of values within 1.5 x IQR at either end of the box (vertical lines)
 23 across 5 SSPs and across 5 IAMs. Outliers (red crosses) are values greater than 1.5 x IQR at either end of the
 24 box. In 2010, total land cover at global scale was estimated 15-16 Mkm² for cropland, 0-0.14 Mkm² for

1 **bioenergy, 30-35 Mkm² for pasture and 37-42 Mkm² for forest, across the IAMs that reported SSP pathways**
2 **(Popp et al. 2017).**
3

4 Different mitigation strategies can achieve the net emissions reductions that would be required to follow a
5 Pathway that limits global warming to 2°C or 1.5°C, with very different consequences on the land system.
6

7 **Figure 2.27** shows six alternative pathways (archetypes) for achieving ambitious climate targets (RCP2.6
8 and RCP1.9) highlighting land-based strategies and GHG emission. All pathways are assessed by different
9 models but are all based on the Shared Socioeconomic Pathway 2 (SSP2) (Riahi et al. 2017), with all based
10 on an RCP 1.9 mitigation pathway expect for Pathway 1, which is RCP2.6. All scenarios show land-based
11 negative emissions but the amount varies across pathways, as do the relative contributions of different land-
12 based Carbon Dioxide Removal (CDR) options, such as afforestation/reforestation and bioenergy with
13 carbon capture and storage (BECCS).
14

15 Pathway 1 RCP2.6 “Portfolio” (Fricko et al. 2017) shows a strong near-term decrease of CO₂ emissions from
16 land-use change, mainly due to reduced deforestation, as well as slightly decreasing N₂O and CH₄ emissions
17 after 2050 from agricultural production due to improved agricultural management and dietary shifts away
18 from emissions-intensive livestock products. However, in contrast to CO₂ emissions, which turn net-negative
19 around 2050 due to afforestation/reforestation, CH₄ and N₂O emissions persist throughout the century due to
20 difficulties of eliminating these residual emissions based on existing agricultural management methods
21 (Stevanović et al. 2017; Frank et al. 2017b). In addition to abating land-related GHG emissions as well as
22 increasing the terrestrial sink, this example also shows the importance of the land sector in providing
23 biomass for BECCS and hence CDR in the energy sector. In this scenario, annual BECCS-based CDR is
24 about 3-times higher than afforestation-based CDR in 2100 (-11.4 and -3.8 GtCO₂ yr⁻¹ respectively).
25 Cumulative CDR throughout the century amounts to -395 GtCO₂ for BECCS and -73 GtCO₂ for
26 afforestation. Based on these GHG dynamics, the land sector turns GHG emission neutral in 2100. However,
27 accounting also for BECCS-based CDR taking place in the energy sector but with biomass provided by the
28 land sector turns the land sector GHG emission neutral already in 2060, and significantly net-negative by the
29 end of the century.
30

31 Pathway 2 RCP1.9 “Increased Ambition” (Rogelj et al. 2018) has dynamics of land-based GHG emissions
32 and removals that are very similar to those in Pathway 1 (RCP2.6) but all GHG emission reductions as well
33 as afforestation/reforestation and BECCS-based CDR start earlier in time at a higher rate of deployment.
34 Cumulative CDR throughout the century amounts to -466 GtCO₂ for BECCS and -117 GtCO₂ for
35 afforestation.
36

37 Pathway 3 RCP 1.9 “Only BECCS”, in contrast to Pathway 2, includes only BECCS-based CDR (Kriegler
38 et al. 2017). In consequence, CO₂ emissions are persistent much longer, predominantly from indirect land-
39 use change due to large-scale bioenergy cropland expansion into non-protected natural areas (Popp et al.
40 2017; Calvin et al. 2014). While annual BECCS CDR rates in 2100 are similar to Pathway 1 and 2 (-15.9
41 GtCO₂ yr⁻¹), cumulative BECCS-based CDR throughout the century is much larger (-944 GtCO₂).
42

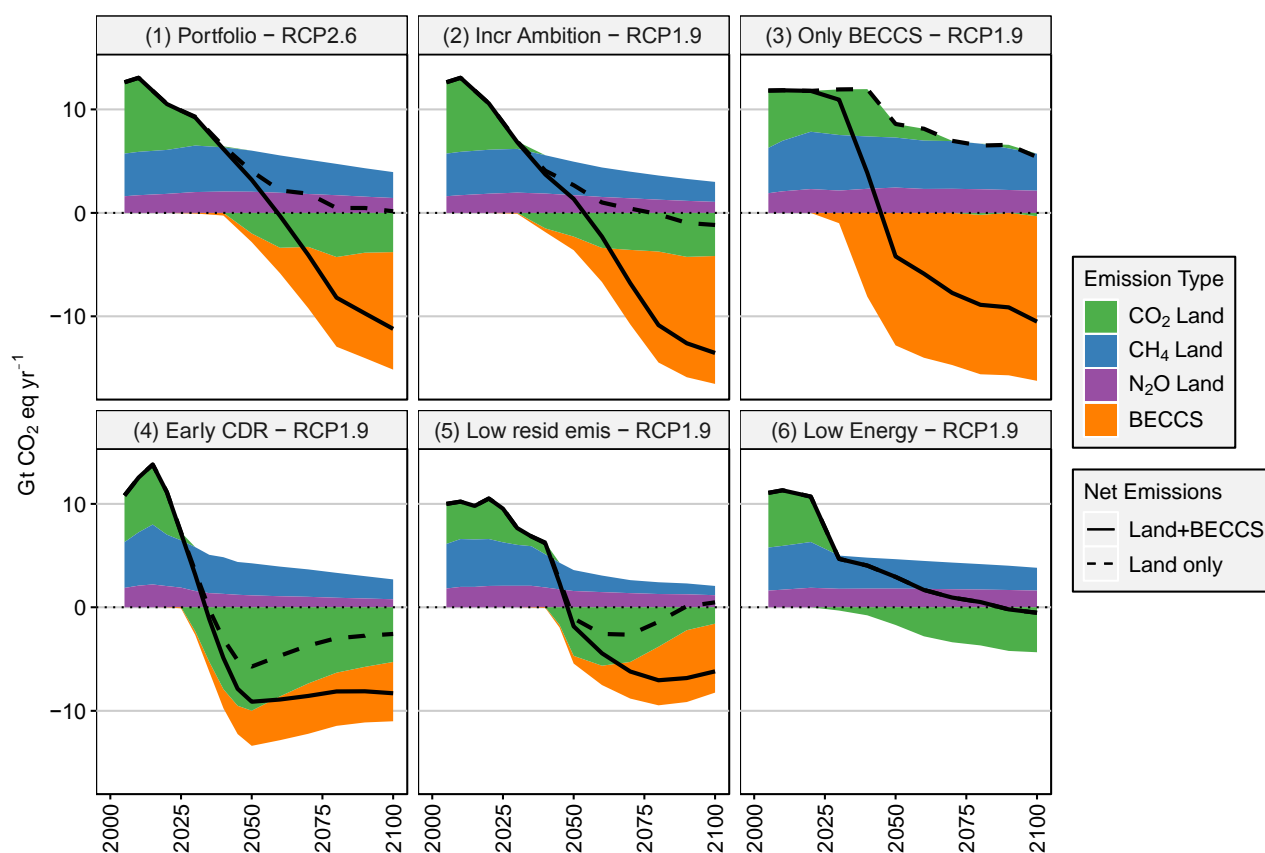

43 Pathway 4 RCP1.9 “Early CDR” (Bertram et al. 2018) indicates that a significant reduction in the later
44 century in the BECCS-related CDR as well as CDR in general can be achieved with earlier and mainly
45 terrestrial CDR, starting already in 2030. In this scenario, terrestrial CDR is based on afforestation but could
46 also be supported by soil organic carbon sequestration (Paustian et al. 2016) or other natural climate
47 solutions such as rangeland or forest management (Griscom et al. 2017b). This scenario highlights the
48 importance of the timing for CDR-based mitigation pathways (Obersteiner et al. 2016). As a result of near-
49 term and mainly terrestrial CDR deployment, cumulative BECCS-based CDR throughout the century is
50 limited to -300 GtCO₂, while cumulative afforestation-based CDR amounts to -428 GtCO₂.
51

52 In Pathway 5 RCP1.9 “Low residual emissions” (van Vuuren et al. 2018), land-based mitigation is driven by
53 stringent enforcement of measures and technologies to reduce end-of-pipe non-CO₂ emissions and by
54 introduction of in-vitro (cultured) meat, reducing residual N₂O and CH₄ emissions from agricultural
55 production. In consequence, much lower amounts of CDR from afforestation and BECCS are needed with
56 much later entry points to compensate for residual emissions. Cumulative CDR throughout the century

1 amounts to -252 GtCO₂ for BECCS and -128 GtCO₂ for afforestation. Therefore, total cumulative land-based
 2 CDR in Pathway 5 is substantially lower compared to Pathways 2-4 (380 GtCO₂).
 3

4 Finally, Pathway 6 RCP1.9 “Low Energy” (Grubler et al. 2018) – equivalent to pathway LED in SR15 –
 5 indicates the importance of other sectoral GHG emission reductions for the land sector. In this example,
 6 rapid and early reductions in energy demand and associated drops in energy-related CO₂ emissions, limit
 7 overshoot and decrease the requirements for negative emissions technologies, especially for land-demanding
 8 CDR such as biomass production for BECCS and afforestation. While BECCS is not used at all in Pathway 6,
 9 cumulative CDR throughout the century for afforestation amounts to -124 GtCO₂.
 10

11 Besides their consequences on mitigation pathways and land consequences, those archetypes can also affect
 12 multiple other sustainable development goals that provide both challenges and opportunities for climate
 13 action (see Chapter 6).

2.6.3 The contribution of response options to the Paris Agreement

The previous sections indicated how land based response options have the potential to contribute to the Paris Agreement, not only through reducing anthropogenic emissions but also for providing anthropogenic sinks that can contribute to “...a balance between anthropogenic emissions by sources and removals by sinks of greenhouse gases in the second half of this century ...” (Paris Agreement, Article 4). The balance applies globally, and relates only to greenhouse gases, not aerosols (Section 2.4) or biophysical effects (Section 2.5).

The Paris Agreement includes an Enhanced Transparency Framework, to track countries’ progress towards achieving their individual targets (i.e., NDCs), and a Global Stocktake (every five years starting in 2023), to assess the countries’ collective progress towards the long-term goals of the Paris Agreement. The importance of robust and transparent definitions and methods (including the approach to separating anthropogenic from natural fluxes) (Fuglestad et al. 2018) and the needs for reconciling country GHG inventories and models (Grassi et al. 2018a) was highlighted in 2.3 in relation to estimating emissions. Issues around estimating mitigation is also key to transparency and credibility and is part of the Paris Rulebook.

The land sector is expected to deliver up to 25% of GHG mitigation pledged by countries by 2025-2030 in their NDCs, based on early assessments of “Intended” NDCs submitted ahead of the Paris Agreement and updates immediately after (*low confidence*) (Grassi et al. 2017; Forsell et al. 2016). While most NDCs submitted to date include commitments related to the land sector, they vary with how much information is given and the type of target, with more ambitious targets for developing countries often being “conditional” on support and climate finance. Some do not specify the role of AFOLU but include it implicitly as part of economy-wide pledges (e.g. reducing total emission or emission intensity), a few mention multi-sectoral mitigation targets which include AFOLU in a fairly unspecified manner. Many NDCs include specific AFOLU response options, with most focused on the role of forests, a few included soil carbon sequestration or agricultural mitigation, few explicitly mention bioenergy (e.g., Cambodia, Indonesia and Malaysia), but this could be implicitly included with reduced emission in energy sector through fuel substitution (see Cross-Chapter Box 7: Bioenergy and BECCS in mitigation scenarios, Chapter 6, for discussion on cross sector flux reporting). The countries indicating AFOLU mitigation most prominently were Brazil and Indonesia, followed by other countries focusing either on avoiding carbon emissions (e.g., Ethiopia, Gabon, Mexico, DRC, Guyana and Madagascar) or on promoting the sink through large afforestation programs (e.g., China, India) (Grassi et al. 2017).

Figure 2.28 shows the CO₂ mitigation potential of NDCs compared to historical fluxes from LULUCF⁴. It shows future fluxes based on current policies in place and on country-stated Business As Usual (BAU) activities (these are different from current policies as many countries are already implementing policies that they do not include as part of their historical business-as-usual baseline) (Grassi et al. 2017). Under implementation of unconditional pledges, the net LULUCF flux in 2030 has been estimated to be a sink of $-0.41 \pm 0.68 \text{ GtCO}_2 \text{ yr}^{-1}$, which increases to $-1.14 \pm 0.48 \text{ GtCO}_2 \text{ yr}^{-1}$ in 2030 with conditional activities. This compares to net LULUCF in 2010 calculated from the GHG Inventories of $0.01 \pm 0.86 \text{ GtCO}_2 \text{ yr}^{-1}$ (Grassi et al. 2017). Forsell et al. (2016) similarly find a reduction in 2030 compared to 2010 of $0.5 \text{ GtCO}_2 \text{ yr}^{-1}$ (range: 0.2–0.8) by 2020 and $0.9 \text{ GtCO}_2 \text{ yr}^{-1}$ (range: 0.5–1.3) by 2030 for unconditional and conditional cases.

The approach of countries to calculating the LULUCF contribution towards the NDC varies, with implications for comparability and transparency. For example, by following the different approaches used to include LULUCF in country NDCs, (Grassi et al. 2017) found a 3-fold difference in estimated mitigation: $1.2\text{--}1.9 \text{ GtCO}_2\text{-eq yr}^{-1}$ when 2030 expected emissions are compared to 2005 emissions; $0.7\text{--}1.4 \text{ GtCO}_2\text{-eq yr}^{-1}$ when 2030 emissions are compared to reference scenarios based on current policies or $2.3\text{--}3.0 \text{ GtCO}_2\text{-eq yr}^{-1}$ when compared to BAU, and $3.0\text{--}3.8 \text{ GtCO}_2\text{-eq yr}^{-1}$ when based on using each countries’ approach to calculation stated in the NDC (i.e., when based on a mix of country approaches, using either past years or BAU projections as reference)

⁴ FOOTNOTE: CO₂ fluxes due to Land Use, Land-Use Change and Forestry, i.e. not including the part of AFOLU fluxes that are from agriculture

Figure 2.28 Global Land Use, Land Use Change and Forestry (LULUCF) net greenhouse gas flux for the historical period and future scenarios based on analyses of countries' Nationally Determined Contributions (NDCs). The LULUCF historical data (black solid line) reflect the following countries' documents (in order of priority): data submitted to UNFCCC (NDCs⁵, 2015 GHG Inventories⁶, recent National Communications^{7, 8}); other official countries' documents; FAO-based datasets, i.e. FAO-FRA for forest (Tian et al. 2015) as elaborated by (Federici et al. 2015) and FAOSTAT for non-forest land use emissions (FAO 2015a). The future four scenarios reflect official countries' information, mostly INDCs or updated NDCs available at the time of the analysis (Feb 2016), complemented by Biennial Update Reports⁹ and National Communications, and show: the Business as Usual (BAU) scenario as defined by the country; the trend based on pre-NDC levels of activity (current policies in place in countries); and the unconditional NDC and conditional NDC scenarios. The shaded area indicates the full range of countries' available projections (min-max), expressing the available countries' information on uncertainties beyond the specific scenarios shown. The range of historical country datasets (dotted lines) reflects differences between alternative selections of country sources, i.e. GHG inventories for developed countries complemented by FAO-based datasets (upper range) or by data in National Communications (lower range) for developing countries

In Exploring the effectiveness of the NDCs, SR15 concluded “Estimates of global average temperature increase are 2.9–3.4°C above preindustrial levels with a greater than 66% probability by 2100 (Roberts et al. 2006; Rogelj et al. 2016), under a full implementation of unconditional NDCs and a continuation of climate action similar to that of the NDCs. In order to achieve 1.5°C or 2°C pathways, this shortfall would imply the need for submission (and achievement) of more ambitious NDCs, and plan for a more rapid transformation of their national energy, industry, transport, and land use sectors (Peters and Geden 2017; Millar et al. 2017; Rogelj et al. 2016).

1
2 Response options relying on the use of land could provide around a third of the additional mitigation needed
3 in the near term (2030) to close the gap between current policy trajectories based on NDCs and what is
4 required to achieve a 2°C (>66% chance) or 1.5°C (50 to 66% chance) pathway according to the UNEP
5 Emissions Gap Report (Roberts et al. 2006). The report estimates annual reduction potentials in 2030 from
6 agriculture 3.0 (2.3–3.7) GtCO₂-eq yr⁻¹, a combination of “uncertain measures” (biochar, peat-related
7 emission reductions, and demand-side management) 3.7 (2.6–4.8) GtCO₂-eq yr⁻¹; forests 5.3 (4.1–6.5)
8 GtCO₂-eq yr⁻¹, bioenergy 0.9 GtCO₂-eq yr⁻¹, and BECCS 0.3 (0.2 to 0.4) GtCO₂-eq yr⁻¹ (UNEP 2017) Table
9 4.1). These response options account for 35% of potential reduction (or 32% without bioenergy and BECCS)
10 out of a total (all sector) potential of 38 (35–41) GtCO₂-eq yr⁻¹. The potentials estimated in the UNEP
11 Emissions Gap Report are based on the technical potential of individual response options from literature
12 including that presented in Section 2.1. CDR related to land use, while not a substitute for strong action in
13 the energy sector, has the technical potential to balance unavoidable emissions that are difficult to eliminate
14 with current technologies (*high confidence*), with early action avoiding deeper and more rapid action later
15 (*very high confidence*) (Strefler et al. 2018; Elmar et al. 2018, SR15).
16
17
18

2.7 Plant and soil processes underlying land-climate interactions

Projecting future complex interactions between land and climate require Earth system models (ESMs). A growing number of studies suggested that many processes important for interactions between land and climate were missing in the CMIP5-class ESMs and that Dynamic vegetation models (DGVM) used tended to elevate CO₂ emission and removals (*high confidence*) (Busch and Sage 2017; Rogers et al. 2017; Anderegg et al. 2016; Tjoelker 2018; Sulman et al. 2014a; Wieder et al. 2018; Davidson et al. 2006a).

Ecosystem complexity stemming from the diversity of plants, animals and microbes, as well as their biological responses to gradual climate changes (e.g., adaptive migration) and disturbance events (e.g., extreme weather events, fire, pest outbreaks; Section 2.2), are of potential importance. Of these processes, this section focuses on plant and soil processes, as recent empirical work, including those explained in the following subsections, offer potential for improved model projections under warmer and CO₂ rich futures.

The magnitude of future uptake and release of CO₂ and other greenhouse gases by vegetation are among the greatest uncertainties (Ciais et al. 2013b). One reason for this uncertainty stems from the lack of understanding of the mechanisms responsible for plant responses to increasing temperatures. The short- and long-term projections of gross photosynthesis responses to changes in temperature, CO₂, nutrient availability vary greatly among the models (Busch and Sage 2017; Rogers et al. 2017). Net CO₂ exchange requires estimation of autotrophic respiration, which is another source of uncertainty in ESM projections (Malhi et al. 2011). The importance of plant acclimation of photosynthesis and respiration in understanding vegetation response to climate change is now widely recognised (*high confidence*) (Rogers et al., 2017; Tan et al., 2017; Tjoelker, 2018; Vanderwel et al., 2015 ; Section 2.7.1). Acclimation is broadly defined as the biochemical, physiological, morphological or developmental adjustments within the lifetime of organisms that result in improved performance at the new condition. Acclimation often operates over a time span of days to weeks, and can mitigate negative effects of climate change on organismal growth and ecosystem functions (Tjoelker 2018).

Soil carbon and microbial processes, which interact with plant responses to climate, represent another large source of uncertainty in model projections (*medium confidence*) (Sections 2.7.2, 2.7.3 and 2.7.4). Given the wide range of uncertainty associated with SOC size estimates, CMIP5 models use a wide range of starting SOC stocks from 510 to 3040 GtC (Todd-Brown et al. 2013). Soil microbial respiration is estimated to release 40–70 GtC annually from the soil to the atmosphere globally (Hawkes et al. 2017). Projections of changes in global SOC stocks during the 21st century by CMIP5 models also ranged widely, from a loss of 37 Gt to a gain of 146 Gt, with differences largely explained by initial SOC stocks, differing C input rates, and different decomposition rates and temperature sensitivities (Todd-Brown et al. 2013). With respect to land-climate interactions, the key processes affecting SOC stocks are warming (which is expected to accelerate SOC losses through microbial respiration) and acceleration of plant growth (which increases inputs of C to soils). However, complex mechanisms underlying SOC responses to moisture regimes, carbon addition, and warming drive considerable uncertainty in projections of future changes in SOC stocks (Sulman et al. 2014a; Singh et al. 2010; Wieder et al. 2018).

2.7.1 Temperature responses of plant and ecosystem production

Climate-change responses of net ecosystem production cannot be modelled by simple instantaneous response functions, because of thermal acclimation responses of plants and soil microbes, as well as delayed responses arising from interactions between plants and the soil (*high confidence*) (Slot et al. 2014; Rogers et al. 2017; Tan et al. 2017; Tjoelker 2018). Photosynthesis and respiration of component plant species exhibit different functional shapes among species (Slot et al. 2014), and carbon balance at the stand level is influenced by respiration of ecosystem biomass other than plants. Large uncertainty remains for thermal responses of bacteria and other soil organisms (Section 2.7.5). Bayesian statistical estimates of global photosynthesis and total ecosystem respirations suggest that they exhibit different responses to thermal anomaly during the last 35 years (Li et al. 2018b).

Thermal responses of plant respiration, which consumes approximately one half of GPP, have not been

1 appropriately incorporated in most ESMs (Davidson et al., 2006; Tjoelker, 2018). Assumptions associated
2 with respiration have been a major source of uncertainty for ESMs at the time of AR5. In most existing
3 models, a simple assumption that respiration doubles with each 10°C increase of temperature (i.e., $Q_{10} = 2$) is
4 adopted, ignoring acclimation. Even a small error stemming from this assumption can strongly influence
5 estimated net carbon balance at large spatial scales of ecosystems and biomes over the time period of
6 multiple decades (Smith and Dukes 2013; Smith et al. 2016b). In order to estimate more appropriate thermal
7 response curves of respiration, a global database including data from 899 plant species has been compiled
8 (Atkin et al. 2015), and respiration data from 231 plants species across seven biomes have been analysed
9 (Heskel et al. 2016). These empirical data on thermal responses of respiration demonstrate a globally
10 convergent pattern (Huntingford et al. 2017). According to a sensitivity analysis of a relatively small number
11 of ESMs, a newly derived function of instantaneous responses of plant respiration to temperature (instead of
12 a traditional exponential function of $Q_{10} = 2$) makes a significant difference in estimated autotrophic
13 respiration especially in cold biomes (Heskel et al. 2016).

14
15 Acclimation results in reduced sensitivity of plant respiration with rising temperature, i.e., down regulation
16 of warming-related increase in respiratory carbon emission (Atkin et al. 2015; Slot and Kitajima 2015;
17 Tjoelker 2018) (*high confidence*). For example, experimental data from a tropical forest canopy show that
18 temperature acclimation ameliorates the negative effects of rising temperature to leaf and plant carbon
19 balance (Slot et al. 2014). Analysis of CO₂ flux data to quantify optimal temperature of net primary
20 production of tropical forests also suggest acclimation potential for many tropical forests (Tan et al. 2017).
21 Comparisons of models with and without thermal acclimation of respiration show that acclimation can halve
22 the increase of plant respiration with projected temperature increase by the end of 21st century (Vanderwel et
23 al. 2015).

24
25 It is typical that acclimation response to warming results in increases of the optimum temperature for
26 photosynthesis and growth (Slot and Winter 2017; Yamori et al. 2014; Rogers et al. 2017). Although such
27 shift is a result of a complex interactions of biochemical, respiratory, and stomatal regulation (Lloyd and
28 Farquhar 2008), it can be approximated by a simple algorithm to address acclimation (Kattge et al. 2007).
29 Mercado et al., (2018), using this approach, found that inclusion of biogeographical variation in
30 photosynthetic temperature response was critically important for estimating future land surface carbon
31 uptake. In the tropics, CO₂ fertilisation effect (c.f., Box 2.3) is suggested to be more important for observed
32 increases in carbon sink strength than increased leaf area index or longer growing season (Zhu et al. 2016).
33 Acclimation responses of photosynthesis and growth to simultaneous changes of temperature and CO₂, as
34 well as stress responses above the optimal temperature for photosynthesis, remain a major knowledge gap in
35 modelling responses of plant productivity under future climate change (Rogers et al. 2017).

36 37 **2.7.2 Water transport through soil-plant-atmosphere continuum and drought mortality**

38
39 How climate change, especially changes of precipitation patterns, influence water transport through the soil-
40 plant-atmosphere continuum, is a key element in projecting the future of water vapour flux from land and
41 cooling via latent heat flux (Sellers et al. 1996; Bonan 2008a; Brodribb 2009; Choat et al. 2012; Sperry and
42 Love 2015; Novick et al. 2016; Sulman et al. 2016)(*high confidence*). Even without changes in leaf area per
43 unit area of land, when plants close stomata in response to water shortage, dry atmosphere, or soil moisture
44 deficit, the stand-level fluxes of water (and associated latent heat flux) decrease (Seneviratne et al. 2018).
45 Closing stomata enhances drought survival at the cost of reduced photosynthetic production, while not
46 closing stomata avoids loss of photosynthetic production at the cost of increased drought mortality (Sperry
47 and Love 2015). Hence, species-specific responses to drought, in terms of whether they close stomata or not,
48 have short and long-term consequences (Anderegg et al. 2018a; Buotte et al. 2019). Increased drought-
49 induced mortality of forest trees, often exacerbated by insect outbreak and fire (e.g., (Breshears et al. 2005;
50 Kurz et al. 2008a; Allen et al. 2010)) (Section 2.2.4), have long-term impact on hydrological interactions
51 between land and atmosphere (Anderegg et al. 2018b).

52
53 New models linking plant water transport with canopy gas exchange and energy fluxes are expected to
54 improved projections of climate change impacts on forests and land-atmosphere interactions (Bohrer et al.,
55 2005; Anderegg et al., 2016; Sperry and Love, 2015; Wolf et al., 2016)(*medium confidence*). Yet, there is
56 much uncertainty in the ability of current vegetation and land surface models to adequately capture tree

1 mortality and the response of forests to climate extremes like drought (Rogers et al. 2017; Hartmann et al.
2 2018). Most vegetation models use climate stress envelopes or vegetation carbon balance estimations to
3 project climate-driven mortality and loss of forests (McDowell et al. 2011); these may not adequately project
4 biome shifts and impacts of disturbance in future climates. For example, a suite of vegetation models was
5 compared to a field drought experiment in the Amazon on mature rainforest trees and all models performed
6 poorly in projecting the timing and magnitude of biomass loss due to drought (Powell et al. 2013). More
7 recently, the loss of water transport due to embolism (disruption of xylem water continuity) (Sperry and
8 Love 2015), rather than carbon starvation (Rowland et al. 2015), is receiving attention as a key physiological
9 process relevant for drought-induced tree mortality (Hartmann et al. 2018). A key challenge to modelling
10 effort is to consider differences among plant species and vegetation types in their drought responses. One
11 approach is to classify plant species to “functional types” that exhibit similar responses to environmental
12 variations (Anderegg et al. 2016). Certain traits of species, such as tree height, is shown to be predictive of
13 growth decline and mortality in response to drought (Xu et al. 2016a). Similarly, tree rooting depth is
14 positively related to mortality, contrary to expectation, during prolonged droughts in tropical dry forest
15 (Chitra-Tarak et al. 2017).

16 2.7.3 Soil microbial effects on soil nutrient dynamics and plant responses to elevated CO₂

17
18
19 Soil microbial processes influencing nutrient and carbon dynamics represent a large source of uncertainty in
20 projecting land-climate interactions. For example, ESMs incorporating nitrogen and phosphorus limitations
21 (but without considering the effects of mycorrhizae and rhizosphere priming) indicate that the simulated
22 future C-uptake on land is reduced significantly when both nitrogen and phosphorus are limited as compared
23 to only C-stimulation, by 63% (of 197 Pg C) under RCP2.6 and by 67% (of 425 Pg C) under RCP8.5 (Zhang
24 et al. 2013c). Mineral nutrient limitation progressively reduces the CO₂ fertilisation effects on plant growth
25 and productivity over time (Norby et al. 2010; Sardans et al. 2012; Reich and Hobbie 2013; Feng et al. 2015;
26 Terrer et al. 2017) (*robust evidence, medium agreement*). The rates at which nutrient limitation develops
27 differ among studies and sites. A recent meta-analysis shows that experimental CO₂ enrichment generally
28 results in lower nitrogen and phosphorus concentrations in plant tissues (Du et al. 2019a), and isotopic
29 analysis also suggest a global trend of decreases in leaf nutrient concentration (Craine et al. 2018; Jonard et
30 al. 2015). However, reduced responses to elevated CO₂ (eCO₂) may not be a simple function of nitrogen
31 dilution per se, as they result from complex interactions of ecosystem factors that influence nitrogen
32 acquisition by plants (Liang et al. 2016; Rutting 2017; Du et al. 2019a).

33
34 Increasing number of case studies suggest that soil microbial processes, such as nitrogen mineralisation rates
35 and symbiosis with plants, influence nutrient limitation on eCO₂ effects on plant growth (Drake et al. 2011;
36 Zak et al. 2011; Hungate et al. 2013; Talhelm et al. 2014; Du et al. 2019a) (*medium confidence*).
37 Rhizosphere priming effects (i.e., release of organic matters by roots to stimulate microbial activities) and
38 mycorrhizal associations are proposed to explain why some sites becoming nitrogen limited after a few years
39 and others sustaining growth through accelerated nitrogen uptake (Phillips et al. 2011; Terrer et al. 2017)
40 (*limited evidence, medium agreement*).

41
42 Model assessments that including rhizosphere priming effects and ectomycorrhizal symbiosis suggest that
43 soil organic matter (SOM) cycling is accelerated through microbial symbiosis (Elbert et al. 2012; Sulman et
44 al. 2017; Orwin et al. 2011; Baskaran et al. 2017) (*medium confidence*). Uncertainty exists in differences
45 among ectomycorrhizal fungal species in their ability to decompose SOM (Pellitier and Zak 2018) and the
46 capacity of ecosystems to sustain long-term growth with these positive symbiotic feedbacks is still under
47 debate (Terrer et al. 2017). ESMs include only biological nitrogen cycles, even though a recent study
48 suggests that bedrock weathering can be a significant source of nitrogen to plants (Houlton et al. 2018). In
49 contrast, rock weathering is widely considered to be the key for P availability, and tropical forests with
50 highly weathered soils are considered to be limited by P availability rather than nitrogen availability (Reed et
51 al. 2015). Yet, evidence from P-fertilisation experiments is lacking (Schulte-Uebbing and de Vries 2018) and
52 P limitation of tropical tree growth may be strongly species-specific (Ellsworth et al. 2017; Turner et al.
53 2018a). Limitation by availability of soil nutrients other than nitrogen and P has not been studied in the
54 context of land-climate interactions, except potassium (K) as a potentially limiting factor for terrestrial plant
55 productivity in interaction with N, P and hydrology (Sardans and Peñuelas 2015; Zhao et al. 2017; Wright et
56 al. 2018).

1
2 Anthropogenic alteration of global and regional nitrogen and P cycles, largely through use of chemical
3 fertilisers and pollution, has major implications for future ecosystem attributes, including C storage, in
4 natural and managed ecosystems (Peñuelas et al. 2013, 2017; Wang et al. 2017c; Schulte-Uebbing and de
5 Vries 2018; Yuan et al. 2018) (*high confidence*). During 1997-2013, the contribution of nitrogen deposition
6 to the global C sink has been estimated at $0.27 (\pm 0.13) \text{ GtC yr}^{-1}$, and the contribution of P deposition as
7 $0.054 (\pm 0.10) \text{ GtC yr}^{-1}$; these constitute about 9% and 2% of the total land C sink, respectively (Wang et al.
8 2017c). Anthropogenic deposition of nitrogen enhances carbon sequestration by vegetation (Schulte-
9 Uebbing and de Vries 2018), but this effect of nitrogen deposition on carbon sequestration may be offset by
10 increased emission of GHGs such as N_2O and CH_4 (Liu and Greaver 2009). Furthermore, nitrogen deposition
11 may lead to imbalance of nitrogen vs. phosphorus availability (Peñuelas et al. 2013), soil microbial activity
12 and SOM decomposition (Janssens et al. 2010), and reduced ecosystem stability (Chen et al. 2016b).

13 14 **2.7.4 Vertical distribution of soil organic carbon**

15
16 It has long been recognised that dynamics of soil organic carbon (SOC) represent a large source of
17 uncertainties on biogeochemical interactions of land with atmosphere and climate as detailed below. Since
18 AR5, there have been new understanding on SOC size, as well as microbial processes that influence SOM
19 dynamics under climate change and LULCC. Three existing data bases (SoilGrids, the Harmonized World
20 Soil Data Base, Northern Circumpolar Soil Database) substantially differ in estimated size of global soil
21 organic carbon (SOC) stock down to 1 m depth, varying between 2500 Pg to 3400 Pg with differences
22 among databases largely attributable to C stored in permafrost (Joosten 2015; Köchy et al. 2015; Tifafi et al.
23 2018). These values are four to eight times larger than the carbon stock associated with the terrestrial
24 vegetation (Bond-Lamberty et al. 2018). New estimates since AR5 show that much larger areas in Amazon
25 and Congo basins are peatlands (Gumbrecht et al. 2017; Dargie et al. 2019).

26
27 Deep soil layers can contain much more carbon than previously assumed (e.g., González-Jaramillo et al.,
28 2016) (*limited evidence, medium agreement*). Based on radiocarbon measurements, deep SOC can be very
29 old, with residence times up to several thousand years (Rumpel and Kögel-Knabner 2011) or even several
30 tens of thousands of years (Okuno and Nakamura 2003). Dynamics associated with such deeply buried
31 carbon remain poorly studied and ignored by the models, and not addressed in most of the studies assessed in
32 this subsection. Deep soil C is thought to be stabilised by mineral interactions, but recent experiments
33 suggest that CO_2 release from deep soils can also be increased by warming, with a 4°C warming enhancing
34 annual soil respiration by 34–37% (Hicks Pries et al. 2017) or addition of fresh carbon (Sebastien
35 Fontaine Pierre Barre, Nadia Bdioui, Bruno Mary, Cornelia Rumpel 2007). While erosion is not typically
36 modelled as a carbon flux in ESMs, erosion and burial of carbon-containing sediments is likely a significant
37 carbon transfer from land to ocean (Berhe et al. 2007; Asefaw et al. 2008; Wang et al. 2017e) (*medium
38 confidence*).

39 40 **2.7.5 Soil carbon responses to warming and changes in soil moisture**

41
42 Annually, 119 GtC is estimated to be emitted from the terrestrial ecosystem to the atmosphere, of which ca.
43 50% is attributed to soil microbial respiration (Auffret et al. 2016; Shao et al. 2013). It is yet not possible yet
44 to make mechanistic and quantitative projections about how multiple environmental factors influence soil
45 microbial respiration (Davidson et al. 2006a; Dungait et al. 2012). Soil warming experiments show
46 significant variability in temperature and moisture responses across biomes and climates; Crowther et al.,
47 (2016) found that warming-induced SOC loss is greater in regions with high initial carbon stocks, while an
48 analysis of an expanded version of the same dataset did not support this conclusion (Gestel et al. 2018).
49 Studies of SOC responses to warming over time have also shown complex responses. In a multi-decadal
50 warming experiment, Melillo et al., (2017) found that soil respiration response to warming went through
51 multiple phases of increasing and decreasing strength, which were related to changes in microbial
52 communities and available substrates over time. (Conant et al., (2011) and Knorr et al., (2005) suggested that
53 transient decomposition responses to warming could be explained by depletion of labile substrates, but that
54 long-term SOC losses could be amplified by high temperature sensitivity of slowly decomposing SOC
55 components. Overall, long-term SOC responses to warming remain uncertain (Davidson et al. 2006a;
56 Dungait et al. 2012; Nishina et al. 2014; Tian et al. 2015).

1
2 It is widely known that soil moisture plays an important role in SOM decomposition by influencing
3 microbial processes (e.g., Monard et al., 2012; Moyano et al., 2013; Yan et al., 2018), as confirmed by a
4 recent global meta-analysis (Hawkes et al. 2017) (*high confidence*). A likely mechanism involves that
5 increased soil moisture lowers C mineralisation rates under anaerobic conditions resulting in enhanced C
6 stocks, but experimental analyses have shown that this effect may last for only 3–4 weeks after which iron
7 reduction can actually accelerate loss of previously protected organic C by facilitating microbial access
8 (Huang and Hall 2017).

9
10 Experimental studies of responses of microbial respiration to warming have found variable results (Luo et al.
11 2001; Bradford et al. 2008; Zhou et al. 2011; Carey et al. 2016; Teramoto et al. 2016). No acclimation was
12 observed in C-rich calcareous temperate forest soils (Schindlbacher et al. 2015) and arctic soils (Hartley et
13 al. 2008), and a variety of ecosystems from the Arctic to the Amazon indicated that microbes appear to
14 enhance the temperature sensitivity of soil respiration in Arctic and boreal soils, thereby releasing even more
15 carbon than currently projected (Karhu et al. 2014). In tropical forests, P limitation of microbial processes is
16 a key factor influencing soil respiration (Camenzind et al. 2018). Temperature responses of symbiotic
17 mycorrhizae differ widely among host plant species, without a clear pattern that may allow generalisation
18 across plant species and vegetation types (Fahey et al. 2016).

19
20 Some new insights have been obtained since AR5 from investigations of improved mechanistic
21 understanding of factors that regulate temperature responses of soil microbial respiration. Carbon use
22 efficiency and soil nitrogen dynamics have large influence on SOC responses to warming (Allison et al.
23 2010; Frey et al. 2013; Wieder, William R., Bonan, Gordon B., Allison 2013; García-Palacios et al. 2015)
24 (*high confidence*). More complex community interactions including competitive and trophic interactions
25 could drive unexpected responses to SOC cycling to changes in temperature, moisture, and C inputs
26 (Crowther et al. 2015; Buchkowski et al. 2017). Competition for nitrogen among bacteria and fungi could
27 also suppress decomposition (Averill et al. 2014). Overall, the roles of soil microbial community and trophic
28 dynamics in global SOC cycling remain very uncertain.

29 30 **2.7.6 Soil carbon responses to changes in organic-matter inputs by plants**

31
32 While current ESM structures mean that increasing C inputs to soils drive corresponding increases in SOC
33 stocks, long-term carbon addition experiments have found contradictory SOC responses. Some litter addition
34 experiments have observed increased SOC accumulation (Lajtha et al. 2014b; Liu et al. 2009), while others
35 suggest insignificant SOC responses (Lajtha et al. 2014a; van Groenigen et al. 2014). Microbial dynamics
36 are believed to have an important role in driving complex responses to C additions. The addition of fresh
37 organic material can accelerate microbial growth and SOM decomposition via priming effects (Kuzyakov et
38 al. 2014; Cheng et al. 2017). SOM cycling is dominated by “hot spots” including the rhizosphere as well as
39 areas surrounding fresh detritus (*medium evidence, high agreement*) (Finzi et al. 2015; Kuzyakov and
40 Blagodatskaya 2015). This complicates projections of SOC responses to increasing plant productivity;
41 increasing C inputs could promote higher SOC storage, but these fresh C inputs could also deplete SOC
42 stocks by promoting faster decomposition (Hopkins et al. 2014; Guenet et al. 2018; Sulman et al. 2014b). A
43 meta-analysis by (van Groenigen et al. 2014) suggested that elevated CO₂ accelerated SOC turnover rates
44 across several biomes. These effects could be especially important in high-latitude regions where soils have
45 high organic matter content and plant productivity is increasing (Hartley et al. 2012), but have also been
46 observed in the tropics (Sayer et al. 2011).

47
48 Along with biological decomposition, another source of uncertainty in projecting responses of SOC to
49 climate change is stabilisation via interactions with mineral particles (Kögel-Knabner et al. 2008; Kleber et
50 al. 2011; Marschner et al. 2008; Schmidt 2011) (*high confidence*). Historically, conceptual models of SOC
51 cycling have centred on the role of chemical recalcitrance, the hypothesis that long-lived components of
52 SOC are formed from organic compounds that are inherently resistant to decomposition. Under the emerging
53 new paradigm, stable SOC is primarily formed by the bonding of microbially-processed organic material to
54 mineral particles, which limits the accessibility of organic material to microbial decomposers (Lützow et al.
55 2006; Keiluweit et al. 2015; Kallenbach et al. 2016; Kleber et al. 2011; Hopkins et al. 2014). SOC in soil
56 aggregates can be protected from microbial decomposition by being trapped in soil pores too small for

1 microbes to access (Blanco-Canqui and Lal 2004; Six et al. 2004) or by oxygen limitation (Keiluweit et al.
2 2016). Some new models are integrating these mineral protection processes into SOC cycling projections
3 (Wang et al. 2017a; Sulman et al. 2014b; Riley et al. 2014; Wieder et al. 2015), although the sensitivity of
4 mineral-associated organic matter to changes in temperature, moisture, fire (see Box 2.1) and carbon inputs
5 is highly uncertain. Improved quantitative understanding of soil ecosystem processes will be critically
6 important for projection of future land-climate feedback interactions.
7
8

9 **Frequently Asked Questions**

10 **FAQ 2.1 How does climate change affect land use and land cover?**

11
12
13 Contemporary land cover and land use is adapted to current climate variability within particular temperature
14 and/or rainfall ranges (referred to as climate envelopes). Anthropogenic greenhouse gas emissions impact
15 land through changes in the weather and climate and also through modifications in atmospheric composition
16 through increased greenhouse gasses, especially CO₂. A warming climate alters the current regional climate
17 variability and results in a shift of regional climate envelopes poleward and to higher elevations. The shift of
18 warmer climate envelopes into high latitude areas has potential benefits for agriculture here through
19 extended growing seasons and warmer seasonal temperatures and increased atmospheric CO₂ concentrations
20 enhances photosynthetic activity. However, this warming will also lead to enhanced snowmelt and reduced
21 albedo, permafrost melting and the further release of methane and CO₂ into the atmosphere as the permafrost
22 begins to decompose. Concurrent with these climate envelope shifts will be the emergence of new, hot
23 climates in the tropics and increases in the frequency, intensity and duration of extreme events (e.g. heat
24 waves, very heavy rainfall, drought). These emergent hot climates will negatively affect land use (through
25 changes in crop productivity, irrigation needs, management practices) and land cover through loss of
26 vegetation productivity in many parts of the world, and overwhelm any benefits to land use and land cover
27 derived from increased atmospheric CO₂ concentrations.
28

29 **FAQ 2.2 How do the land and land use contribute to climate change?**

30
31 Any changes to the land and how it is used can affect exchanges of water, energy, greenhouse gases (e.g.,
32 CO₂, CH₄, N₂O), non-greenhouse gases (e.g., biogenic volatile organic compounds – BVOCs), and aerosols
33 (mineral, e.g., dust, or, carbonaceous, e.g., black carbon) between the land and the atmosphere. Land and
34 land use change therefore alter the state (e.g., chemical composition and air quality, temperature and
35 humidity) and the dynamics (e.g., strength of horizontal and vertical winds) of the atmosphere, which in turn
36 can dampen or amplify local climate change. Land-induced changes in energy, moisture and wind can affect
37 neighbouring, and sometimes more distant, areas. For example, deforestation in Brazil warms the surface, in
38 addition to global warming, and enhances convection which increases the relative temperature difference
39 between the land and the ocean, boosting moisture advection from the ocean and thus rainfall further inland.
40 Vegetation absorbs carbon dioxide (CO₂) to use for growth and maintenance. Forests contain more carbon in
41 their biomass and soils than croplands and so a conversion of forest to cropland, for example, results in
42 emissions of CO₂ to the atmosphere, thereby enhancing the greenhouse gas-induced global warming.
43 Terrestrial ecosystems are both sources and sinks of chemical compounds such as nitrogen and ozone.
44 BVOCs contribute to forming tropospheric ozone and secondary aerosols, which respectively affect surface
45 warming and cloud formation. Semi-arid and arid regions release dust, as do cropland areas after harvest.
46 Increasing the amount of aerosols in the atmosphere impacts temperature in both positive and negative ways
47 depending on the particle size, altitude, and nature (carbonaceous or mineral for example). Although global
48 warming will impact the functioning and state of the land (see FAQ 2.1), this is not a one-way interaction as
49 changes in land and land use can also affect climate and thus modulate climate change. Understanding this
50 two-way interaction can help improve adaptation and mitigation strategies as well as manage landscapes.
51

52 **FAQ 2.3 How does climate change affect water resources?**

1
2 Renewable freshwater resources are essential for the survival of terrestrial and aquatic ecosystems and
3 human use in agriculture, industry and domestically. As increased water vapour concentrations are expected
4 in a warmer atmosphere, climate change will alter the hydrological cycle and therefore regional freshwater
5 resources. In general, wet regions are projected to get wetter and dry regions drier, although there are
6 regional exceptions to this. The consequent impacts vary regionally; where rainfall is projected to be lower
7 in the future (many arid subtropical regions and those with a Mediterranean climate), a reduction of water
8 resources is expected. Here increased temperatures and decreased rainfall will reduce surface and
9 groundwater resources, increase plant evapotranspiration and increase evaporation rates from open water
10 (rivers, lakes, wetlands) and water supply infrastructure (canals, reservoirs). In regions where rainfall is
11 projected to be higher in the future (many high latitude regions and the wet tropics), an increase in water
12 resources can be expected to benefit terrestrial and freshwater ecosystems, agriculture and domestic use,
13 however, these benefits may be limited due to increased temperatures. An increase in extreme rainfall events
14 is also expected which will lead to increases in surface runoff, regional flooding and nutrient removal as well
15 as a reduction in soil water and groundwater recharge in many places. Anthropogenic land use change may
16 amplify or moderate the climate change effect on water resources therefore informed land management
17 strategies need to be developed. A warming climate will exacerbate the existing pressures on renewable
18 freshwater resources in water-stressed regions of the Earth and result in increased competition for water
19 between human and natural systems.

Appendix

This appendix provides all numbers that support **Figure 2.14** and **Figure 2.17** located in Section 2.5. It lists all model-based studies, with their references, that have been used to create the figures. Studies that examine the effects of historical and future scenarios of changes in anthropogenic land cover are presented in Table 1. The responses to idealised latitudinal deforestation and forestation can be found in Table A2.2.

The biophysical effects of changes in anthropogenic land cover reflect the impacts of changes in physical land surface characteristics such as albedo, evapotranspiration, and roughness length. The biogeochemical effects reflect changes in atmospheric CO₂ composition resulting from anthropogenic changes in land cover. The biogeochemical effects are estimated using three different methods:

1. Directly calculated within global climate models (Tables A2.1 and A2.2);
2. Calculated from off-line dynamic global vegetation models (DGVMs) estimates of net changes in the emissions of CO₂ from land (Table A2.1);
3. Calculated from observation-based estimates of net changes in the emissions of CO₂ from land (for historical reconstruction only, Table A2.1)

The mean annual and global temperature change (ΔT) resulting from biogeochemical effects is calculated as follows, for both DGVMs and observation-based estimates:

$$\Delta T = \Delta LCO_2 * TCRE$$

Where ΔLCO_2 is the cumulative changes in net emissions of CO₂ resulting from anthropogenic land cover changes during the time period considered (in Tera tons of carbon, TtC), and TCRE is the transient climate response to cumulative carbon emissions (Gillett et al. 2013; Matthews et al. 2009). TCRE is a measure of the global temperature response to cumulative emissions of CO₂ and has been identified as a useful and practical tool for evaluating CO₂-induced climate changes (expressed in °C per Tera tons of Carbon, °C/TtC). TCRE values have been estimated for a range of Earth system models (Gillett et al. 2013), (MacDougall et al. 2016). In the following, we use the 5th percentile, mean, and 95th percentile derived from the range of available TCRE values. For each DGVM or observation-based estimate, we then calculate three potential temperature change to bracket the range of climate sensitivities.

6
7

Table A2.1: Model-based and observation-based estimates of the effects historical and future anthropogenic land cover changes have on mean annual global surface air temperature (°C). BGC and BPH correspond to the change in temperature resulting from respectively biogeochemical processes (e.g., changes in atmospheric CO₂ composition) and biophysical processes (e.g., changes in physical land surface characteristics such as albedo, evapotranspiration, and roughness length).

Reference of the study	Time period	Cumulative CO ₂ emissions from anthropogenic land cover change (TtC)	TCRE (°C/TtC)	Change in mean global annual (°C)	
				BGC	BPH

2 **Executive Summary**

3 **Desertification is land degradation in arid, semi-arid, and dry sub-humid areas, collectively**
4 **known as drylands, resulting from many factors, including human activities and climatic**
5 **variations. The range and intensity of desertification have increased in some dryland areas over**
6 **the past several decades (*high confidence*).** Drylands currently cover about 46.2% ($\pm 0.8\%$) of the
7 global land area and are home to 3 billion people. The multiplicity and complexity of the processes of
8 desertification make its quantification difficult. Desertification hotspots, as identified by a decline in
9 vegetation productivity between 1980s and 2000s, extended to about 9.2% of drylands ($\pm 0.5\%$),
10 affecting about 500 (± 120) million people in 2015. The highest numbers of people affected are in
11 South and East Asia, North Africa and Middle East (*low confidence*). Desertification has already
12 reduced agricultural productivity and incomes (*high confidence*) and contributed to the loss of
13 biodiversity in some dryland regions (*medium confidence*). In many dryland areas, spread of invasive
14 plants has led to losses in ecosystem services (*high confidence*), while over-extraction is leading to
15 groundwater depletion (*high confidence*). Unsustainable land management, particularly when coupled
16 with droughts, has contributed to higher dust storm activity, reducing human wellbeing in drylands
17 and beyond (*high confidence*). Dust storms were associated with global cardiopulmonary mortality of
18 about 402,000 people in a single year. Higher intensity of sand storms and sand dune movements are
19 causing disruption and damage to transportation and solar and wind energy harvesting infrastructures
20 (*high confidence*). {3.1.1, 3.1.4, 3.2.1, 3.3.1, 3.4.1, 3.4.2, 3.4.2, 3.7.3, 3.7.4}

21 **Attribution of desertification to climate variability and change and human activities varies in**
22 **space and time (*high confidence*).** Climate variability and anthropogenic climate change, particularly
23 through increases in both land surface air temperature and evapotranspiration, and decreases in
24 precipitation, are *likely* to have played a role, in interaction with human activities, in causing
25 desertification in some dryland areas. The major human drivers of desertification interacting with
26 climate change are expansion of croplands, unsustainable land management practices and increased
27 pressure on land from population and income growth. Poverty is limiting both capacities to adapt to
28 climate change and availability of financial resources to invest in sustainable land management (SLM)
29 (*high confidence*). {3.1.4, 3.2.2, 3.4.2}

30 **Climate change will exacerbate several desertification processes (*medium confidence*).** Although
31 CO₂-fertilisation effect is enhancing vegetation productivity in drylands (*high confidence*), decreases
32 in water availability have a larger effect than CO₂-fertilisation in many dryland areas. There is *high*
33 *confidence* that aridity will increase in some places, but no evidence for a projected global trend in
34 dryland aridity (*medium confidence*). The area at risk of salinisation is projected to increase in the
35 future (*limited evidence, high agreement*). Future climate change is projected to increase the potential
36 for water driven soil erosion in many dryland areas (*medium confidence*), leading to soil organic
37 carbon decline in some dryland areas. {3.1.1, 3.2.2, 3.5.1, 3.5.2, 3.7.1, 3.7.3}

38 **Risks from desertification are projected to increase due climate change (*high confidence*).** Under
39 shared socioeconomic pathway SSP2 (“Middle of the Road”) at 1.5°C, 2°C and 3°C of global
40 warming, the number of dryland population exposed (vulnerable) to various impacts related to water,
41 energy and land sectors (e.g. water stress, drought intensity, habitat degradation) are projected to
42 reach 951 (178) million, 1,152 (220) million and 1,285 (277) million, respectively. While at global
43 warming of 2°C, under SSP1 (sustainability), the exposed (vulnerable) dryland population is 974 (35)
44 million, and under SSP3 (Fragmented World) it is 1,267 (522) million. Around half of the vulnerable
45 population is in South Asia, followed by Central Asia, West Africa and East Asia. {2.2, 3.1.1, 3.2.2,
46 3.5.1, 3.5.2, 7.2.2}

1 **Desertification and climate change, both individually and in combination, will reduce the**
2 **provision of dryland ecosystem services and lower ecosystem health, including losses in**
3 **biodiversity (*high confidence*).** Desertification and changing climate are projected to cause
4 reductions in crop and livestock productivity (*high confidence*), modify the composition of plant
5 species and reduce biological diversity across drylands (*medium confidence*). Rising CO₂ levels will
6 favour more rapid expansion of some invasive plant species in some regions. A reduction in the
7 quality and quantity of resources available to herbivores can have knock-on consequences for
8 predators, which can potentially lead to disruptive ecological cascades (*limited evidence, low*
9 *agreement*). Projected increases in temperature and the severity of drought events across some
10 dryland areas can increase chances of wildfire occurrence (*medium confidence*). {3.1.4, 3.4.1, 3.5.2,
11 3.7.3}

12 **Increasing human pressures on land combined with climate change will reduce the resilience of**
13 **dryland populations and constrain their adaptive capacities (*medium confidence*).** The
14 combination of pressures coming from climate variability, anthropogenic climate change and
15 desertification will contribute to poverty, food insecurity, and increased disease burden (*high*
16 *confidence*), as well as potentially to conflicts (*low confidence*). Although strong impacts of climate
17 change on migration in dryland areas are disputed (*medium evidence, low agreement*), in some places,
18 desertification under changing climate can provide an added incentive to migrate (*medium*
19 *confidence*). Women will be impacted more than men by environmental degradation, particularly in
20 those areas with higher dependence on agricultural livelihoods (*medium evidence, high agreement*).
21 {3.4.2, 3.6.2}

22 **Desertification exacerbates climate change through several mechanisms such as changes in**
23 **vegetation cover, sand and dust aerosols and greenhouse gas fluxes (*high confidence*).** The
24 **extent of areas in which dryness controls CO₂ exchange (rather than temperature) has increased**
25 **by 6% between 1948-2012, and is projected to increase by at least another 8% by 2050 if the**
26 **expansion continues at the same rate. In these areas, net carbon uptake is about 27% lower than**
27 **in other areas (*low confidence*).** Desertification also tends to increase albedo, decreasing energy
28 available at the surface and associated surface temperatures, producing a negative feedback on climate
29 change (*high confidence*). Through its effect on vegetation and soils, desertification changes the
30 absorption and release of associated greenhouse gases (GHGs). Vegetation loss and drying of surface
31 cover due to desertification increases the frequency of dust storms (*high confidence*). Arid ecosystems
32 could be an important global carbon sink depending on soil water availability (*medium evidence, high*
33 *agreement*). {3.3.3, 3.4.1, 3.5.2}

34 **Site-specific technological solutions, based both on new scientific innovations and indigenous**
35 **and local knowledge (ILK), are available to avoid, reduce and reverse desertification,**
36 **simultaneously contributing to climate change mitigation and adaptation (*high confidence*).**
37 SLM practices in drylands increase agricultural productivity and contribute to climate change
38 adaptation and mitigation (*high confidence*). Integrated crop, soil and water management measures
39 can be employed to reduce soil degradation and increase the resilience of agricultural production
40 systems to the impacts of climate change (*high confidence*). These measures include crop
41 diversification and adoption of drought-tolerant crops, reduced tillage, adoption of improved irrigation
42 techniques (e.g. drip irrigation) and moisture conservation methods (e.g. rainwater harvesting using
43 indigenous and local practices), and maintaining vegetation and mulch cover. Conservation
44 agriculture increases the capacity of agricultural households to adapt to climate change (*high*
45 *confidence*) and can lead to increases in soil organic carbon over time, with quantitative estimates of
46 the rates of carbon sequestration in drylands following changes in agricultural practices ranging
47 between 0.04-0.4 t ha⁻¹(*medium confidence*). Rangeland management systems based on sustainable

1 grazing and re-vegetation increase rangeland productivity and the flow of ecosystem services (*high*
2 *confidence*). The combined use of salt-tolerant crops, improved irrigation practices, chemical
3 remediation measures and appropriate mulch and compost is effective in reducing the impact of
4 secondary salinisation (*medium confidence*). Application of sand dune stabilisation techniques
5 contributes to reducing sand and dust storms (*high confidence*). Agroforestry practices and
6 shelterbelts help reduce soil erosion and sequester carbon. Afforestation programmes aimed at
7 creating windbreaks in the form of “green walls” and “green dams” can help stabilise and reduce dust
8 storms, avert wind erosion, and serve as carbon sinks, particularly when done with locally adapted
9 tree species (*high confidence*). {3.4.2, 3.6.1, 3.7.2}

10 **Investments into SLM, land restoration and rehabilitation in dryland areas have positive**
11 **economic returns (*high confidence*)**. Each USD invested into land restoration can have social returns
12 of about 3–6 USD over a 30-year period. Most SLM practices can become financially profitable
13 within three to 10 years (*medium evidence, high agreement*). Despite their benefits in addressing
14 desertification, mitigating and adapting to climate change, and increasing food and economic security,
15 many SLM practices are not widely adopted due to insecure land tenure, lack of access to credit and
16 agricultural advisory services, and insufficient incentives for private land users (*robust evidence, high*
17 *agreement*). {3.6.3}

18 **Indigenous and local knowledge (ILK) often contribute to enhancing resilience against climate**
19 **change and combating desertification (*medium confidence*)**. Dryland populations have developed
20 traditional agroecological practices which are well adapted to resource-sparse dryland environments.
21 However, there is *robust evidence* documenting losses of traditional agroecological knowledge.
22 Traditional agroecological practices are also increasingly unable to cope with growing demand for
23 food. Combined use of ILK and new SLM technologies can contribute to raising the resilience to the
24 challenges of climate change and desertification (*high confidence*). {3.1.3, 3.6.1, 3.6.2}

25 **Policy frameworks promoting the adoption of SLM solutions contribute to addressing**
26 **desertification as well as mitigating and adapting to climate change, with co-benefits for poverty**
27 **reduction and food security among dryland populations (*high confidence*)**. **Implementation of**
28 **Land Degradation Neutrality policies allows to avoid, reduce and reverse desertification, thus,**
29 **contributing to climate change adaptation and mitigation (*high confidence*)**. Strengthening land
30 tenure security is a major factor contributing to the adoption of soil conservation measures in
31 croplands (*high confidence*). On-farm and off-farm livelihood diversification strategies increase the
32 resilience of rural households against desertification and extreme weather events, such as droughts
33 (*high confidence*). Strengthening collective action is important for addressing causes and impacts of
34 desertification, and for adapting to climate change (*medium confidence*). A greater emphasis on
35 understanding gender-specific differences over land use and land management practices can help
36 make land restoration projects more successful (*medium confidence*). Improved access to markets
37 raises agricultural profitability and motivates investment into climate change adaptation and SLM
38 (*medium confidence*). Payments for ecosystem services give additional incentives to land users to
39 adopt SLM practices (*medium confidence*). Expanding access to rural advisory services increases the
40 knowledge on SLM and facilitates their wider adoption (*medium confidence*). Transition to modern
41 renewable energy sources can contribute to reducing desertification and mitigating climate change
42 through decreasing the use of fuelwood and crop residues for energy (*medium confidence*). Policy
43 responses to droughts based on pro-active drought preparedness and drought risk mitigation are more
44 efficient in limiting drought-caused damages than reactive drought relief efforts (*high confidence*).
45 {3.4.2, 3.6.2, 3.6.3, Cross-Chapter Box 5 in this chapter}

46 **The knowledge on limits to adaptation to combined effects of climate change and desertification**
47 **is insufficient. However, the potential for residual risks and maladaptive outcomes is high (*high***
48 ***confidence*)**. Empirical evidence on the limits to adaptation in dryland areas is limited, potential limits

1 to adaptation include losses of land productivity due to irreversible forms of desertification. Residual
2 risks can emerge from the inability of SLM measures to fully compensate for yield losses due to
3 climate change impacts, as well as foregone reductions in ecosystem services due to soil fertility loss
4 even when applying SLM measures could revert land to initial productivity after some time. Some
5 activities favouring agricultural intensification in dryland areas can become maladaptive due to their
6 negative impacts on the environment (*medium confidence*) {3.6.4}.

7 **Improving capacities, providing higher access to climate services, including local level early**
8 **warning systems, and expanding the use of remote sensing technologies are high return**
9 **investments for enabling effective adaptation and mitigation responses that help address**
10 **desertification (*high confidence*)**. Reliable and timely climate services, relevant to desertification,
11 can aid the development of appropriate adaptation and mitigation options reducing the impact of
12 desertification on human and natural systems (*high confidence*), with quantitative estimates pointing
13 that every USD invested in strengthening hydro-meteorological and early warning services in
14 developing countries can yield between 4 to 35 USD (*low confidence*). Knowledge and flow of
15 knowledge on desertification is currently fragmented. Improved knowledge and data exchange and
16 sharing will increase the effectiveness of efforts to achieve Land Degradation Neutrality (*high*
17 *confidence*). Expanded use of remotely sensed information for data collection helps in measuring
18 progress towards achieving Land Degradation Neutrality (*low evidence, high agreement*). {3.2.1,
19 3.6.2, 3.6.3, Cross-Chapter Box 5 in this chapter}

20

3.1. The Nature of Desertification

3.1.1. Introduction

In this report, desertification is defined as land degradation in arid, semi-arid, and dry sub-humid areas resulting from many factors, including climatic variations and human activities (United Nations Convention to Combat Desertification (UNCCD 1994). Land degradation is a negative trend in land condition, caused by direct or indirect human-induced processes including anthropogenic climate change, expressed as long-term reduction or loss of at least one of the following: biological productivity, ecological integrity or value to humans (4.1.3). Arid, semi-arid, and dry sub-humid areas, together with hyper-arid areas, constitute drylands (UNEP, 1992), home to about 3 billion people (van der Esch et al., 2017). The difference between desertification and land degradation is not process-based but geographic. Although land degradation can occur anywhere across the world, when it occurs in drylands, it is considered desertification (FAQ 1.3). Desertification is not limited to irreversible forms of land degradation, nor is it equated to desert expansion, but represents all forms and levels of land degradation occurring in drylands.

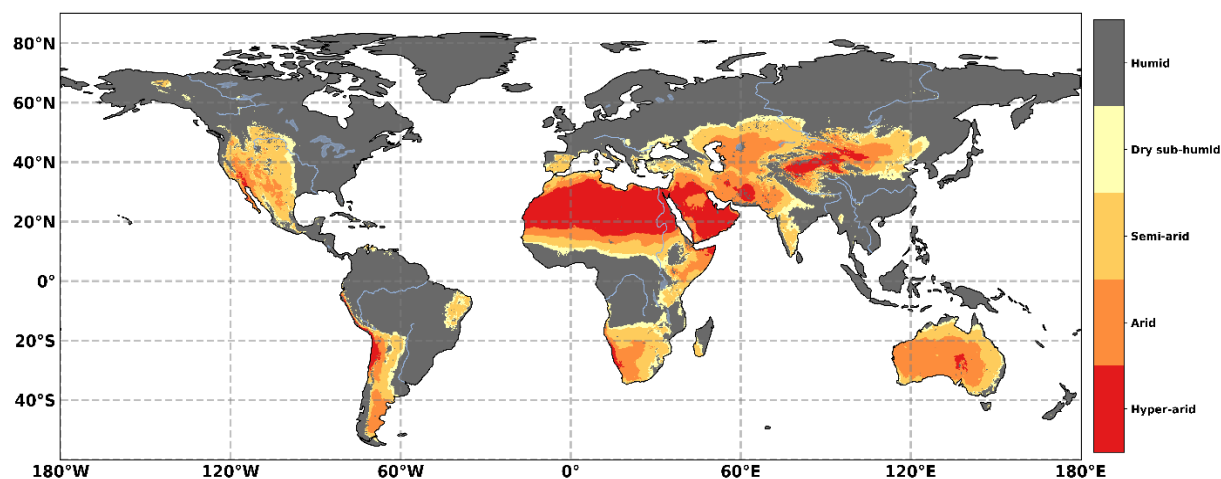

Figure 3.1 Geographical distribution of drylands, delimited based on the Aridity Index (AI). The classification of AI is: Humid $AI > 0.65$, Dry sub-humid $0.50 < AI \leq 0.65$, Semi-arid $0.20 < AI \leq 0.50$, Arid $0.05 < AI \leq 0.20$, Hyper-arid $AI < 0.05$. Data: TerraClimate precipitation and potential evapotranspiration (1980-2015) (Abatzoglou et al., 2018).

The geographic classification of drylands is often based on the aridity index (AI) - the ratio of average annual precipitation amount (P) to potential evapotranspiration amount (PET, see glossary) (Figure 3.1). Recent estimates, based on AI, suggest that drylands cover about 46.2% ($\pm 0.8\%$) of the global land area (Koutroulis, 2019; Průvák, 2016) (*low confidence*). Hyper-arid areas, where the aridity index is below 0.05, are included in drylands, but are excluded from the definition of desertification (UNCCD, 1994). Deserts are valuable ecosystems (UNEP, 2006; Safriel, 2009) geographically located in drylands and vulnerable to climate change. However, they are not considered prone to desertification. Aridity is a long-term climatic feature characterised by low average precipitation or available water (Gbeckor-Kove, 1989; Türkeş, 1999). Thus, aridity is different from drought which is a temporary climatic event (Maliva and Missimer, 2012). Moreover, droughts are not restricted to drylands, but occur both in drylands and humid areas (Wilhite et al., 2014). Following the Synthesis Report (SYR) of the IPCC Fifth Assessment Report (AR5), drought is defined here as “a period of abnormally dry weather long enough to cause a serious hydrological imbalance” (Mach et al., 2014; Cross-Chapter Box 5: Case study on policy responses to drought, in this chapter).

1 AI is not an accurate proxy for delineating drylands in an increasing CO₂ environment (3.2.1). The
 2 suggestion that most of the world has become more arid, since the AI has decreased, is not supported
 3 by changes observed in precipitation, evaporation or drought (Sheffield et al., 2012; Greve et al.,
 4 2014). While climate change is expected to decrease the AI due to increases in potential evaporation,
 5 the assumptions that underpin the potential evaporation calculation are not consistent with a changing
 6 CO₂ environment and the effect this has on transpiration rates (3.2.1; Roderick et al., 2015; Milly and
 7 Dunne, 2016; Greve et al., 2017). Given that future climate is characterised by significant increases in
 8 CO₂, the usefulness of currently applied AI thresholds to estimate dryland areas is limited under
 9 climate change. If instead of the AI, other variables such as precipitation, soil moisture, and primary
 10 productivity are used to identify dryland areas, there is no clear indication that the extent of drylands
 11 will change overall under climate change (Roderick et al., 2015; Greve et al., 2017; Lemordant et al.,
 12 2018). Thus, some dryland borders will expand, while some others will contract (*high confidence*).

13 Approximately 70% of dryland areas are located in Africa and Asia (Figure 3.2). The biggest land
 14 use/cover in terms of area in drylands, if deserts are excluded, are grasslands, followed by forests and
 15 croplands (Figure 3.3). The category of “other lands” in Figure 3.3 includes bare soil, ice, rock, and
 16 all other land areas that are not included within the other five categories (FAO, 2016). Thus, hyper-
 17 arid areas contain mostly deserts, with some small exceptions, for example, where grasslands and
 18 croplands are cultivated under oasis conditions with irrigation (3.7.4). Moreover, FAO (2016) defines
 19 grasslands as permanent pastures and meadows used continuously for more than five years. In
 20 drylands, transhumance, i.e. seasonal migratory grazing, often leads to non-permanent pasture
 21 systems, thus, some of the areas under “other land” category are also used as non-permanent pastures
 22 (Ramankutty et al., 2008; Fetzel et al., 2017; Erb et al., 2016).

23

24 **Figure 3.2 Dryland categories across geographical areas (continents and Pacific region). Data:**
 25 **TerraClimate precipitation and potential evapotranspiration (1980-2015) (Abatzoglou et al., 2018).**

26 In the earlier global assessments of desertification (since the 1970s), which were based on qualitative
 27 expert evaluations, the extent of desertification was found to range between 4% and 70% of the area
 28 of drylands (Safriel, 2007). More recent estimates, based on remotely sensed data, show that about
 29 24–29% of the global land area experienced reductions in biomass productivity between 1980s and

1 2000s (Bai et al., 2008; Le et al., 2016), corresponding to about 9.2% of drylands ($\pm 0.5\%$)
 2 experiencing declines in biomass productivity during this period (*low confidence*), mainly due to
 3 anthropogenic causes. Both of these studies consider rainfall dynamics, thus, accounting for the effect
 4 of droughts. While less than 10% of drylands is undergoing desertification, it is occurring in areas that
 5 contain around 20% of dryland population (Klein Goldewijk et al., 2017). In these areas the population
 6 has increased from ~172 million in 1950 to over 630 million today (Figure 1.1).

7
 8 **Figure 3.3 Land use and land cover in drylands and share of each dryland category in global land area.**
 9 **Source: FAO (2016).**

10 Available assessments of the global extent and severity of desertification are relatively crude
 11 approximations with considerable uncertainties, for example, due to confounding effects of invasive
 12 bush encroachment in some dryland regions. Different indicator sets and approaches have been
 13 developed for monitoring and assessment of desertification from national to global scales (Imeson,
 14 2012; Sommer et al., 2011; Zucca et al., 2012; Bestelmeyer et al., 2013). Many indicators of
 15 desertification only include a single factor or characteristic of desertification, such as the patch size
 16 distribution of vegetation (Maestre and Escudero, 2009; Kéfi et al., 2010), Normalized Difference
 17 Vegetation Index (NDVI) (Piao et al., 2005), drought-tolerant plant species (An et al., 2007), grass
 18 cover (Bestelmeyer et al., 2013), land productivity dynamics (Baskan et al., 2017), ecosystem net
 19 primary productivity (Zhou et al., 2015) or environmentally sensitive land area index (Symeonakis et
 20 al., 2016). In addition, some synthetic indicators of desertification have also been used to assess
 21 desertification extent and desertification processes, such as climate, land use, soil, and socioeconomic
 22 parameters (Dharumarajan et al., 2018), or changes in climate, land use, vegetation cover, soil
 23 properties and population as the desertification vulnerability index (Salvati et al., 2009). Current data
 24 availability and methodological challenges do not allow for accurately and comprehensively mapping
 25 desertification at a global scale (Cherlet et al., 2018). However, the emerging partial evidence points
 26 to a lower global extent of desertification than previously estimated (*medium confidence*) (3.2).

1 This assessment examines the socio-ecological links between drivers (3.1) and feedbacks (3.3) that
2 influence desertification-climate change interactions, and then examines associated observed and
3 projected impacts (3.4, 3.5) and responses (3.6). Moreover, this assessment highlights that dryland
4 populations are highly vulnerable to desertification and climate change (3.2, 3.4). At the same time,
5 dryland populations also have significant past experience and sources of resilience embodied in
6 indigenous and local knowledge and practices in order to successfully adapt to climatic changes and
7 address desertification (3.6). Numerous site-specific technological response options are also available
8 for SLM in drylands that can help increase the resilience of agricultural livelihood systems to climate
9 change (3.6). However, continuing environmental degradation combined with climate change are
10 straining the resilience of dryland populations. Enabling policy responses for SLM and livelihoods
11 diversification can help maintain and strengthen the resilience and adaptive capacities in dryland areas
12 (3.6). The assessment finds that policies promoting SLM in drylands will contribute to climate change
13 adaptation and mitigation, with co-benefits for broader sustainable development (*high confidence*)
14 (3.4).

16 3.1.2. Desertification in previous IPCC and related reports

17 The IPCC Fifth Assessment report (AR5) and Special Report on Global Warming of 1.5°C include a
18 limited discussion of desertification. In AR5 Working Group I desertification is mentioned as a
19 forcing agent for the production of atmospheric dust (Myhre et al., 2013). The same report had *low*
20 *confidence* in the available projections on the changes in dust loadings due to climate change
21 (Boucher et al., 2013). In AR5 Working Group II, desertification is identified as a process that can
22 lead to reductions in crop yields and the resilience of agricultural and pastoral livelihoods (Field et al.,
23 2014; Klein et al., 2015). AR5 Working Group II notes that climate change will amplify water
24 scarcity with negative impacts on agricultural systems, particularly in semi-arid environments of
25 Africa (*high confidence*), while droughts could exacerbate desertification in south-western parts of
26 Central Asia (Field et al., 2014). AR5 Working Group III identifies desertification as one of a number
27 of often overlapping issues that must be dealt with when considering governance of mitigation and
28 adaptation (Fleurbaey et al., 2014). The IPCC Special Report on Global Warming of 1.5°C noted that
29 limiting global warming to 1.5°C instead of 2°C is strongly beneficial for land ecosystems and their
30 services (*high confidence*) such as soil conservation, contributing to avoidance of desertification
31 (Hoegh-Guldberg et al., 2018).

32 The recent Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services
33 (IPBES) Assessment report on land degradation and restoration (IPBES, 2018a) is also of particular
34 relevance. While acknowledging a wide variety of past estimates of the area undergoing degradation,
35 IPBES (2018a) pointed at their lack of agreement about where degradation is taking place. IPBES
36 (2018a) also recognised the challenges associated with differentiating the impacts of climate
37 variability and change on land degradation from the impacts of human activities at a regional or
38 global scale.

39 The third edition of the World Atlas of Desertification (Cherlet et al., 2018) indicated that it is not
40 possible to deterministically map the global extent of land degradation, and its subset - desertification,
41 pointing out that the complexity of interactions between social, economic, and environmental systems
42 make land degradation not amenable to mapping at a global scale. Instead, Cherlet et al. (2018)
43 presented global maps highlighting the convergence of various pressures on land resources.

3.1.3. Dryland Populations: Vulnerability and Resilience

Drylands are home to approximately 38.2% ($\pm 0.6\%$) of the global population (Koutroulis, 2019; van der Esch et al., 2017), that is about 3 billion people. The highest number of people live in the drylands of South Asia (Figure 3.4), followed by Sub-Saharan Africa and Latin America (van der Esch et al., 2017). In terms of the number of people affected by desertification, Reynolds et al. (2007) indicated that desertification was directly affecting 250 million people. More recent estimates show that 500 (± 120) million people lived in 2015 in those dryland areas which experienced significant loss in biomass productivity between 1980s and 2000s (Bai et al., 2008; Le et al., 2016). The highest numbers of affected people were in South and East Asia, North Africa and Middle East (*low confidence*). The population in drylands is projected to increase about twice as rapidly as non-drylands, reaching 4 billion people by 2050 (van der Esch et al., 2017). This is due to higher population growth rates in drylands. About 90% of the population in drylands live in developing countries (UN-EMG, 2011).

Dryland populations are highly vulnerable to desertification and climate change (Howe et al., 2013; Huang et al., 2016, 2017; Liu et al., 2016b; Thornton et al., 2014; Lawrence et al., 2018) because their livelihoods are predominantly dependent on agriculture; one of the sectors most susceptible to climate change (Rosenzweig et al., 2014; Schlenker and Lobell, 2010). Climate change is projected to have substantial impacts on all types of agricultural livelihood systems in drylands (CGIAR-RPDS, 2014) (3.4.1, 3.4.2).

Figure 3.4 Current (a) and projected population (under SSP2) (b) in drylands, in billions.
Source: van der Esch et al. (2017)

One key vulnerable group in drylands are pastoral and agropastoral households¹. There are no precise figures about the number of people practicing pastoralism globally. Most estimates range between 100 to 200 million (Rass, 2006; Secretariat of the Convention on Biological Diversity, 2010), of whom 30–63 million are nomadic pastoralists (Dong, 2016; Carr-Hill, 2013)². Pastoral production systems represent an adaptation to high seasonal climate variability and low biomass productivity in dryland ecosystems (Varghese and Singh, 2016; Krätli and Schareika, 2010), which require large areas for

¹FOOTNOTE: Pastoralists derive more than 50% of their income from livestock and livestock products, whereas agro-pastoralists generate more than 50% of their income from crop production and at least 25% from livestock production (Swift, 1988).

²FOOTNOTE: The estimates of the number of pastoralists, and especially of nomadic pastoralists, are very uncertain, because often nomadic pastoralists are not fully captured in national surveys and censuses (Carr-Hill, 2013).

1 livestock grazing through migratory pastoralism (Snorek et al., 2014). Grazing lands across dryland
2 environments are being degraded, and/or being converted to crop production, limiting the
3 opportunities for migratory livestock systems, and leading to conflicts with sedentary crop producers
4 (Abbass, 2014; Dimelu et al., 2016). These processes, coupled with ethnic differences, perceived
5 security threats, and misunderstanding of pastoral rationality, have led to increasing marginalisation
6 of pastoral communities and disruption of their economic and cultural structures (Elhadary, 2014;
7 Morton, 2010). As a result, pastoral communities are not well prepared to deal with increasing
8 weather/climate variability and weather/climate extremes due to changing climate (Dong, 2016;
9 López-i-Gelats et al., 2016), and remain amongst the most food insecure groups in the world (FAO,
10 2018).

11 There is an increasing concentration of poverty in the dryland areas of Sub-Saharan Africa and South
12 Asia (von Braun and Gatzweiler, 2014; Barbier and Hochard, 2016), where 41% and 12% of the total
13 populations live in extreme poverty, respectively (World Bank, 2018). For comparison, the average
14 share of global population living in extreme poverty is about 10% (World Bank, 2018).
15 Multidimensional poverty, prevalent in many dryland areas, is a key source of vulnerability (Safriel et
16 al., 2005; Thornton et al., 2014; Fraser et al., 2011; Thomas, 2008). Multidimensional poverty
17 incorporates both income-based poverty, and also other dimensions such as poor healthcare services,
18 lack of education, lack of access to water, sanitation and energy, disempowerment, and threat from
19 violence (Bourguignon and Chakravarty, 2003; Alkire and Santos, 2010, 2014). Contributing
20 elements to this multidimensional poverty in drylands are rapid population growth, fragile
21 institutional environment, lack of infrastructure, geographic isolation and low market access, insecure
22 land tenure systems, and low agricultural productivity (Sietz et al., 2011; Reynolds et al., 2011;
23 Safriel and Adeel, 2008; Stafford Smith, 2016). Even in high-income countries, those dryland areas
24 that depend on agricultural livelihoods represent relatively poorer locations nationally, with fewer
25 livelihood opportunities, for example in Italy (Salvati, 2014). Moreover, in many drylands areas,
26 female-headed households, women and subsistence farmers (both male and female) are more
27 vulnerable to the impacts of desertification and climate change (Nyantakyi-Frimpong and Bezner-
28 Kerr, 2015; Sultana, 2014; Rahman, 2013). Some local cultural traditions and patriarchal relationships
29 were found to contribute to higher vulnerability of women and female-headed households through
30 restrictions on their access to productive resources (Nyantakyi-Frimpong and Bezner-Kerr, 2015;
31 Sultana, 2014; Rahman, 2013) (3.4.2, 3.6.3; Cross-Chapter Box 11: Gender, Chapter 7).

32 Despite these environmental, socio-economic and institutional constraints, dryland populations have
33 historically demonstrated remarkable resilience, ingenuity and innovations, distilled into indigenous
34 and local knowledge to cope with high climatic variability and sustain livelihoods (Safriel and Adeel,
35 2008; Davis, 2016; Davies, 2017; 3.6.1, 3.6.2; Cross-Chapter Box 13: Indigenous and Local
36 Knowledge, Chapter 7). For example, across the Arabian Peninsula and North Africa, informal
37 community bylaws were successfully used for regulating grazing, collection and cutting of herbs and
38 wood, that limited rangeland degradation (Gari, 2006; Hussein, 2011). Pastoralists in Mongolia
39 developed indigenous classifications of pasture resources which facilitated ecologically optimal
40 grazing practices (Fernandez-Gimenez, 2000) (3.6.2). Currently, however, indigenous and local
41 knowledge and practices are increasingly lost or can no longer cope with growing demands for land-
42 based resources (Dominguez, 2014; Fernández-Giménez and Fillat Estaque, 2012; Hussein, 2011;
43 Kodirekkala, 2017; Moreno-Calles et al., 2012; 3.4.2). Unsustainable land management is increasing
44 the risks from droughts, floods and dust storms (3.4.2, 3.5). Policy actions promoting the adoption of
45 SLM practices in dryland areas, based on both indigenous and local knowledge and modern science,
46 and expanding alternative livelihood opportunities outside agriculture can contribute to climate
47 change adaptation and mitigation, addressing desertification, with co-benefits for poverty reduction
48 and food security (*high confidence*) (Cowie et al., 2018; Liniger et al., 2017; Safriel and Adeel, 2008;
49 Stafford-Smith et al., 2017).

3.1.4. Processes and Drivers of Desertification under Climate Change

3.1.4.1 Processes of Desertification and Their Climatic Drivers

Processes of desertification are mechanisms by which drylands are degraded. Desertification consists of both biological and non-biological processes. These processes are classified under broad categories of degradation of physical, chemical and biological properties of terrestrial ecosystems. The number of desertification processes is large and they are extensively covered elsewhere (IPBES, 2018a; Lal, 2016; Racine, 2008; UNCCD, 2017). Section 4.2.1 and Tables 4.1-4.2 in Chapter 4 highlight those which are particularly relevant for this assessment in terms of their links to climate change and land degradation, including desertification.

Drivers of desertification are factors which trigger desertification processes. Initial studies of desertification during the early-to-mid 20th century attributed it entirely to human activities. In one of the influential publications of that time, Lavauden (1927) stated that: "Desertification is purely artificial. It is only the act of the man..." However, such a uni-causal view on desertification was shown to be invalid (Geist et al., 2004; Reynolds et al., 2007) (3.1.4.2, 3.1.4.3). Tables 4.1-4.2 in Chapter 4 summarise drivers, linking them to the specific processes of desertification and land degradation under changing climate.

Erosion refers to removal of soil by the physical forces of water, wind, or often caused by farming activities such as tillage (Ginoux et al., 2012). The global estimates of soil erosion differ significantly, depending on scale, study period and method used (García-Ruiz et al., 2015), ranging from approximately 20 Gt yr⁻¹ to more than 200 Gt yr⁻¹ (Boix-Fayos et al., 2006; FAO, 2015). There is a significant potential for climate change to increase soil erosion by water particularly in those regions where precipitation volumes and intensity are projected to increase (Panthou et al., 2014; Nearing et al., 2015). On the other hand, while it is a dominant form of erosion in areas such as West Asia and the Arabian Peninsula (Prakash et al., 2015; Klingmüller et al., 2016), there is *limited evidence* concerning climate change impacts on wind erosion (Tables 4.1-4.2 in Chapter 4; 3.5).

Saline and sodic soils (see glossary) occur naturally in arid, semiarid and dry sub-humid regions of the world. Climate change or hydrological change can cause soil salinisation by increasing the mineralised ground water level. However, secondary salinisation occurs when the concentration of dissolved salts in water and soil is increased by anthropogenic processes, mainly through poorly managed irrigation schemes. The threat of soil and groundwater salinisation induced by sea level rise and sea water intrusion are amplified by climate change (4.9.7).

Global warming is expected to accelerate soil organic carbon (SOC) turnover, since the decomposition of the soil organic matter by microbial activity begins with low soil water availability, but this moisture is insufficient for plant productivity (Austin et al., 2004; 3.4.1.1), as well as losses by soil erosion (Lal, 2009); therefore, in some dryland areas leading to SOC decline (3.3.3; 3.5.2) and the transfer of carbon (C) from soil to the atmosphere (Lal, 2009).

Sea surface temperature (SST) anomalies can drive rainfall changes, with implications for desertification processes. North Atlantic SST anomalies are positively correlated with Sahel rainfall anomalies (Knight et al., 2006; Gonzalez-Martin et al., 2014; Sheen et al., 2017). While the eastern tropical Pacific SST anomalies have a negative correlation with Sahel rainfall (Pomposi et al., 2016), a cooler north Atlantic is related to a drier Sahel, with this relationship enhanced if there is a simultaneous relative warming of the south Atlantic (Hoerling et al., 2006). Huber and Fensholt (2011) explored the relationship between SST anomalies and satellite observed Sahel vegetation dynamics finding similar relationships but with substantial west-east variations in both the significant SST regions and the vegetation response. Concerning the paleoclimatic evidence on aridification after the early Holocene "Green Sahara" period (11,000 to 5000 years ago), Tierney et al. (2017) indicate

1 that a cooling of the north Atlantic played a role (Collins et al., 2017; Otto-Bliesner et al., 2014;
2 Niedermeyer et al., 2009) similar to that found in modern observations. Besides these SST
3 relationships, aerosols have also been suggested as a potential driver of the Sahel droughts (Rotstayn
4 and Lohmann, 2002; Booth et al., 2012; Ackerley et al., 2011). For Eastern Africa, both recent
5 droughts and decadal declines have been linked to human-induced warming in the western Pacific
6 (Funk et al., 2018).

7 Invasive plants contributed to desertification and loss of ecosystem services in many dryland areas in
8 the last century (*high confidence*) (3.7.3). Extensive woody plant encroachment altered runoff and soil
9 erosion across much of the drylands, because the bare soil between shrubs is very susceptible to water
10 erosion, mainly in high-intensity rainfall events (Manjoro et al., 2012; Pierson et al., 2013; Eldridge et
11 al., 2015). Rising CO₂ levels due to global warming favour more rapid expansion of some invasive
12 plant species in some regions. An example is the Great Basin region in western North America where
13 over 20% of ecosystems have been significantly altered by invasive plants, especially exotic annual
14 grasses and invasive conifers resulting in loss of biodiversity. This land cover conversion has resulted
15 in reductions in forage availability, wildlife habitat, and biodiversity (Pierson et al., 2011, 2013;
16 Miller et al., 2013).

17 The wildfire is a driver of desertification, because it reduces vegetation cover, increases runoff and
18 soil erosion, reduces soil fertility and affects the soil microbial community (Vega et al., 2005; Nyman
19 et al., 2010; Holden et al., 2013; Pourreza et al., 2014; Weber et al., 2014; Liu and Wimberly, 2016).
20 Predicted increases in temperature and the severity of drought events across some dryland areas (2.2)
21 can increase chances of wildfire occurrence (*medium confidence*) (Jolly et al., 2015; Williams et al.,
22 2010; Clarke and Evans, 2018; Cross-Chapter Box 3: Fire and Climate Change, Chapter 2). In
23 semiarid and dry sub-humid areas, fire can have a profound influence on observed vegetation and
24 particularly the relative abundance of grasses to woody plants (Bond et al., 2003; Bond and Keeley,
25 2005; Balch et al., 2013).

26 While large uncertainty exists concerning trends in droughts globally (AR5, 2.2), examining the
27 drought data by Ziese et al. (2014) for drylands only reveals a large inter-annual variability combined
28 with a trend toward increasing dryland area affected by droughts since 1950s (Figure 1.1).

29 **3.1.4.2. Anthropogenic Drivers of Desertification under Climate Change**

30 The literature on the human drivers of desertification is substantial (D'Odorico et al., 2013; Sietz et
31 al., 2011; Yan and Cai, 2015; Sterk et al., 2016; Varghese and Singh, 2016; to list a few) and there
32 have been several comprehensive reviews and assessments of these drivers very recently (Cherlet et
33 al., 2018; IPBES, 2018a; UNCCD, 2017). IPBES (2018a) identified cropland expansion,
34 unsustainable land management practices including overgrazing by livestock, urban expansion,
35 infrastructure development, and extractive industries as the main drivers of land degradation. IPBES
36 (2018a) also found that the ultimate driver of land degradation is high and growing consumption of
37 land-based resources, e.g. through deforestation and cropland expansion, escalated by population
38 growth. What is particularly relevant in the context of the present assessment is to evaluate if, how
39 and which human drivers of desertification will be modified by climate change effects.

40 Growing food demand is driving conversion of forests, rangelands, and woodlands into cropland
41 (Bestelmeyer et al., 2015; D'Odorico et al., 2013). Climate change is projected to reduce crop yields
42 across dryland areas (3.4.1; 5.2.2), potentially reducing local production of food and feed. Without
43 research breakthroughs mitigating these productivity losses through higher agricultural productivity,
44 and reducing food waste and loss, meeting increasing food demands of growing populations will
45 require expansion of cropped areas to more marginal areas (with most prime areas in drylands already
46 being under cultivation) (Lambin, 2012; Lambin et al., 2013; Eitelberg et al., 2015; Gutiérrez-Elorza,
47 2006; Kapović Solomun et al., 2018). Borrelli et al. (2017) showed that the primary driver of soil
48 erosion in 2012 was cropland expansion. Although local food demands could also be met by

1 importing from other areas, this would mean increasing the pressure on land in those areas (Lambin
2 and Meyfroidt, 2011). The net effects of such global agricultural production shifts on land condition
3 in drylands are not known.

4 Climate change will exacerbate poverty among some categories of dryland populations (3.4.2; 3.5.2).
5 Depending on the context, this impact comes through declines in agricultural productivity, changes in
6 agricultural prices and extreme weather events (Hertel and Lobell, 2014; Hallegatte and Rozenberg,
7 2017). There is *high confidence* that poverty limits both capacities to adapt to climate change and
8 availability of financial resources to invest into SLM (3.5.2; 3.6.2; 3.6.3; Gerber et al., 2014; Way,
9 2016; Vu et al., 2014).

10 Labour mobility is another key human driver which will interact with climate change. Although
11 strong impacts of climate change on migration in dryland areas are disputed, in some places, it is
12 *likely* to provide an added incentive to migrate (3.4.2.7). Out-migration will have several
13 contradictory effects on desertification. On one hand, it reduces an immediate pressure on land if it
14 leads to less dependence on land for livelihoods (Chen et al., 2014; Liu et al., 2016a). Moreover,
15 migrant remittances could be used to fund the adoption of SLM practices. Labour mobility from
16 agriculture to non-agricultural sectors could allow land consolidation, gradually leading to
17 mechanisation and agricultural intensification (Wang et al., 2014, 2018). On the other hand, this can
18 increase the costs of labour-intensive SLM practices due to lower availability of rural agricultural
19 labour and/or higher rural wages. Out-migration increases the pressure on land if higher wages that
20 rural migrants earn in urban centres will lead to their higher food consumption. Moreover, migrant
21 remittances could also be used to fund land use expansion to marginal areas (Taylor et al., 2016; Gray
22 and Bilsborrow, 2014). The net effect of these opposite mechanisms varies from place to place (Qin
23 and Liao, 2016). There is very little literature evaluating these joint effects of climate change,
24 desertification and labour mobility (7.3.2).

25 There are also many other institutional, policy and socio-economic drivers of desertification, such as
26 land tenure insecurity, lack of property rights, lack of access to markets, and to rural advisory
27 services, lack of technical knowledge and skills, agricultural price distortions, agricultural support and
28 subsidies contributing to desertification, and lack of economic incentives for SLM (D’Odorico et al.,
29 2013; Geist et al., 2004; Moussa et al., 2016; Mythili and Goedecke, 2016; Sow et al., 2016; Tun et
30 al., 2015; García-Ruiz, 2010). There is no evidence that these factors will be materially affected by
31 climate change, however, serving as drivers of unsustainable land management practices, they do play
32 a very important role in modulating responses for climate change adaptation and mitigation (3.6.3).

33 ***3.1.4.3 Interaction of Drivers: Desertification Syndrome versus Drylands Development*** 34 ***Paradigm***

35 Two broad narratives have historically emerged to describe responses of dryland populations to
36 environmental degradation. The first is “desertification syndrome” which describes the vicious cycle
37 of resource degradation and poverty, whereby dryland populations apply unsustainable agricultural
38 practices leading to desertification, and exacerbating their poverty, which then subsequently further
39 limits their capacities to invest in SLM (MEA, 2005; Safriel and Adeel, 2008). The alternative
40 paradigm is one of “drylands development”, which refers to social and technical ingenuity of dryland
41 populations as a driver of dryland sustainability (MEA, 2005; Reynolds et al., 2007; Safriel and
42 Adeel, 2008). The major difference between these two frameworks is that the “drylands development
43 paradigm” recognises that human activities are not the sole and/or most important drivers of
44 desertification, but there are interactions of human and climatic drivers within coupled social-
45 ecological systems (Reynolds et al., 2007). This led Behnke and Mortimore (2016), and earlier Swift
46 (1996), to conclude that the concept of desertification as irreversible degradation distorts policy and
47 governance in the dryland areas. Mortimore (2016) suggested that instead of externally imposed
48 technical solutions, what is needed is for populations in dryland areas to adapt to this variable

1 environment which they cannot control. All in all, there is *high confidence* that anthropogenic and
2 climatic drivers interact in complex ways in causing desertification. As discussed in Section 3.2.2, the
3 relative influence of human or climatic drivers on desertification varies from place to place (*high*
4 *confidence*) (Bestelmeyer et al., 2018; D’Odorico et al., 2013; Geist and Lambin, 2004; Kok et al.,
5 2016; Polley et al., 2013; Ravi et al., 2010; Scholes, 2009; Sietz et al., 2017; Sietz et al., 2011).

7 **3.2. Observations of Desertification**

8 **3.2.1. Status and Trends of Desertification**

9 Current estimates of the extent and severity of desertification vary greatly due to missing and/or
10 unreliable information (Gibbs and Salmon, 2015). The multiplicity and complexity of the processes of
11 desertification make its quantification difficult (Prince, 2016; Cherlet et al., 2018). The most common
12 definition for the drylands is based on defined thresholds of the AI (Figure 3.1) (UNEP, 1992). While
13 past studies have used the AI to examine changes in desertification or extent of the drylands (Feng
14 and Fu, 2013; Zarch et al., 2015; Ji et al., 2015; Spinoni et al., 2015; Huang et al., 2016; Ramarao et
15 al., 2018), this approach has several key limitations: (i) the AI does not measure desertification, (ii)
16 the impact of changes in climate on the land surface and systems is more complex than assumed by
17 AI, and (iii) the relationship between climate change and changes in vegetation is complex due to the
18 influence of CO₂. Expansion of the drylands does not imply desertification by itself, if there is no
19 long-term loss of at least one of the following: biological productivity, ecological integrity, and value
20 to humans.

21 The use of the AI to define changing aridity levels and dryland extent in an environment with
22 changing atmospheric CO₂ has been strongly challenged (Roderick et al., 2015; Milly and Dunne,
23 2016; Greve et al., 2017; Liu et al., 2017). The suggestion that most of the world has become more
24 arid, since the AI has decreased, is not supported by changes observed in precipitation, evaporation or
25 drought (Sheffield et al., 2012; Greve et al., 2014) (*medium confidence*). A key issue is the
26 assumption in the calculation of potential evapotranspiration that stomatal conductance remains
27 constant which is invalid if atmospheric CO₂ changes. Given that atmospheric CO₂ has been
28 increasing over the last century or more, and is projected to continue increasing, this means that AI
29 with constant thresholds (or any other measure that relies on potential evapotranspiration) is not an
30 appropriate way to estimate aridity or dryland extent (Donohue et al., 2013; Roderick et al., 2015;
31 Greve et al., 2017). This issue helps explain the apparent contradiction between the drylands
32 becoming more arid according to the AI and also becoming greener according to satellite observations
33 (Fensholt et al., 2012; Andela et al., 2013; Figure 3.5). Other climate type classifications based on
34 various combinations of temperature and precipitation (Köppen-Trewartha, Köppen-Geiger) have also
35 been used to examine historical changes in climate zones finding a tendency toward drier climate
36 types (Feng et al., 2014; Spinoni et al., 2015).

37 The need to establish a baseline when assessing change in the land area degraded has been extensively
38 discussed in Prince et al. (2018). Desertification is a process not a state of the system, hence an
39 “absolute” baseline is not required; however, every study uses a baseline defined by the start of their
40 period of interest.

41 Depending on the definitions applied and methodologies used in evaluation, the status and extent of
42 desertification globally and regionally still show substantial variations (D’Odorico et al., 2013) (*high*
43 *confidence*). There is *high confidence* that the range and intensity of desertification has increased in
44 some dryland areas over the past several decades (3.2.1.1, 3.2.1.2). The three methodological
45 approaches applied for assessing the extent of desertification: expert judgement, satellite observation
46 of net primary productivity, and use of biophysical models, together provide a relatively holistic

1 assessment but none on its own captures the whole picture (Gibbs and Salmon, 2015; Vogt et al.,
2 2011; Prince, 2016; 4.2.4).

3 3.2.1.1. Global Scale

4 Complex human-environment interactions coupled with biophysical, social, economic and political
5 factors unique to any given location render desertification difficult to map at a global scale (Cherlet et
6 al., 2018). Early attempts to assess desertification focused on expert knowledge in order to obtain
7 global coverage in a cost-effective manner. **Expert judgement** continues to play an important role
8 because degradation remains a subjective feature whose indicators are different from place to place
9 (Sonneveld and Dent, 2007). GLASOD (Global Assessment of Human-Induced Soil Degradation)
10 estimated nearly 2000 million hectares (M ha) (15.3% of the total land area) had been degraded by
11 early 1990s since mid-20th century. GLASOD was criticised for perceived subjectiveness and
12 exaggeration (Helldén and Tottrup, 2008; Sonneveld and Dent, 2007). Dregne and Chou (1992) found
13 3000 M ha in drylands (i.e. about 50% of drylands) were undergoing degradation. Significant
14 improvements have been made through the efforts of WOCAT (World Overview of Conservation
15 Approaches and Technologies), LADA (Land Degradation Assessment in Drylands) and DESIRE
16 (Desertification Mitigation and Remediation of Land) who jointly developed a mapping tool for
17 participatory expert assessment, with which land experts can estimate current area coverage, type and
18 trends of land degradation (Reed et al., 2011).

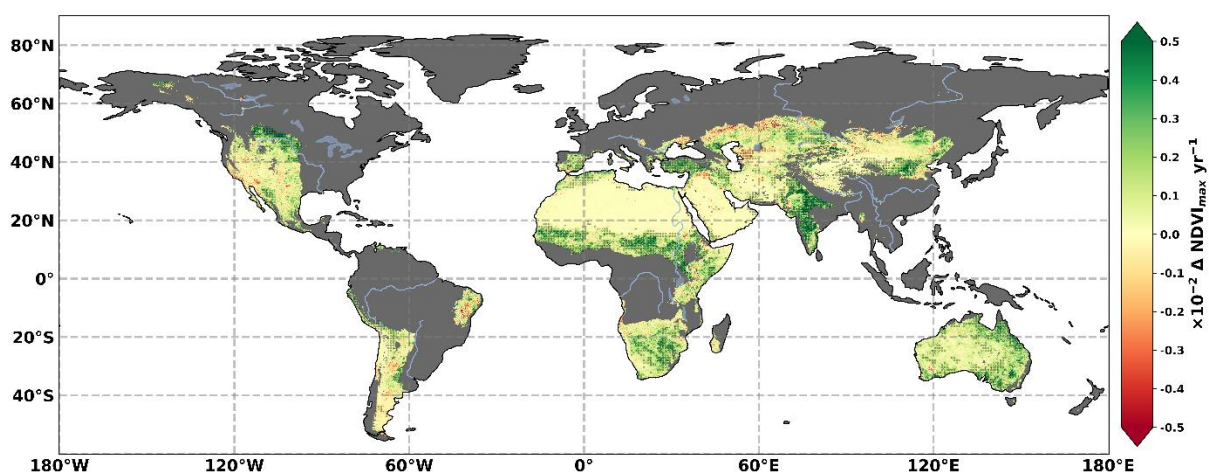

Figure 3.5 Mean Annual Maximum NDVI 1982-2015 (Global Inventory Modelling and Mapping Studies NDVI3g v1). Non-dryland regions (Aridity Index > 0.65) are masked in grey.

1 **Figure 3.6 Trend in the Annual Maximum NDVI 1982-2015 (Global Inventory Modelling and Mapping**
2 **Studies NDVI3g v1) calculated using the Theil-Sen estimator which is a median based estimator, and is**
3 **robust to outliers. Non-dryland regions (Aridity Index > 0.65) are masked in grey.**

4 A number of studies have used **satellite-based remote sensing** to investigate long-term changes in
5 the vegetation and thus identify parts of the drylands undergoing desertification. Satellite data
6 provides information at the resolution of the sensor which can be relatively coarse (up to 25 km) and
7 interpretations of the data at sub-pixel levels are challenging. The most widely used remotely sensed
8 vegetation index is the NDVI providing a measure of canopy greenness, which is related to the
9 quantity of standing biomass (Bai et al., 2008; de Jong et al., 2011; Fensholt et al., 2012; Andela et al.,
10 2013; Fensholt et al., 2015; Le et al., 2016; Figure 3.5). A main challenge associated with NDVI is
11 that although biomass and productivity are closely related in some systems, they can differ widely
12 when looking across land uses and ecosystem types, giving a false positive in some instances
13 (Pattison et al., 2015; Aynekulu et al., 2017). For example, bush encroachment in rangelands and
14 intensive monocropping with high fertiliser application gives an indication of increased productivity
15 in satellite data though these could be considered as land degradation. According to this measure there
16 are regions undergoing desertification, however, the drylands are greening on average (Figure 3.6).

17 A simple linear trend in NDVI is an unsuitable measure for dryland degradation for several reasons
18 (Wessels et al., 2012; de Jong et al., 2013; Higginbottom and Symeonakis, 2014; Le et al., 2016).
19 NDVI is strongly coupled to precipitation in drylands where precipitation has high inter-annual
20 variability. This means that NDVI trend can be dominated by any precipitation trend and is sensitive
21 to wet or dry periods, particularly if they fall near the beginning or end of the time series. Degradation
22 may only occur during part of the time series, while NDVI is stable or even improving during the rest
23 of the time series. This reduces the strength and representativeness of a linear trend. Other factors
24 such as CO₂ fertilisation also influence the NDVI trend. Various techniques have been proposed to
25 address these issues, including the residual trends (RESTREND) method to account for rainfall
26 variability (Evans and Geerken, 2004), time-series break point identification methods to find major
27 shifts in the vegetation trends (de Jong et al., 2013; Verbesselt et al., 2010a) and methods to explicitly
28 account for the effect of CO₂ fertilisation (Le et al., 2016).

29 Using the RESTREND method, Andela et al. (2013) found that human activity contributed to a
30 mixture of improving and degrading regions in drylands. In some locations these regions differed
31 substantially from those identified using the NDVI trend alone, including an increase in the area being
32 desertified in southern Africa and northern Australia, and a decrease in southeast and west Australia
33 and Mongolia. De Jong et al. (2013) examined the NDVI time series for major shifts in vegetation
34 activity and found that 74% of drylands experienced such a shift between 1981 and 2011. This
35 suggests that monotonic linear trends are unsuitable for accurately capturing the changes that have
36 occurred in the majority of the drylands. Le et al. (2016) explicitly accounted for CO₂ fertilisation
37 effect and found that the extent of degraded areas in the world is 3% larger when compared to the
38 linear NDVI trend.

39 Besides NDVI, there are many vegetation indices derived from satellite data in the optical and
40 infrared wavelengths. Each of these datasets has been derived to overcome some limitation in existing
41 indices. Studies have compared vegetation indices globally (Zhang et al., 2017) and specifically over
42 drylands (Wu, 2014). In general, the data from these vegetation indices are available only since
43 around 2000, while NDVI data is available since 1982. With less than 20 years of data, the trend
44 analysis remains problematic with vegetation indices other than NDVI. However, given the various
45 advantages in terms of resolution and other characteristics, these newer vegetation indices will
46 become more useful in the future as more data accumulates.

47 Vegetation Optical Depth (VOD) has been available since the 1980s. VOD is based on microwave
48 measurements and is related to total above ground biomass water content. Unlike NDVI which is only

1 sensitive to green canopy cover, VOD is also sensitive to water in woody parts of the vegetation and
2 hence provides a view of vegetation changes that can be complementary to NDVI. Liu et al. (2013)
3 used VOD trends to investigate biomass changes and found that VOD was closely related to
4 precipitation changes in drylands. To complement their work with NDVI, Andela et al. (2013) also
5 applied the RESTREND method to VOD. By interpreting NDVI and VOD trends together they were
6 able to differentiate changes to the herbaceous and woody components of the biomass. They reported
7 that many dryland regions are experiencing an increase in the woody fraction often associated with
8 shrub encroachment and suggest that this was aided by CO₂ fertilisation.

9 A major shortcoming of these studies based on vegetation datasets derived from satellite sensors is
10 that they do not account for changes in vegetation composition, thus leading to inaccuracies in the
11 estimation of the extent of degraded areas in drylands. For example, drylands of Eastern Africa
12 currently face growing encroachment of invasive plant species, such as *Prosopis juliflora* (Ayanu et
13 al., 2015), which constitutes land degradation since it leads to losses in economic productivity of
14 affected areas but appears as a greening in the satellite data. Another case study in central Senegal
15 found degradation manifested through a reduction in species richness despite satellite observed
16 greening (Herrmann and Tappan, 2013). A number of efforts to identify changes in vegetation
17 composition from satellites have been made (Brandt et al., 2016a,b; Evans and Geerken, 2006;
18 Geerken, 2009; Geerken et al., 2005; Verbesselt et al., 2010a,b). These depend on well-identified
19 reference NDVI time series for particular vegetation groupings, can only differentiate vegetation types
20 that have distinct spectral phenology signatures and require extensive ground observations for
21 validation. A recent alternative approach to differentiating woody from herbaceous vegetation
22 involves the combined use of optical/infrared based vegetation indices, indicating greenness, with
23 microwave based Vegetation Optical Depth (VOD) which is sensitive to both woody and leafy
24 vegetation components (Andela et al., 2013; Tian et al., 2017).

25 **Biophysical models** use global data sets that describe climate patterns and soil groups, combined with
26 observations of land use, to define classes of potential productivity and map general land degradation
27 (Gibbs and Salmon, 2015). All biophysical models have their own set of assumptions and limitations
28 that contribute to their overall uncertainty, including: model structure; spatial scale; data requirements
29 (with associated errors); spatial heterogeneities of socioeconomic conditions; and agricultural
30 technologies used. Models have been used to estimate the vegetation productivity potential of land
31 (Cai et al., 2011) and to understand the causes of observed vegetation changes. Zhu et al. (2016) used
32 an ensemble of ecosystem models to investigate causes of vegetation changes from 1982-2009, using
33 a factorial simulation approach. They found CO₂ fertilisation to be the dominant effect globally
34 though climate and land cover change were the dominant effects in various dryland locations. Borrelli
35 et al. (2017) modelled that about 6.1% of the global land area experienced very high soil erosion rates
36 (exceeding 10 Mg ha⁻¹ yr⁻¹) in 2012, particularly in South America, Africa, and Asia.

37 Overall, improved estimation and mapping of areas undergoing desertification are needed. This
38 requires a combination of rapidly expanding sources of remotely sensed data, ground observations
39 and new modelling approaches. This is a critical gap, especially in the context of measuring progress
40 towards achieving the land degradation-neutrality target by 2030 in the framework of SDGs.

41 3.2.1.2. Regional Scale

42 While global scale studies provide information for any region, there are numerous studies that focus
43 on sub-continental scales, providing more in-depth analysis and understanding. Regional and local
44 studies are important to detect location-specific trends in desertification and heterogeneous influences
45 of climate change on desertification. However, these regional and local studies use a wide variety of
46 methodologies, making direct comparisons difficult. For details of the methodologies applied by each
47 study refer to the individual papers.

1 3.2.1.2.1 Africa

2 It is estimated that 46 out of the 54 countries in Africa are vulnerable to desertification, with some
3 already affected (Právālie, 2016). Moderate or higher severity degradation over recent decades have
4 been identified in many river basins including the Nile (42% of area), Niger (50%), Senegal (51%),
5 Volta (67%), Limpopo (66%) and Lake Chad (26%) (Thiombiano and Tourino-Soto, 2007).

6 The Horn of Africa is getting drier (Damberg and AghaKouchak, 2014; Marshall et al., 2012)
7 exacerbating the desertification already occurring (Oroda, 2001). The observed decline in vegetation
8 cover is diminishing ecosystem services (Pricope et al., 2013). Based on NDVI residuals, Kenya
9 experienced persistent negative (positive) trends over 21.6% (8.9%) of the country, for the period
10 1992–2015 (Gichenje and Godinho, 2018). Fragmentation of habitats, reduction in the range of
11 livestock grazing, higher stocking rates are considered to be the main drivers for vegetation structure
12 loss in the rangelands of Kenya (Kihuu, 2016; Otuoma et al., 2009)

13 Despite desertification in the Sahel being a major concern since the 1970s, wetting and greening
14 conditions have been observed in this region over the last three decades (Anyamba and Tucker, 2005;
15 Huber et al., 2011; Brandt et al., 2015; Rishmawi et al., 2016; Tian et al., 2016; Leroux et al., 2017;
16 Herrmann et al., 2005; Damberg and AghaKouchak, 2014). Cropland areas in the Sahel region of
17 West Africa have doubled since 1975, with settlement area increasing by about 150% (Traore et al.,
18 2014). Thomas and Nigam (2018) found that the Sahara expanded by 10% over the 20th century based
19 on annual rainfall. In Burkina Faso, Dimobe et al. (2015) estimated that from 1984 to 2013, bare soils
20 and agricultural lands increased by 18.8% and 89.7%, respectively, while woodland, gallery forest,
21 tree savannas, shrub savannas and water bodies decreased by 18.8%, 19.4%, 4.8%, 45.2% and 31.2%,
22 respectively. In Fakara region in Niger, 5% annual reduction in herbaceous yield between 1994 and
23 2006 was largely explained by changes in land use, grazing pressure and soil fertility (Hiernaux et al.,
24 2009). Aladejana et al. (2018) found that between 1986 and 2015, 18.6% of the forest cover around
25 the Owena River basin was lost. For the period 1982–2003, Le et al. (2012) found that 8% of the
26 Volta River basin's landmass had been degraded with this increasing to 65% after accounting for the
27 effects of CO₂ (+NO_x) fertilisation.

28 Greening has also been observed in parts of Southern Africa but it is relatively weak compared to
29 other regions of the continent (Helldén and Tottrup, 2008; Fensholt et al., 2012). However, greening
30 can be accompanied by desertification when factors such as decreasing species richness, changes in
31 species composition and shrub encroachment are observed (Smith et al., 2013; Herrmann and Tappan,
32 2013; Kaptué et al., 2015; Herrmann and Sop, 2016; Saha et al., 2015) (3.1.4, 3.7.3). In the Okavango
33 river Basin in Southern Africa, conversion of land towards higher utilisation intensities, unsustainable
34 agricultural practises and overexploitation of the savanna ecosystems have been observed in recent
35 decades (Weinzierl et al., 2016).

36 In arid Algerian High Plateaus, desertification due to both climatic and human causes led to the loss
37 of indigenous plant biodiversity between 1975 and 2006 (Hirche et al., 2011). Ayoub (1998)
38 identified 64 M ha in Sudan as degraded, with the Central North Kordofan state being most affected.
39 However, reforestation measures in the last decade sustained by improved rainfall conditions have led
40 to low-medium regrowth conditions in about 20% of the area (Dawelbait and Morari, 2012). In
41 Morocco, areas affected by desertification were dominantly on plains with high population and
42 livestock pressure (del Barrio et al., 2016; Kouba et al., 2018; Lahlaoui et al., 2017). The annual costs
43 of soil degradation were estimated at about 1% of Gross Domestic Product (GDP) in Algeria and
44 Egypt, and about 0.5% in Morocco and Tunisia (Réquier-Desjardins and Bied-Charretton, 2006).

45 3.2.1.2.2 Asia

46 Právālie (2016) found that desertification is currently affecting 38 of 48 countries in Asia. The
47 changes in drylands in Asia over the period 1982–2011 were mixed, with some areas experiencing
48 vegetation improvement while others showed reduced vegetation (Miao et al., 2015a). Major river

1 basins undergoing salinisation include: Indo-Gangetic Basin in India (Lal and Stewart, 2012), Indus
2 Basin in Pakistan (Aslam and Prathapar, 2006), Yellow River Basin in China (Chengrui and Dregne,
3 2001), Yinchuan Plain, in China (Zhou et al., 2013), Aral Sea Basin of Central Asia (Cai et al., 2003;
4 Pankova, 2016; Qadir et al., 2009).

5 Helldén and Tottrup (2008) highlighted a greening trend in East Asia between 1982 and 2003. Over
6 the past several decades, air temperature and the rainfall increased in the arid and hyper-arid region of
7 Northwest China (Chen et al., 2015; Wang et al., 2017). Within China, rainfall erosivity has shown a
8 positive trend in dryland areas between 1961 and 2012 (Yang and Lu, 2015). While water erosion
9 area in Xinjiang China, has decreased by 23.2%, erosion considered as severe or intense was still
10 increasing (Zhang et al., 2015). Xue et al. (2017) used remote sensing data covering 1975 to 2015 to
11 show that wind-driven desertified land in north Shanxi in China had expanded until 2000, before
12 contracting again. Li et al. (2012) used satellite data to identify desertification in Inner Mongolia
13 China and found a link between policy changes and the locations and extent of human-caused
14 desertification. Several oasis regions in China have seen increases in cropland area, while forests,
15 grasslands and available water resources have decreased (Fu et al. 2017; Muyibul et al., 2018; Xie et
16 al., 2014). Between 1990 and 2011 15.3% of Hognu Khaan nature reserve in central Mongolia was
17 subjected to desertification (Lamchin et al., 2016). Using satellite data Liu et al. (2013) found the area
18 of Mongolia undergoing non-climatic desertification was associated with increases in goat density and
19 wildfire occurrence.

20 In Central Asia, drying up of the Aral Sea is continuing having negative impacts on regional
21 microclimate and human health (Issanova and Abuduwaili, 2017; Lioubimtseva, 2015; Micklin, 2016;
22 Xi and Sokolik, 2015). Half of the region's irrigated lands, especially in the Amudarya and Syrdarya
23 river basins, were affected by secondary salinisation (Qadir et al., 2009). Le et al., (2016) showed that
24 about 57% of croplands in Kazakhstan and about 20% of croplands in Kyrgyzstan had lost in their
25 vegetation productivity between 1982 and 2006. Chen et al. (2019) indicated that about 58% of the
26 grasslands in the region lost in their vegetation productivity between 1999 and 2015. Anthropogenic
27 factors were the main driver of this loss in Turkmenistan and Uzbekistan, while the role of human
28 drivers was smaller than that of climate-related factors in Tajikistan and Kyrgyzstan (Chen et al.,
29 2019). The total costs of land degradation in Central Asia were estimated to equal about USD 6
30 billion annually (Mirzabaev et al., 2016).

31 Damberg and AghaKouchak (2014) found that parts of South Asia experienced drying over the last
32 three decades. More than 75% of the area of northern, western and southern Afghanistan is affected
33 by overgrazing and deforestation (UNEP-GEF, 2008). Desertification is a serious problem in Pakistan
34 with a wide range of human and natural causes (Irshad et al., 2007; Lal, 2018). Similarly,
35 desertification affects parts of India (Kundu et al., 2017; Dharumarajan et al., 2018; Christian et al.,
36 2018). Using satellite data to map various desertification processes, Ajai et al. (2009) identified 81.4
37 M ha were subject to various processes of desertification in India in 2005, while salinisation affected
38 6.73 M ha in the country (Singh, 2009).

39 Saudi Arabia is highly vulnerable to desertification (Ministry of Energy Industry and Mineral
40 Resources, 2016), with this vulnerability expected to increase in the north-western parts of the country
41 in the coming decades. Yahiya (2012) found that Jazan, south-western Saudi Arabia, lost about 46%
42 of its vegetation cover from 1987 to 2002. Droughts and frequent dust storms were shown to impose
43 adverse impacts over Saudi Arabia especially under global warming and future climate change
44 (Hasanean et al., 2015). In north-west Jordan, 18% of the area was prone to severe to very severe
45 desertification (Al-Bakri et al., 2016). Large parts of the Syrian drylands have been identified as
46 undergoing desertification (Evans and Geerken, 2004; Geerken and Ilaiwi, 2004). Moridnejad et al.
47 (2015) identified newly desertified regions in the Middle East based on dust sources, finding that

1 these regions accounted for 39% of all detected dust source points. Desertification has increased
2 substantially in Iran since the 1930s. Despite numerous efforts to rehabilitate degraded areas, it still
3 poses a major threat to agricultural livelihoods in the country (Amiraslani and Dragovich, 2011).

4 *3.2.1.2.3 Australia*

5 Damberg and AghaKouchak (2014) found that wetter conditions were experienced in northern
6 Australia over the last three decades with widespread greening observed between 1981 and 2006 over
7 much of Australia, except for eastern Australia where large areas were affected by droughts from
8 2002 to 2009 based on Advanced High Resolution Radiometer (AVHRR) satellite data (Donohue,
9 McVicar, and Roderick, 2009). For the period 1982–2013, Burrell et al. (2017) also found widespread
10 greening over Australia including eastern Australia over the post-drought period. This dramatic
11 change in the trend found for eastern Australia emphasises the dominant role played by precipitation
12 in the drylands. Degradation due to anthropogenic activities and other causes affects over 5% of
13 Australia, particularly near the central west coast. Jackson and Prince (2016) used a local NPP scaling
14 approach applied with MODIS derived vegetation data to quantify degradation in a dryland watershed
15 in Northern Australia from 2000 to 2013. They estimated that 20% of the watershed was degraded.
16 Salinisation has also been found to be degrading parts of the Murray-Darling Basin in Australia
17 (Rengasamy, 2006). Eldridge and Soliveres (2014) examined areas undergoing woody encroachment
18 in eastern Australia and found that rather than degrading the landscape, the shrubs often enhanced
19 ecosystem services.

20 *3.2.1.2.4 Europe*

21 Drylands cover 33.8% of northern Mediterranean countries; approximately 69% of Spain, 66% of
22 Cyprus, and between 16% and 62% in Greece, Portugal, Italy and France (Zdruli, 2011). The
23 European Environment Agency (EEA) indicated that 14 M ha, i.e. 8% of the territory of the European
24 Union (in Bulgaria, Cyprus, Greece, Italy, Romania, Spain and Portugal), had a “very high” and “high
25 sensitivity” to desertification (European Court of Auditors, 2018). This figure increases to 40 M ha
26 (23% of the EU territory) if “moderately” sensitive areas are included (Právělie et al., 2017; European
27 Court of Auditors, 2018). Desertification in the region is driven by irrigation developments and
28 encroachment of cultivation on rangelands (Safriel, 2009) caused by population growth, agricultural
29 policies and markets. According to a recent assessment report (ECA, 2018), Europe is increasingly
30 affected by desertification leading to significant consequences on land use, particularly in Portugal,
31 Spain, Italy, Greece, Malta, Cyprus, Bulgaria and Romania. Using the Universal Soil Loss Equation,
32 it was estimated that soil erosion can be as high as $300 \text{ t ha}^{-1}\text{yr}^{-1}$ (equivalent to a net loss of 18 mm yr^{-1})
33 in Spain (López-Bermúdez, 1990). For the badlands region in south-east Spain, however, it was
34 shown that biological soil crusts effectively prevent soil erosion (Lázaro et al., 2008). In
35 Mediterranean Europe, Guerra et al. (2016) found a reduction of erosion due to greater effectiveness
36 of soil erosion prevention between 2001 and 2013. Helldén and Tottrup (2008) observed a greening
37 trend in the Mediterranean between 1982–2003, while Fensholt et al. (2012) also show a dominance
38 of greening in Eastern Europe.

39 In Russia, at the beginning of the 2000s, about 7% of the total area (i.e. ~130 M ha) was threatened by
40 desertification (Gunin and Pankova, 2004; Kust et al., 2011). Turkey is considered highly vulnerable
41 to drought, land degradation and desertification (Türkeş, 1999; Türkeş, 2003). About 60% of Turkey’s
42 land area is characterised with hydro-climatological conditions favourable for desertification (Türkeş,
43 2013). ÇEMGM (2017) estimated that about half of Turkey’s land area (48.6%) is prone to moderate
44 to high desertification.

45 *3.2.1.2.5 North America*

46 Drylands cover approximately 60% of Mexico. According to Pontifes et al. (2018), 3.5% of the area
47 was converted from natural vegetation to agriculture and human settlements between 2002 to 2011.

1 The region is highly vulnerable to desertification due to frequent droughts and floods (Méndez and
2 Magaña, 2010; Stahle et al., 2009; Becerril-Pina Rocio et al., 2015).

3 For the period 2000-2011 the overall difference between potential and actual NPP in different land
4 capability classes in the south-western United States was 11.8% (Noojipady et al., 2015); reductions
5 in grassland-savanna and livestock grazing area and forests were the highest. Bush encroachment is
6 observed over a fairly wide area of western USA grasslands; including Jornada Basin within the
7 Chihuahuan Desert, and is spreading at a fast rate despite grazing restrictions intended to curb the
8 spread (Yanoff and Muldavin, 2008; Browning and Archer, 2011; Van Auken, 2009; Rachal et al.,
9 2012). In comparing sand dune migration patterns and rates between 1995 and 2014, Potter and
10 Weigand (2016) established that the area covered by stable dune surfaces, and sand removal zones,
11 decreased while sand accumulation zones increased from 15.4 to 25.5 km² for Palen dunes in
12 Southern California Desert, while movement of Kelso Dunes is less clear (Lam et al., 2011). Within
13 the United States, average soil erosion rates on all croplands decreased by about 38% between 1982-
14 2003 due to better soil management practices (Kertis, 2003).

15 3.2.1.2.6 Central and South America

16 Morales et al. (2011) indicated that desertification costs between 8 and 14% of gross agricultural
17 product in many Central and South American countries. Parts of the dry Chaco and Caldenal regions
18 in Argentina have undergone widespread degradation over the last century (Verón et al., 2017;
19 Fernández et al., 2009). Bisigato and Laphitz (2009) identified overgrazing as a cause of
20 desertification in the Patagonian Monte region of Argentina. Vieira et al. (2015) found that 94% of
21 northeast Brazilian drylands were susceptible to desertification. It is estimated that up to 50% of the
22 area was being degraded due to frequent prolonged droughts and clearing of forests for agriculture.
23 This land-use change threatens the extinction of around 28 native species (Leal et al., 2005). In
24 Central Chile, dryland forest and shrubland area was reduced by 1.7% and 0.7%, respectively,
25 between 1975-2008 (Schulz et al., 2010).

26

27 **3.2.2. Attribution of Desertification**

28 Desertification is a result of complex interactions within coupled social-ecological systems. Thus, the
29 relative contributions of climatic, anthropogenic and other drivers of desertification vary depending
30 on specific socioeconomic and ecological contexts. The high natural climate variability in dryland
31 regions is a major cause of vegetation changes but does not necessarily imply degradation. Drought is
32 not degradation as the land productivity may return entirely once the drought ends (Kassas, 1995).
33 However, if droughts increase in frequency, intensity and/or duration they may overwhelm the
34 vegetation's ability to recover (ecosystem resilience, Prince et al., 2018), causing degradation.
35 Assuming a stationary climate and no human influence, rainfall variability results in fluctuations in
36 vegetation dynamics which can be considered temporary as the ecosystem tends to recover with
37 rainfall, and desertification does not occur (Ellis, 1995; Vetter, 2005; von Wehrden et al., 2012).
38 Climate change on the other hand, exemplified by a non-stationary climate, can gradually cause a
39 persistent change in the ecosystem through aridification and CO₂ changes. Assuming no human
40 influence, this 'natural' climatic version of desertification may take place rapidly, especially when
41 thresholds are reached (Prince et al., 2018), or over longer periods of time as the ecosystems slowly
42 adjust to a new climatic norm through progressive changes in the plant community composition.
43 Accounting for this climatic variability is required before attributions to other causes of desertification
44 can be made.

45 For attributing vegetation changes to climate versus other causes, rain use efficiency (RUE - the
46 change in net primary productivity (NPP) per unit of precipitation) and its variations in time have
47 been used (Prince et al., 1998). Global applications of RUE trends to attribute degradation to climate
48 or other (largely human) causes has been performed by Bai et al. (2008) and Le et al. (2016) (3.2.1.1).

1 The RESTREND (residual trend) method analyses the correlation between annual maximum NDVI
2 (or other vegetation index as a proxy for NPP) and precipitation by testing accumulation and lag
3 periods for the precipitation (Evans and Geerken, 2004). The identified relationship with the highest
4 correlation represents the maximum amount of vegetation variability that can be explained by the
5 precipitation, and corresponding RUE values can be calculated. Using this relationship, the climate
6 component of the NDVI time series can be reconstructed, and the difference between this and the
7 original time series (the residual) is attributed to anthropogenic and other causes.

8 The RESTREND method, or minor variations of it, have been applied extensively. (Herrmann and
9 Hutchinson, 2005) concluded that climate was the dominant causative factor for widespread greening
10 in the Sahel region from 1982 to 2003, and anthropogenic and other factors were mostly producing
11 land improvements or no change. However, pockets of desertification were identified in Nigeria and
12 Sudan. Similar results were also found from 1982 to 2007 by Huber et al. (2011). Wessels et al.
13 (2007) applied RESTREND to South Africa and showed that RESTREND produced a more accurate
14 identification of degraded land than RUE alone. RESTREND identified a smaller area undergoing
15 desertification due to non-climate causes compared to the NDVI trends. Liu et al. (2013) extended the
16 climate component of RESTREND to include temperature and applied this to VOD observations of
17 the cold drylands of Mongolia. They found the area undergoing desertification due to non-climatic
18 causes is much smaller than the area with negative VOD trends. RESTREND has also been applied in
19 several other studies to the Sahel (Leroux et al., 2017), Somalia (Omuto et al., 2010), West Africa
20 (Ibrahim et al., 2015), China (Li et al., 2012; Yin et al., 2014), Central Asia (Jiang et al., 2017),
21 Australia (Burrell et al., 2017) and globally (Andela et al., 2013). In each of these studies the extent to
22 which desertification can be attributed to climate versus other causes varies across the landscape.

23 These studies represent the best regional, remote sensing based attribution studies to date, noting that
24 RESTREND and RUE have some limitations (Higginbottom and Symeonakis, 2014). Vegetation
25 growth (NPP) changes slowly compared to rainfall variations and may be sensitive to rainfall over
26 extended periods (years) depending on vegetation type. Detection of lags and the use of weighted
27 antecedent rainfall can partially address this problem though most studies do not do this. The method
28 addresses changes since the start of the time series, it cannot identify whether an area is already
29 degraded at the start time. It is assumed that climate, particularly rainfall, are principal factors in
30 vegetation change which may not be true in more humid regions.

31 Another assumption in RESTREND is that any trend is linear throughout the period examined. That
32 is, there are no discontinuities (break points) in the trend. Browning et al. (2017) have shown that
33 break points in NDVI time series reflect vegetation changes based on long-term field sites. To
34 overcome this limitation, Burrell et al. (2017) introduced the Time Series Segmentation-RESTREND
35 (TSS-RESTREND) which allows a breakpoint or turning point within the period examined (Figure
36 3.7). Using TSS-RESTREND over Australia they identified more than double the degrading area than
37 could be identified with a standard RESTREND analysis. The occurrence and drivers of abrupt
38 change (turning points) in ecosystem functioning were also examined by Horion et al. (2016) over the
39 semi-arid Northern Eurasian agricultural frontier. They combined trend shifts in RUE, field data and
40 expert knowledge, to map environmental hotspots of change and attribute them to climate and human
41 activities. One third of the area showed significant change in RUE, mainly occurring around the fall
42 of the Soviet Union (1991) or as the result of major droughts. Recent human-induced turning points in
43 ecosystem functioning were uncovered nearby Volgograd (Russia) and around Lake Balkhash
44 (Kazakhstan), attributed to recultivation, increased salinisation, and increased grazing.

45 Attribution of vegetation changes to human activity has also been done within modelling frameworks.
46 In these methods ecosystem models are used to simulate potential natural vegetation dynamics, and
47 this is compared to the observed state. The difference is attributed to human activities. Applied to the
48 Sahel region during the period of 1982–2002, it showed that people had a minor influence on

1 vegetation changes (Sequist et al., 2009). Similar model/observation comparisons performed globally
2 found that CO₂ fertilisation was the strongest forcing at global scales, with climate having regionally
3 varying effects (Mao et al., 2013; Zhu et al., 2016). Land use/land cover change was a dominant
4 forcing in localised areas. The use of this method to examine vegetation changes in China (1982–
5 2009) attributed most of the greening trend to CO₂ fertilisation and nitrogen (N) deposition (Piao et
6 al., 2015). However in some parts of northern and western China, which includes large areas of
7 drylands, Piao et al. (2015) found climate changes could be the dominant forcing. In the northern
8 extratropical land surface, the observed greening was consistent with increases in greenhouse gases
9 (notably CO₂) and the related climate change, and not consistent with a natural climate that does not
10 include anthropogenic increase in greenhouse gases (Mao et al., 2016). While many studies found
11 widespread influence of CO₂ fertilisation, it is not ubiquitous, for example, Lévesque et al. (2014)
12 found little response to CO₂ fertilisation in some tree species in Switzerland/northern Italy.

1
2 **Figure 3.7 The Drivers of Dryland Vegetation Change.** The mean annual change in NDVI_{max} between
3 1982 and 2015 (See Figure 3.6 for total change using Global Inventory Modelling and Mapping Studies
4 NDVI3g v1 dataset) attributable to a) CO₂ fertilisation b) climate and c) land use. The change
5 attributable to CO₂ fertilisation was calculated using the CO₂ fertilisation relationship described in
6 (Franks et al., 2013). The Time Series Segmented Residual Trends (TSS-RESTREND) method (Burrell et
7 al., 2017) applied to the CO₂ adjusted NDVI was used to separate Climate and Land Use. A multi climate
8 dataset ensemble was used to reduce the impact of dataset errors (Burrell et al., 2018). Non-dryland
9 regions (Aridity Index > 0.65) are masked in dark grey. Areas where the change did not meet the multi-
10 run ensemble significance criteria, or are smaller than the error in the sensors (± 0.00001) are masked in
11 white.

1 Using multiple extreme event attribution methodologies, Uhe et al. (2018) shows that the dominant
2 influence for droughts in Eastern Africa during October to December ‘short rains’ season is the
3 prevailing tropical SST patterns, although temperature trends mean that the current drought conditions
4 are hotter than it would have been without climate change. Similarly, Funk et al. (2019) found that
5 2017 March-June East African drought was influenced by Western Pacific SST, with high SST
6 conditions attributed to climate change.

7 There are numerous local case studies on attribution of desertification, which use different periods,
8 focus on different land uses and covers, and consider different desertification processes. For example,
9 two-thirds of the observed expansion of the Sahara Desert from 1920–2003 has been attributed to
10 natural climate cycles (the cold phase of Atlantic Multi-Decadal Oscillation and Pacific Decadal
11 Oscillation) (Thomas and Nigam, 2018). Some studies consider drought to be the main driver of
12 desertification in Africa (e.g. Masih et al., 2014). However, other studies suggest that although
13 droughts may contribute to desertification, the underlying causes are human activities (Kouba et al.,
14 2018). Brandt et al. (2016a) found that woody vegetation trends are negatively correlated with human
15 population density. Changes in land use, water pumping and flow diversion have enhanced drying of
16 wetlands and salinisation of freshwater aquifers in Israel (Inbar, 2007). The dryland territory of China
17 has been found to be very sensitive to both climatic variations and land use/land cover changes (Fu et
18 al., 2000; Liu and Tian, 2010; Zhao et al., 2013, 2006). Feng et al. (2015) shows that socioeconomic
19 factors were dominant in causing desertification in north Shanxi, China, between 1983 and 2012,
20 accounting for about 80% of desertification expansion. Successful grass establishment has been
21 impeded by overgrazing and nutrient depletion leading to the encroachment of shrubs into the
22 northern Chihuahuan Desert (USA) since the mid-1800s (Kidron and Gutschick, 2017). Human
23 activities led to rangeland degradation in Pakistan and Mongolia during 2000-2011 (Lei et al., 2011).
24 More equal shares of climatic (temperature and precipitation trends) and human factors were
25 attributed for changes in rangeland condition in China (Yang et al., 2016).

26 This kaleidoscope of local case studies demonstrates how attribution of desertification is still
27 challenging for several reasons. Firstly, desertification is caused by an interaction of different drivers
28 which vary in space and time. Secondly, in drylands, vegetation reacts closely to changes in rainfall so
29 the effect of rainfall changes on biomass needs to be ‘removed’ before attributing desertification to
30 human activities. Thirdly, human activities and climatic drivers impact vegetation/ecosystem changes
31 at different rates. Finally, desertification manifests as a gradual change in ecosystem composition and
32 structure (e.g., woody shrub invasion into grasslands). Although initiated at a limited location,
33 ecosystem change may propagate throughout an extensive area via a series of feedback mechanisms.
34 This complicates the attribution of desertification to human and climatic causes as the process can
35 develop independently once started.

36 Rasmussen et al. (2016) studied the reasons behind the overall lack of scientific agreement in trends
37 of environmental changes in the Sahel, including their causes. The study indicated that these are due
38 to differences in conceptualisations and choice of indicators, biases in study site selection, differences
39 in methods, varying measurement accuracy, differences in time and spatial scales. High resolution,
40 multi-sensor airborne platforms provide a way to address some of these issues (Asner et al., 2012).

41 The major conclusion of this section is that, with all the shortcomings of individual case studies,
42 relative roles of climatic and human drivers of desertification are location-specific and evolve over
43 time (*high confidence*). Biophysical research on attribution and socio-economic research on drivers of
44 land degradation have long studied the same topic, but in parallel, with little interdisciplinary
45 integration. Interdisciplinary work to identify typical patterns, or typologies, of such interactions of
46 biophysical and human drivers of desertification (not only of dryland vulnerability), and their relative
47 shares, done globally in comparable ways, will help in the formulation of better informed policies to
48 address desertification and achieve land degradation neutrality.

3.3. Desertification Feedbacks to Climate

While climate change can drive desertification (3.1.4.1), the process of desertification can also alter the local climate providing a feedback (Sivakumar, 2007). These feedbacks can alter the carbon cycle, and hence the level of atmospheric CO₂ and its related global climate change, or they can alter the surface energy and water budgets directly impacting the local climate. While these feedbacks occur in all climate zones (Chapter 2), here we focus on their effects in dryland regions and assess the literature concerning the major desertification feedbacks to climate. The main feedback pathways discussed throughout section 3.3 are summarised in Figure 3.8.

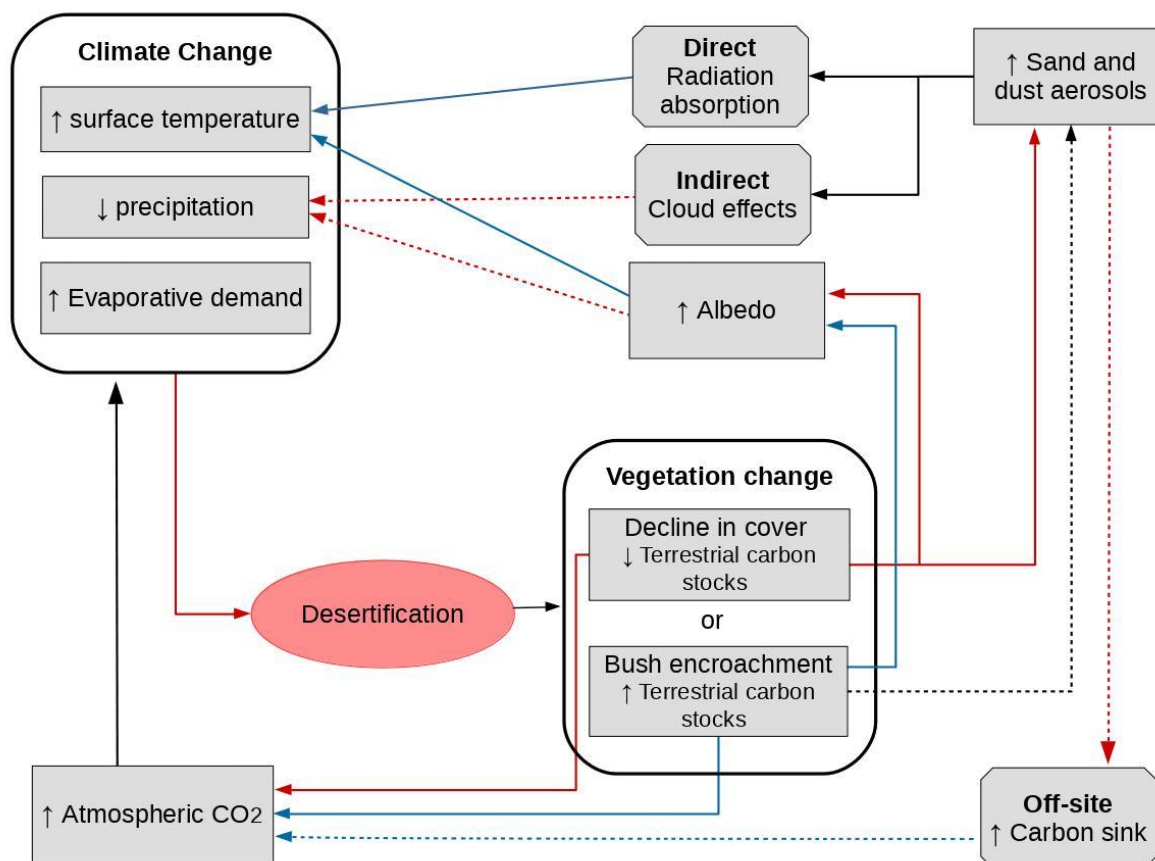

Drylands are characterised by limited soil moisture compared to humid regions. Thus, the sensible heat (heat that causes the atmospheric temperature to rise) accounts for more of the surface net radiation than latent heat (evaporation) in these regions (Wang and Dickinson, 2013). This tight coupling between the surface energy balance and the soil moisture in semi-arid and dry sub-humid zones makes these regions susceptible to land-atmosphere feedback loops that can amplify changes to the water cycle (Seneviratne et al., 2010). Changes to the land surface caused by desertification can change the surface energy budget, altering the soil moisture and triggering these feedbacks.

3.3.1. Sand and Dust Aerosols

Sand and mineral dust are frequently mobilised from sparsely vegetated drylands forming “sand storms” or “dust storms” (UNEP et al., 2016). The African continent is the most important source of desert dust, perhaps 50% of atmospheric dust comes from the Sahara (Middleton, 2017). Ginoux et al. (2012) estimated that 25% of global dust emissions have anthropogenic origins, often in drylands. These events can play an important role in the local energy balance. Through reducing vegetation cover and drying the surface conditions, desertification can increase the frequency of these events. Biological or structural soil crusts have been shown to effectively stabilise dryland soils and thus their loss, due to intense land use and/or climate change, can be expected to cause an increase in sand and dust storms (*high confidence*) (Rajot et al., 2003; Field et al., 2010; Rodriguez-Caballero et al., 2018). These sand and dust aerosols impact the regional climate in several ways (Chooari et al., 2014). The direct effect is the interception, reflection and absorption of solar radiation in the atmosphere, reducing the energy available at the land surface and increasing the temperature of the atmosphere in layers with sand and dust present (Kaufman et al., 2002; Middleton, 2017; Kok et al., 2018). The heating of the dust layer can alter the relative humidity and atmospheric stability, which can change cloud lifetimes and water content. This has been referred to as the semi-direct effect (Huang et al., 2017). Aerosols also have an indirect effect on climate through their role as cloud condensation nuclei, changing cloud radiative properties as well as the evolution and development of precipitation (Kaufman et al., 2002). While these indirect effects are more variable than the direct effects, depending on the types and amounts of aerosols present, the general tendency is toward an increase in the number, but a reduction in the size of cloud droplets, increasing the cloud reflectivity and decreasing the chances of precipitation. These effects are referred to as aerosol-radiation and aerosol-cloud interactions (Boucher et al., 2013).

There is *high confidence* that there is a negative relationship between vegetation green-up and the occurrence of dust storms (Engelstaedter et al., 2003; Fan et al., 2015; Yu et al., 2015; Zou and Zhai, 2004). Changes in groundwater can affect vegetation and the generation of atmospheric dust (Elmore et al., 2008). This can occur through groundwater processes such as the vertical movement of salt to the surface causing salinisation, supply of near surface soil moisture, and sustenance of groundwater dependent vegetation. Groundwater dependent ecosystems have been identified in many dryland regions around the world (Decker et al., 2013; Lamontagne et al., 2005; Patten et al., 2008). In these locations declining groundwater levels can decrease vegetation cover. Cook et al., (2009) found that dust aerosols intensified the “dust bowl” drought in North America during the 1930s.

1 By decreasing the amount of green cover and hence increasing the occurrence of sand and dust
 2 storms, desertification will increase the amount of shortwave cooling associated with the direct effect
 3 (*high confidence*). There is *medium confidence* that the semi-direct and indirect effects of this dust
 4 would tend to decrease precipitation and hence provide a positive feedback to desertification (Huang
 5 et al., 2009; Konare et al., 2008; Rosenfeld et al., 2001; Solmon et al., 2012; Zhao et al., 2015).
 6 However, the combined effect of dust has also been found to increase precipitation in some areas
 7 (Islam and Almazroui, 2012; Lau et al., 2009; Sun et al., 2012). The overall combined effect of dust
 8 aerosols on desertification remains uncertain with *low agreement* between studies that find positive
 9 (Huang et al., 2014), negative (Miller et al., 2004) or no feedback on desertification (Zhao et al.,
 10 2015).

11
 12 **Figure 3.8 Schematic of main pathways through which desertification can feedback on climate as**
 13 **discussed in section 3.4. Note: red arrows indicate a positive effect. Blue arrows indicate a negative effect.**
 14 **Black arrows indicate an indeterminate effect (potentially both positive and negative). Solid arrows are**
 15 **direct while dashed arrows are indirect.**

16 3.3.1.1. Off-site Feedbacks

17 Aerosols can act as a vehicle for the long-range transport of nutrients to oceans (Jickells et al., 2005;
 18 Okin et al., 2011) and terrestrial land surfaces (Das et al., 2013). In several locations, notably the
 19 Atlantic Ocean, west of northern Africa and the Pacific Ocean east of northern China, a considerable
 20 amount of mineral dust aerosols, sourced from nearby drylands, reaches the oceans. It was estimated
 21 that 60% of dust transported off Africa is deposited in the Atlantic Ocean (Kaufman et al., 2005),
 22 while 50% of the dust generated in Asia reaches the Pacific Ocean or further (Uno et al., 2009; Zhang
 23 et al., 1997). The Sahara is also a major source of dust for the Mediterranean basin (Varga et al.,
 24 2014). The direct effect of atmospheric dust over the ocean was found to be a cooling of the ocean
 25 surface (*limited evidence, high agreement*) (Evan and Mukhopadhyay, 2010; Evan et al., 2009) with
 26 the tropical North Atlantic mixed layer cooling by over 1°C (Evan et al., 2009).

1 It has been suggested that dust may act as a source of nutrients for the upper ocean biota, enhancing
2 the biological activity and related C sink (*medium evidence, low agreement*) (Lenes et al., 2001; Shaw
3 et al., 2008; Neuer et al., 2004). The overall response depends on the environmental controls on the
4 ocean biota, the type of aerosols including their chemical constituents, and the chemical environment
5 in which they dissolve (Boyd et al., 2010).

6 Dust deposited on snow can increase the amount of absorbed solar radiation leading to more rapid
7 melting (Painter et al., 2018), impacting a region's hydrological cycle (*high confidence*). Dust
8 deposition on snow and ice has been found in many regions of the globe (e.g. Painter et al., 2018;
9 Kaspari et al., 2014; Qian et al., 2015; Painter et al. 2013), however quantification of the effect
10 globally and estimation of future changes in the extent of this effect remain knowledge gaps.

11 **3.3.2. Changes in Surface Albedo**

12 Increasing surface albedo in dryland regions will impact the local climate, decreasing surface
13 temperature and precipitation, and provide a positive feedback on the albedo (*high confidence*)
14 (Charney et al., 1975). This albedo feedback can occur in desert regions worldwide (Zeng and Yoon,
15 2009). Similar albedo feedbacks have also been found in regional studies over the Middle East
16 (Zaitchik et al., 2007), Australia (Evans et al., 2017; Meng et al., 2014a,b), South America (Lee and
17 Berbery, 2012) and the USA (Zaitchik et al., 2013).

18 Recent work has also found albedo in dryland regions can be associated with soil surface communities
19 of lichens, mosses and cyanobacteria (Rodriguez-Caballero et al., 2018). These communities compose
20 the soil crust in these ecosystems and due to the sparse vegetation cover, directly influence the albedo.
21 These communities are sensitive to climate changes with field experiments indicating albedo changes
22 greater than 30% are possible. Thus, changes in these communities could trigger surface albedo
23 feedback processes (*limited evidence, high agreement*) (Rutherford et al., 2017).

24 A further pertinent feedback relationship exists between changes in land-cover, albedo, C stocks and
25 associated GHG emissions, particularly in drylands with low levels of cloud cover. One of the first
26 studies to focus on the subject was Rotenberg and Yakir (2010), who used the concept of 'radiative
27 forcing' to compare the relative climatic effect of a change in albedo with a change in atmospheric
28 GHGs due to the presence of forest within drylands. Based on this analysis, it was estimated that the
29 change in surface albedo due to the degradation of semi-arid areas has decreased radiative forcing in
30 these areas by an amount equivalent to approximately 20% of global anthropogenic GHG emissions
31 between 1970 and 2005 (Rotenberg and Yakir, 2010).

32 **3.3.3. Changes in Vegetation and Greenhouse Gas Fluxes**

33 Terrestrial ecosystems have the ability to alter atmospheric GHGs through a number of processes
34 (Schlesinger et al., 1990). This may be through a change in plant and soil C stocks, either sequestering
35 atmospheric carbon dioxide (CO₂) during growth or releasing C during combustion and respiration, or
36 through processes such as enteric fermentation of domestic and wild ruminants that lead to the release
37 of methane and nitrous oxide (Sivakumar, 2007). It is estimated that 241-470 Gt C is stored in dryland
38 soils (top 1m Lal, 2004; Plaza et al., 2018). When evaluating the effect of desertification, the net
39 balance of all the processes and associated GHG fluxes needs to be considered.

40 Desertification usually leads to a loss in productivity and a decline in above- and below-ground C
41 stocks (Abril et al., 2005; Asner et al., 2003). Drivers such as overgrazing lead to a decrease in both
42 plant and SOC pools (Abdalla et al., 2018). While dryland ecosystems are often characterised by open
43 vegetation, not all drylands have low biomass and C stocks in an intact state (Lechmere-Oertel et al.,
44 2005; Maestre et al., 2012). Vegetation types such as the subtropical thicket of South Africa have over
45 70 t C ha⁻¹ in an intact state, greater than 60% of which is released into the atmosphere during
46 degradation through overgrazing (Lechmere-Oertel et al., 2005; Powell, 2009). In comparison, semi-

1 arid grasslands and savannas with similar rainfall, may have only 5-35 t C ha⁻¹ (Scholes and Walker,
2 1993; Woomeer et al., 2004)

3 At the same time, it is expected that a decline in plant productivity may lead to a decrease in fuel
4 loads and a reduction in CO₂, nitrous oxide and methane emissions from fire. In a similar manner,
5 decreasing productivity may lead to a reduction in ruminant animals that in turn would decrease
6 methane emissions. Few studies have focussed on changes in these sources of emissions due to
7 desertification and it remains a field that requires further research.

8 In comparison to desertification through the suppression of primary production, the process of woody
9 plant encroachment can result in significantly different climatic feedbacks. Increasing woody plant
10 cover in open rangeland ecosystems leads to an increase in woody C stocks both above- and below-
11 ground (Asner et al., 2003; Hughes et al., 2006; Petrie et al., 2015; Li et al., 2016). Within the
12 drylands of Texas, shrub encroachment led to a 32% increase in aboveground C stocks over a period
13 of 69 years (3.8 t C ha⁻¹ to 5.0 t C ha⁻¹) (Asner et al., 2003). Encroachment by taller woody species,
14 can lead to significantly higher observed biomass and C stocks, for example, encroachment by
15 *Dichrostachys cinerea* and several *Vachellia* species in the sub-humid savannas of north-west South
16 Africa led to an increase of 31–46 t C ha⁻¹ over a 50–65 year period (1936–2001) (Hudak et al., 2003).
17 In terms of potential changes in SOC stocks, the effect may be dependent on annual rainfall and soil
18 type. Woody cover generally leads to an increase in SOC stocks in drylands that have less than 800
19 mm of annual rainfall, while encroachment can lead to a loss of soil C in more humid ecosystems
20 (Barger et al., 2011; Jackson et al., 2002).

21 The suppression of the grass layer through the process of woody encroachment may lead to a decrease
22 in C stocks within this relatively small C pool (Magandana, 2016). Conversely, increasing woody
23 cover may lead to a decrease and even halt in surface fires and associated GHG emissions. In analysis
24 of drivers of fire in southern Africa, Archibald et al. (2009) note that there is a potential threshold
25 around 40% canopy cover, above which surface grass fires are rare. Whereas there have been a
26 number of studies on changes in C stocks due to desertification in North America, southern Africa and
27 Australia, a global assessment of the net change in C stocks as well as fire and ruminant GHG
28 emissions due to woody plant encroachment has not been done yet.

29

30 **3.4. Desertification Impacts on Natural and Socio-Economic Systems** 31 **under Climate Change**

32 **3.4.1. Impacts on Natural and Managed Ecosystems**

33 **3.4.1.1. Impacts on Ecosystems and their Services in Drylands**

34 The Millenium Ecosystem Assesment (2005) proposed four classes of ecosystem services:
35 provisioning, regulating, supporting and cultural services (Cross-Chapter Box 8: Ecosystem Services,
36 Chapter 6). These ecosystem services in drylands are vulnerable to the impacts of climate change due
37 to high variability in temperature, precipitation and soil fertility (Enfors and Gordon, 2008;
38 Mortimore, 2005). There is *high confidence* that desertification processes such as soil erosion,
39 secondary salinisation, and overgrazing have negatively impacted provisioning ecosystem services in
40 drylands, particularly food and fodder production (Majeed and Muhammad, 2019; Mirzabaev et al.,
41 2016; Qadir et al., 2009; Van Loo et al., 2017; Tokbergenova et al., 2018) (3.4.2.2). Zika and Erb
42 (2009) reported an estimation of NPP losses between 0.8 and 2.0 Gt C yr⁻¹ due to desertification,
43 comparing the potential NPP and the NPP calculated for the year 2000. In terms of climatic factors,
44 although climatic changes between 1976 and 2016 were found overall favourable for crop yields in
45 Russia (Ivanov et al., 2018), yield decreases of up to 40-60% in dryland areas were caused by severe
46 and extensive droughts (Ivanov et al., 2018). Increase in temperature can have a direct impact on

1 animals in the form of increased physiological stress (Rojas-Downing et al., 2017), increased water
2 requirements for drinking and cooling, a decrease in the production of milk, meat and eggs, increased
3 stress during conception and reproduction (Nardone et al., 2010) or an increase in seasonal diseases
4 and epidemics (Thornton et al., 2009; Nardone et al., 2010). Furthermore, changes in temperature can
5 indirectly impact livestock through reducing the productivity and quality of feed crops and forages
6 (Thornton et al., 2009; Polley et al., 2013). On the other hand, fewer days with extreme cold
7 temperatures during winter in the temperate zones are associated with lower livestock mortality. The
8 future projection of impacts on ecosystems is presented in section 3.5.2.

9 Over-extraction is leading to groundwater depletion in many dryland areas (*high confidence*) (Mudd,
10 2000; Mays, 2013; Mahmud and Watanabe, 2014; Jolly et al., 2008). Globally, groundwater reserves
11 have been reduced since 1900, with the highest rate of estimated reductions of 145 km³ yr⁻¹ between
12 2000 and 2008 (Konikow, 2011). Some arid lands are very vulnerable to groundwater reductions,
13 because the current natural recharge rates are lower than during the previous wetter periods (e.g.,
14 Atacama Desert and Nubian aquifer system in Africa; (Squeo et al., 2006; Mahmud and Watanabe,
15 2014; Herrera et al., 2018).

16 Among regulating services, desertification can influence levels of atmospheric CO₂. In drylands, the
17 majority of C is stored below ground in the form of biomass and SOC (FAO, 1995) (3.3.3). Land-use
18 changes often lead to reductions in SOC and organic matter inputs into soil (Albaladejo et al., 2013;
19 Almagro et al., 2010; Hoffmann et al., 2012; Lavee et al., 1998; Rey et al., 2011), increasing soil
20 salinity and soil erosion (Lavee et al., 1998; Martinez-Mena et al., 2008). In addition to the loss of
21 soil, erosion reduces soil nutrients and organic matter, thereby impacting land's productive capacity.
22 To illustrate, soil erosion by water is estimated to result in the loss of 23–42 M t of N and 14.6–26.4
23 Mt of phosphorus from soils annually in the world (Pierzynski et al., 2017).

24 Precipitation, by affecting soil moisture content, is considered to be the principal determinant of the
25 capacity of drylands to sequester C (Fay et al., 2008; Hao et al., 2008; Mi et al., 2015; Serrano-Ortiz
26 et al., 2015; Vargas et al., 2012; Sharkhuu et al., 2016). Lower annual rainfall resulted in the release
27 of C into the atmosphere for a number of sites located in Mongolia, China and North America
28 (Biederman et al., 2017; Chen et al., 2009; Fay et al., 2008; Hao et al., 2008; Mi et al., 2015;
29 Sharkhuu et al., 2016). Low soil water availability promotes soil microbial respiration, yet there is
30 insufficient moisture to stimulate plant productivity (Austin et al., 2004), resulting in net C emissions
31 at an ecosystem level. Under even drier conditions, photodegradation of vegetation biomass may often
32 constitute an additional loss of C from ecosystem (Rutledge et al., 2010). In contrast, years of good
33 rainfall in drylands resulted in the sequestration of C (Biederman et al., 2017; Chen et al., 2009; Hao
34 et al., 2008) In an exceptionally rainy year (2011) in the southern hemisphere, the semiarid
35 ecosystems of this region contributed 51% of the global net C sink (Poulter et al., 2014). These results
36 suggest that arid ecosystems could be an important global C sink depending on soil water availability
37 (*medium evidence, high agreement*). However, drylands are generally predicted to become warmer
38 with an increasing frequency of extreme drought and high rainfall events (Donat et al., 2016).

39 When desertification reduces vegetation cover, this alters the soil surface, affecting the albedo and the
40 water balance (Gonzalez-Martin et al., 2014) (3.3). In such situations, erosive winds have no more
41 obstacles, which favour the occurrence of wind erosion and dust storms. Mineral aerosols have an
42 important influence on the dispersal of soil nutrients and lead to changes in soil characteristics
43 (Goudie and Middleton, 2001; Middleton, 2017). Thereby, the soil formation as a supporting
44 ecosystem service is negatively affected (3.3.1.). Soil erosion by wind results in a loss of fine soil
45 particles (silt and clay), reducing the ability of soil to sequester C (Wiesmeier et al., 2015). Moreover,
46 dust storms reduce crop yields by loss of plant tissue caused by sandblasting (resulting loss of plant
47 leaves and hence reduced photosynthetic activity (Field et al., 2010), exposing crop roots, crop seed
48 burial under sand deposits, and leading to losses of nutrients and fertiliser from top soil (Stefanski and

1 Sivakumar, 2009). Dust storms also impact crop yields by reducing the quantity of water available for
2 irrigation because it could decrease the storage capacity of reservoirs by siltation and block
3 conveyance canals (Middleton, 2017; Middleton and Kang, 2017; Stefanski and Sivakumar, 2009).
4 Livestock productivity is reduced by injuries caused by dust storms (Stefanski and Sivakumar, 2009).
5 Additionally, dust storms favor the dispersion of microbial and plants species, which can make local
6 endemic species vulnerable to extinction and promote the invasion of plant and microbial species
7 (Asem and Roy, 2010; Womack et al., 2010). Dust storms increase microbial species in remote sites
8 (*high confidence*); (Kellogg et al., 2004; Prospero et al., 2005; Griffin et al., 2006; Schlesinger et al.,
9 2006; Griffin, 2007; De Deckker et al., 2008; Jeon et al., 2011; Abed et al., 2012; Favet et al., 2013;
10 Woo et al., 2013; Pointing and Belnap, 2014).

11

12 **3.4.1.2. Impacts on Biodiversity: Plant and Wildlife**

13 **3.4.1.2.1. Plant Biodiversity**

14 Over 20% of global plant biodiversity centres are located within drylands (White and Nackoney,
15 2003). Plant species located within these areas are characterised by high genetic diversity within
16 populations (Martínez-Palacios et al., 1999). The plant species within these ecosystems are often
17 highly threatened by climate change and desertification (Millennium Ecosystem Assessment, 2005b;
18 Maestre et al., 2012). Increasing aridity exacerbates the risk of extinction of some plant species,
19 especially those that are already threatened due to small populations or restricted habitats (Gitay et al.,
20 2002). Desertification, including through land use change, already contributed to the loss of
21 biodiversity across drylands (*medium confidence*) (Newbold et al., 2015; Wilting et al., 2017). For
22 example, species richness decreased from 234 species in 1978 to 95 in 2011 following long periods of
23 drought and human driven degradation on the steppe land of south western Algeria (Observatoire du
24 Sahara et du Sahel, 2013). Similarly, drought and overgrazing led to loss of biodiversity in Pakistan,
25 where only drought-adapted species have by now survived on arid rangelands (Akhter and Arshad,
26 2006). Similar trends were observed in desert steppes of Mongolia (Khishigbayar et al., 2015). In
27 contrast, the increase in annual moistening of southern European Russia from the late 1980s to the
28 beginning of the 21st century caused the restoration of steppe vegetation, even under conditions of
29 strong anthropogenic pressure (Ivanov et al., 2018). The seed banks of annual species can often
30 survive over the long-term, germinating in wet years, suggesting that these species could be resilient
31 to some aspects of climate change (Vetter et al., 2005). Yet, Hiernaux and Houérou (2006) showed
32 that overgrazing in the Sahel tended to decrease the seed bank of annuals which could make them
33 vulnerable to climate change over time. Perennial species, considered as the structuring element of the
34 ecosystem, are usually less affected as they have deeper roots, xeromorphic properties and
35 physiological mechanisms that increase drought tolerance (Le Houérou, 1996). However, in North
36 Africa, long-term monitoring (1978–2014) has shown that important plant perennial species have also
37 disappeared due to drought (*Stipa tenacissima* and *Artemisia herba alba*) (Hirche et al., 2018;
38 Observatoire du Sahara et du Sahel, 2013). The aridisation of the climate in the south of Eastern
39 Siberia led to the advance of the steppes to the north and to the corresponding migration of steppe
40 mammal species between 1976 and 2016 (Ivanov et al., 2018). The future projection of impacts on
41 plant biodiversity is presented in the section 3.5.2.

42 **3.4.1.2.2. Wildlife biodiversity**

43 Dryland ecosystems have high levels of faunal diversity and endemism (MEA, 2005; Whitford,
44 2002). Over 30% of the endemic bird areas are located within these regions, which is also home to
45 25% of vertebrate species (Maestre et al., 2012; MEA, 2005). Yet, many species within drylands are
46 threatened with extinction (Durant et al., 2014; Walther, 2016). Habitat degradation and
47 desertification are generally associated with biodiversity loss (Ceballos et al. 2010; Tang et al. 2018;
48 Newbold et al. 2015). The “grazing value” of land declines with both a reduction in vegetation cover
49 and shrub encroachment, with the former being more detrimental to native vertebrates (Parsons et al.,

1 2017). Conversely, shrub encroachment may buffer desertification by increasing resource and
2 microclimate availability, resulting in an increase in vertebrate species abundance and richness
3 observed in the shrub encroached arid grasslands of North America (Whitford, 1997) and Australia
4 (Parsons et al., 2017). However, compared to historically resilient drylands, these encroached habitats
5 and their new species assemblages may be more sensitive to droughts, which may be more prevalent
6 with climate change (Schooley et al., 2018). Mammals and birds may be particularly sensitive to
7 droughts because they rely on evaporative cooling to maintain their body temperatures within an
8 optimal range (Hetem et al., 2016) and risk lethal dehydration in water limited environments (Albright
9 et al., 2017). The direct effects of reduced rainfall and water availability are *likely* to be exacerbated
10 by the indirect effects of desertification through a reduction in primary productivity. A reduction in
11 the quality and quantity of resources available to herbivores due to desertification under changing
12 climate can have knock-on consequences for predators and may ultimately disrupt trophic cascades
13 (*limited evidence, low agreement*) (Rey et al. 2017; Walther 2010). Reduced resource availability may
14 also compromise immune response to novel pathogens, with increased pathogen dispersal associated
15 with dust storms (Zinabu et al., 2018). Responses to desertification are species-specific and
16 mechanistic models are not yet able to accurately predict individual species responses to the many
17 factors associated with desertification (Fuller et al., 2016).

18 19 **3.4.2. Impacts on Socio-economic Systems**

20 Combined impacts of desertification and climate change on socio-economic development in drylands
21 are complex. Figure 3.9 schematically represents our qualitative assessment of the magnitudes and the
22 uncertainties associated with these impacts on attainment of the SDGs in dryland areas (UN, 2015).
23 The impacts of desertification and climate change are difficult to isolate from the effects of other
24 socio-economic, institutional and political factors (Pradhan et al., 2017). However, there is *high*
25 *confidence* that climate change will exacerbate the vulnerability of dryland populations to
26 desertification, and that the combination of pressures coming from climate change and desertification
27 will diminish opportunities for reducing poverty, enhancing food and nutritional security, empowering
28 women, reducing disease burden, improving access to water and sanitation. Desertification is
29 embedded in SDG 15 (target 15.3) and climate change is under SDG 13, the *high confidence* and high
30 magnitude impacts depicted for these SDGs (Figure 3.9) indicate that the interactions between
31 desertification and climate change strongly affect the achievement of the targets of SDGs 13 and 15.3,
32 pointing at the need for the coordination of policy actions on land degradation neutrality and
33 mitigation and adaptation to climate change. The following subsections present the literature and the
34 assessment which serve as the basis for Figure 3.9.

35 **3.4.2.1 Impacts on Poverty**

36 Climate change has a high potential to contribute to poverty particularly through the risks coming
37 from extreme weather events (Olsson et al., 2014). However, the evidence rigorously attributing
38 changes in observed poverty to climate change impacts is currently not available. On the other hand,
39 most of the research on links between poverty and desertification (or more broadly, land degradation)
40 focused on whether or not poverty is a cause of land degradation (Gerber et al., 2014; Vu et al., 2014;
41 Way, 2016; 4.7.1). The literature measuring to what extent desertification contributed to poverty
42 globally is lacking: the related literature remains qualitative or correlational (Barbier and Hochard,
43 2016). At the local level, on the other hand, there is *limited evidence* and *high agreement* that
44 desertification increased multidimensional poverty. For example, Diao and Sarpong (2011) estimated
45 that land degradation lowered agricultural incomes in Ghana by USD 4.2 billion between 2006 and
46 2015, increasing the national poverty rate by 5.4% in 2015. Land degradation increased the
47 probability of households becoming poor by 35% in Malawi and 48% in Tanzania (Kirui, 2016).
48 Desertification in China was found to have resulted in substantial losses in income, food production

1 and jobs (Jiang et al., 2014). On the other hand, Ge et al. (2015) indicated that desertification was
 2 positively associated with growing incomes in Inner Mongolia in China in the short run since no costs
 3 were incurred for SLM, while in the long run higher incomes allowed allocation of more investments
 4 to reduce desertification. This relationship corresponds to the Environmental Kuznets Curve, which
 5 posits that environmental degradation initially rises and subsequently falls with rising income (e.g.
 6 Stern, 2017). There is *limited evidence* on the validity of this hypothesis regarding desertification.

9
10 **Figure 3.9 Socio-economic impacts of desertification and climate change with the SDG framework**

11 3.4.2.2 Impacts on Food and Nutritional Insecurity

12 About 821 million people globally were food insecure in 2017, of whom 63% in Asia, 31% in Africa
 13 and 5% in Latin America and the Caribbean (FAO et al., 2018). The global number of food insecure
 14 people rose by 37 million since 2014. Changing climate variability, combined with a lack of climate
 15 resilience, was suggested as a key driver of this increase (FAO et al., 2018). Sub-Saharan Africa, East
 16 Africa and South Asia had the highest share of undernourished populations in the world in 2017, with
 17 28.8%, 31.4% and 33.7%, respectively (FAO et al., 2018). The major mechanism through which
 18 climate change and desertification affect food security is through their impacts on agricultural
 19 productivity. There is *robust evidence* pointing to negative impacts of climate change on crop yields
 20 in dryland areas (*high agreement*) (Hochman et al., 2017; Nelson et al., 2010; Zhao et al., 2017; 3.4.1;
 21 5.2.2; 4.7.2). There is also *robust evidence and high agreement* on the losses in agricultural
 22 productivity and incomes due to desertification (Kirui, 2016; Moussa et al., 2016; Mythili and
 23 Goedecke, 2016; Tun et al., 2015). Nkonya et al. (2016a) estimated that cultivating wheat, maize, and
 24 rice with unsustainable land management practices is currently resulting in global losses of USD 56.6
 25 billion annually, with another USD 8.7 billion of annual losses due to lower livestock productivity
 26 caused by rangeland degradation. However, the extent to which these losses affected food insecurity
 27 in dryland areas is not known. Lower crop yields and higher agricultural prices worsen existing food

1 insecurity, especially for net-food buying rural households and urban dwellers. Climate change and
2 desertification are not the sole drivers of food insecurity, but especially in the areas with high
3 dependence on agriculture, they are among the main contributors.

4 **3.4.2.3 Impacts on Human Health through Dust Storms**

5 The frequency and intensity of dust storms are increasing due to land use and land cover changes and
6 climate-related factors (2.4) particularly in some regions of the world such as the Arabian Peninsula
7 (Jish Prakash et al., 2015; Yu et al., 2015; Gherboudj et al., 2017; Notaro et al., 2013; Yu et al. 2013;
8 Alobaidi et al., 2017; Maghrabi et al., 2011; Almazroui et al. 2018) and broader Middle East (Rashki
9 et al., 2012; Türkeş, 2017; Namdari et al., 2018) as well as Central Asia (Indoitu et al., 2015; Xi and
10 Sokolik, 2015), with growing negative impacts on human health (Díaz et al., 2017; Goudarzi et al.,
11 2017; Goudie, 2014; Samoli et al., 2011) (*high confidence*). Dust storms transport particulate matter,
12 pollutants, pathogens and potential allergens that are dangerous for human health over long distances
13 (Goudie and Middleton, 2006; Sprigg, 2016). Particulate matter (PM), i.e. the suspended particles in
14 the air having sizes of 10 micrometre (PM10) or less, have damaging effects on human health (Díaz et
15 al., 2017; Goudarzi et al., 2017; Goudie, 2014; Samoli et al., 2011). The health effects of dust storms
16 are largest in areas in the immediate vicinity of their origin, primarily the Sahara Desert, followed by
17 Central and Eastern Asia, the Middle East and Australia (Zhang et al., 2016), however, there is *robust*
18 *evidence* showing that the negative health effects of dust storms reach a much wider area (Bennett et
19 al., 2006; Díaz et al., 2017; Kashima et al., 2016; Lee et al., 2014; Samoli et al., 2011; Zhang et al.,
20 2016). The primary health effects of dust storms include damage to the respiratory and cardiovascular
21 systems (Goudie, 2013). Dust particles with a diameter smaller than 2.5µm were associated with
22 global cardiopulmonary mortality of about 402,000 people in 2005, with 3.47 million years of life lost
23 in that single year (Giannadaki et al., 2014). If globally only 1.8% of cardiopulmonary deaths were
24 caused by dust storms, in the countries of the Sahara region, Middle East, South and East Asia, dust
25 storms were suggested to be the reason for 15–50% of all cardiopulmonary deaths (Giannadaki et al.,
26 2014). A 10µgm⁻³ increase in PM10 dust particles was associated with mean increases in non-
27 accidental mortality from 0.33% to 0.51% across different calendar seasons in China, Japan and South
28 Korea (Kim et al., 2017). The percentage of all-cause deaths attributed to fine particulate matter in
29 Iranian cities affected by Middle Eastern dust storms (MED) were 0.56–5.02%, while the same
30 percentage for non-affected cities were 0.16–4.13% (Hopke et al., 2018). The Meningococcal
31 Meningitis epidemics occur in the Sahelian region during the dry seasons with dusty conditions
32 (Agier et al., 2012; Molesworth et al., 2003). Despite a strong concentration of dust storms in the
33 Sahel, North Africa, the Middle East and Central Asia, there is relatively little research on human
34 health impacts of dust storms in these regions. More research on health impacts and related costs of
35 dust storms as well as on public health response measures can help in mitigating these health impacts.

36 **3.4.2.4. Impacts on Gender Equality**

37 Environmental issues such as desertification and impacts of climate change have been increasingly
38 investigated through a gender lens (Bose; Broeckhoven and Cliquet, 2015; Kaijser and Kronsell,
39 2014; Kiptot et al., 2014; Villamor and van Noordwijk, 2016). There is *medium evidence* and *high*
40 *agreement* that women will be impacted more than men by environmental degradation (Arora-
41 Jonsson, 2011; Gurung et al., 2006; Cross-Chapter Box 11: Gender, Chapter 7). Socially structured
42 gender-specific roles and responsibilities, daily activities, access and control over resources, decision-
43 making and opportunities lead men and women to interact differently with natural resources and
44 landscapes. For example, water scarcity affected women more than men in rural Ghana as they had to
45 spend more time in fetching water, which has implications on time allocations for other activities
46 (Ahmed et al., 2016). Despite the evidence pointing to differentiated impact of environmental
47 degradation on women and men, gender issues have been marginally addressed in many land
48 restoration and rehabilitation efforts, which often remain gender-blind. Although there is *robust*
49

1 *evidence* on the location-specific impacts of climate change and desertification on gender equality,
2 however, there is *limited evidence* on the gender-related impacts of land restoration and rehabilitation
3 activities. Women are usually excluded from local decision making on actions regarding
4 desertification and climate change. Socially constructed gender-specific roles and responsibilities are
5 not static because they are shaped by other factors such as wealth, age, ethnicity, and formal education
6 (Kajiser and Kronsell, 2014; Villamor et al., 2014). Hence, women's and men's environmental
7 knowledge and priorities for restoration often differ (Sijapati Basnett et al., 2017). In some areas
8 where sustainable land options (e.g. agroforestry) are being promoted, women were not able to
9 participate due to culturally-embedded asymmetries in power relations between men and women
10 (Catacutan and Villamor, 2016). Nonetheless, women particularly in the rural areas remain heavily
11 involved in securing food for their households. Food security for them is associated with land
12 productivity and women's contribution to address desertification is crucial.

13 **3.4.2.5. Impacts on Water Scarcity and Use**

14 Reduced water retention capacity of degraded soils amplifies floods (de la Paix et al., 2011),
15 reinforces degradation processes through soil erosion, and reduces annual intake of water to aquifers,
16 exacerbating existing water scarcities (Le Roux et al., 2017; Cano et al., 2018). Reduced vegetation
17 cover and more intense dust storms were found to intensify droughts (Cook et al., 2009). Moreover,
18 secondary salinisation in the irrigated drylands often requires leaching with considerable amounts of
19 water (Greene et al., 2016; Wichelns and Qadir, 2015). Thus, different types of soil degradation
20 increase water scarcity both through lower water quantity and quality (Liu et al., 2017; Liu et al.,
21 2016c). All these processes reduce water availability for other needs. In this context, climate change
22 will further intensify water scarcity in some dryland areas and increase the frequency of droughts
23 (*medium confidence*) (2.2; IPCC, 2013; Zheng et al., 2018). Higher water scarcity may imply growing
24 use of wastewater effluents for irrigation (Pedrero et al., 2010). The use of untreated wastewater
25 exacerbates soil degradation processes (Tal, 2016; Singh et al., 2004; Qishlaqi et al., 2008; Hanjra et
26 al., 2012), in addition to negative human health impacts (Faour-Klingbeil and Todd, 2018; Hanjra et
27 al., 2012). Climate change, thus, will amplify the need for integrated land and water management for
28 sustainable development.

29 **3.4.2.6 Impacts on Energy Infrastructure through Dust Storms**

30 Desertification leads to conditions that favour the production of dust storms (*high confidence*) (3.3.1).
31 There is *robust evidence and high agreement* that dust storms negatively affect the operational
32 potential of solar and wind power harvesting equipment through dust deposition, reduced reach of
33 solar radiation and increasing blade surface roughness, and can also reduce effective electricity
34 distribution in high-voltage transmission lines (Zidane et al., 2016; Costa et al., 2016; Lopez-Garcia et
35 al., 2016; Maliszewski et al., 2012; Mani and Pillai, 2010; Mejia and Kleissl, 2013; Mejia et al., 2014;
36 Middleton, 2017; Sarver et al., 2013; Kaufman et al., 2002; Kok et al., 2018). Direct exposure to
37 desert dust storm can reduce energy generation efficiency of solar panels by 70–80% in one hour
38 (Ghazi et al., 2014). Saidan et al.(2016) indicated that in the conditions of Baghdad, Iraq, one month
39 exposure to weather reduced the efficiency of solar modules by 18.74% due to dust deposition. In
40 Atacama desert, Chile, one month exposure reduced thin-film solar module performance by 3.7-4.8%
41 (Funtealba et al., 2015). This has important implications for climate change mitigation efforts using
42 the expansion of solar and wind energy generation in dryland areas for substituting fossil fuels.
43 Abundant access to solar energy in many dryland areas makes them high potential locations for the
44 installation of solar energy generating infrastructure. Increasing desertification, resulting in higher
45 frequency and intensity of dust storms imposes additional costs for climate change mitigation through
46 deployment of solar and wind energy harvesting facilities in dryland areas. Most frequently used
47 solutions to this problem involve physically wiping or washing the surface of solar devices with
48 water. These result in additional costs and excessive use of already scarce water resources and labour

1 (Middleton, 2017). The use of special coatings on the surface of solar panels can help prevent the
2 deposition of dusts (Costa et al., 2016; Costa et al., 2018; Gholami et al., 2017).

3 **3.4.2.7 Impacts on Transport Infrastructure through Dust Storms and Sand Movement**

4 Dust storms and movement of sand dunes often threaten the safety and operation of railway and road
5 infrastructure in arid and hyper-arid areas, and can lead to road and airport closures due to reductions
6 in visibility. For example, the dust storm on 10th March 2009 over Riyadh was assessed to be the
7 strongest in the previous two decades in Saudi Arabia, causing limited visibility, airport shutdown and
8 damages to infrastructure and environment across the city (Maghrabi et al., 2011). There are
9 numerous historical examples of how moving sand dunes led to the forced decommissioning of early
10 railway lines built in Sudan, Algeria, Namibia and Saudi Arabia in the late 19th and early 20th century
11 (Bruno et al., 2018). Currently, the highest concentration of railways vulnerable to sand movements
12 are located in north-western China, Middle East and North Africa (Bruno et al., 2018; Cheng and
13 Xue, 2014). In China, sand dune movements are periodically disrupting the railway transport in
14 Linhai-Ceke line in north-western China and Lanzhou-Xinjiang High-speed Railway in western
15 China, with considerable clean-up and maintenance costs (Bruno et al., 2018; Zhang et al., 2010).
16 There are large-scale plans for expansion of railway networks in arid areas of China, Central Asia,
17 North Africa, the Middle East, and Eastern Africa. For example, “The Belt and Road Initiative”
18 promoted by China, the Gulf Railway project by the countries of the Arab Gulf Cooperation Council
19 (GCC), or Lamu Port-South Sudan- Ethiopia Transport Corridor in Eastern Africa. These investments
20 have long-term return and operation periods. Their construction and associated engineering solutions
21 will therefore benefit from careful consideration of potential desertification and climate change effects
22 on sand storms and dune movements.

23 **3.4.2.8 Impacts on Conflicts**

24 There is *low confidence* in climate change and desertification leading to violent conflicts. There is
25 *medium evidence* and *low agreement* that climate change and desertification contribute to already
26 existing conflict potentials (Herrero, 2006; von Uexkull et al., 2016; Theisen, 2017; Olsson, 2017;
27 Wischnath and Buhaug, 2014; 4.7.3). To illustrate, Hsiang et al. (2013) found that each one standard
28 deviation increase in temperature or rainfall was found to increase interpersonal violence by 4% and
29 intergroup conflict by 14% (Hsiang et al., 2013). However, this conclusion was disputed by Buhaug et
30 al., (2014), who found no evidence linking climate variability to violent conflict after replicating
31 Hsiang et al. (2013) by studying only violent conflicts. Almer et al. (2017) found that a one-standard
32 deviation increase in dryness raised the likelihood of riots in Sub-Saharan African countries by 8.3%
33 during the 1990–2011 period. On the other hand, Owain and Maslin (2018) found that droughts and
34 heatwaves were not significantly affecting the level of regional conflict in East Africa. Similarly, it
35 was suggested that droughts and desertification in the Sahel have played a relatively minor role in the
36 conflicts in the Sahel in the 1980s, with the major reasons for the conflicts during this period being
37 political, especially the marginalisation of pastoralists (Benjaminsen, 2016), corruption and rent-
38 seeking (Benjaminsen et al., 2012). Moreover, the role of environmental factors as the key drivers of
39 conflicts were questioned in the case of Sudan (Verhoeven, 2011) and Syria (De Châtel, 2014).
40 Selection bias, when the literature focuses on the same few regions where conflicts occurred and
41 relates them to climate change, is a major shortcoming, as it ignores other cases where conflicts did
42 not occur (Adams et al., 2018) despite degradation of the natural resource base and extreme weather
43 events.

44 **3.4.2.9 Impacts on Migration**

45 Environmentally-induced migration is complex and accounts for multiple drivers of mobility as well
46 as other adaptation measures undertaken by populations exposed to environmental risk (*high*
47 *confidence*). There is *medium evidence* and *low agreement* that climate change impacts migration. The
48 World Bank (2018) predicted that 143 million people would be forced to move internally by 2050 if
49

1 no climate action is taken. Focusing on asylum seekers alone, rather than the total number of
2 migrants, Missirian and Schlenker (2017) predict the asylum applications to the European Union will
3 increase from 28% (98,000 additional asylum applications per year) up to 188% (660,000 additional
4 applications per year) depending on the climate scenario by 2100. While the modelling efforts have
5 greatly improved over the years (Hunter et al., 2015; McLeman, 2011; Sherbinin and Bai, 2018) and
6 in particular, these recent estimates provide an important insight into potential future developments,
7 the quantitative projections are still based on the number of people exposed to risk rather than the
8 number of people who would actually engage in migration as a response to this risk (Gemenne, 2011;
9 McLeman, 2013) and they do not take into account individual agency in migration decision nor
10 adaptive capacities of individuals (Hartmann, 2010; Kniveton et al., 2011; Piguet, 2010) (see Section
11 3.6.2 discussing migration as a response to desertification). Accordingly, the available micro-level
12 evidence suggests that climate-related shocks are one of the many drivers of migration (Adger et al.,
13 2014; London Government Office for Science and Foresight, 2011; Melde et al., 2017), but the
14 individual responses to climate risk are more complex than commonly assumed (Gray and Mueller,
15 2012a). For example, despite strong focus on natural disasters, neither flooding (Gray and Mueller,
16 2012b; Mueller et al., 2014) nor earthquakes (Halliday, 2006) were found to induce long-term
17 migration; but instead, slow-onset changes, especially those provoking crop failures and heat stress,
18 could affect household or individual migration decisions (Gray and Mueller, 2012a; Missirian and
19 Schlenker, 2017; Mueller et al., 2014). Out-migration from drought-prone areas has received
20 particular attention (de Sherbinin et al., 2012; Ezra and Kiros, 2001) and indeed, a substantial body of
21 literature suggests that households engage in local or internal migration as a response to drought
22 (Findlay, 2011; Gray and Mueller, 2012a), while international migration decreases with drought in
23 some contexts (Henry et al., 2004), but might increase in contexts where migration networks are well
24 established (Feng et al., 2010; Nawrotzki and DeWaard, 2016; Nawrotzki et al., 2015, 2016).
25 Similarly, the evidence is not conclusive with respect to the effect of environmental drivers, in
26 particular desertification, on mobility. While it has not consistently entailed out-migration in the case
27 of Ecuadorian Andes (Gray, 2009, 2010) environmental and land degradation increased mobility in
28 Kenya and Nepal (Gray, 2011; Massey et al., 2010), but marginally decreased mobility in Uganda
29 (Gray, 2011). These results suggest that in some contexts, environmental shocks actually undermine
30 household's financial capacity to undertake migration (Nawrotzki and Bakhtsiyarava, 2017),
31 especially in the case of the poorest households (Barbier and Hochard, 2018; Koubi et al., 2016;
32 Kubik and Maurel, 2016; McKenzie and Yang, 2015). Adding to the complexity, migration,
33 especially to frontier areas, by increasing pressure on land and natural resources, might itself
34 contribute to environmental degradation at the destination (Hugo, 2008; IPBES, 2018a; McLeman,
35 2017). The consequences of migration can also be salient in the case of migration to urban or peri-
36 urban areas; indeed, environmentally-induced migration can add to urbanisation (3.6.2.2), often
37 exacerbating problems related to poor infrastructure and unemployment.

38 **3.4.2.10 Impacts on Pastoral Communities**

39 Pastoral production systems occupy a significant portion of the world (Rass, 2006; Dong, 2016). Food
40 insecurity among pastoral households is often high (3.1.3; Gomes, 2006). The Sahelian droughts of
41 the 1970-80s provided an example of how droughts could affect livestock resources and crop
42 productivity, contributing to hunger, out-migration and suffering for millions of pastoralists (Hein and
43 De Ridder, 2006; Molua and Lambi, 2007). During these Sahelian droughts low and erratic rainfall
44 exacerbated desertification processes, leading to ecological changes that forced people to use marginal
45 lands and ecosystems. Similarly, the rate of rangeland degradation is now increasing because of
46 environmental changes and overexploitation of resources (Kassahun et al., 2008; Vetter, 2005).
47 Desertification coupled with climate change is negatively affecting livestock feed and grazing species
48 (Hopkins and Del Prado, 2007), changing the composition in favour of species with low forage
49 quality, ultimately reducing livestock productivity (D'Odorico et al., 2013; Dibari et al., 2016) and

1 increasing livestock disease prevalence (Thornton et al., 2009). There is *robust evidence and high*
2 *agreement* that weak adaptive capacity, coupled with negative effects from other climate-related
3 factors, are predisposing pastoralists to increased poverty from desertification and climate change
4 globally (López-i-Gelats et al., 2016; Giannini et al., 2008; IPCC, 2007). On the other hand,
5 misguided policies such as enforced sedentarisation and in certain cases protected area delineation
6 (fencing), which restrict livestock mobility have hampered optimal use of grazing land resources (Du,
7 2012); and led to degradation of resources and out-migration of people in search of better livelihoods
8 (Gebeye, 2016; Liao et al., 2015). Restrictions on the mobile lifestyle is reducing the resilient adaptive
9 capacity of pastoralists to natural hazards including extreme and variable weather conditions, drought
10 and climate change (Schilling et al., 2014). Furthermore, the exacerbation of the desertification
11 phenomenon due to agricultural intensification (D’Odorico et al., 2013) and land fragmentation
12 caused by encroachment of agriculture into rangelands (Otuoma et al., 2009; Behnke and Kerven,
13 2013) is threatening pastoral livelihoods. For example, commercial cotton (*Gossypium hirsutum*)
14 production is crowding out pastoral systems in Benin (Tamou et al., 2018). Food shortages and the
15 urgency to produce enough crop for public consumption are leading to the encroachment of
16 agriculture into productive rangelands and those converted rangelands are frequently prime lands used
17 by pastoralists to produce feed and graze their livestock during dry years (Dodd, 1994). The
18 sustainability of pastoral systems is therefore coming into question because of social and political
19 marginalisation of the system (Davies et al., 2016) and also because of the fierce competition it is
20 facing from other livelihood sources such as crop farming (Haan et al., 2016).

21 22 **3.5. Future Projections**

23 **3.5.1. Future Projections of Desertification**

24 Assessing the impact of climate change on future desertification is difficult as several environmental
25 and anthropogenic variables interact to determine its dynamics. The majority of modelling studies
26 regarding the future evolution of desertification rely on the analysis of specific climate change
27 scenarios and Global Climate Models and their effect on a few processes or drivers that trigger
28 desertification (Cross-Chapter Box 1: Scenarios, Chapter 1).

29 With regards to climate impacts, the analysis of global and regional climate models concludes that
30 under all representative concentration pathways (RCPs) potential evapotranspiration (PET) would
31 increase worldwide as a consequence of increasing surface temperatures and surface water vapour
32 deficit (Sherwood and Fu, 2014). Consequently, there would be associated changes in aridity indices
33 that depend on this variable (*high agreement, robust evidence*) (Cook et al., 2014a; Dai, 2011;
34 Dominguez et al., 2010; Feng and Fu, 2013; Ficklin et al., 2016; Fu et al., 2016; Greve and
35 Seneviratne, 1999; Koutroulis, 2019; Scheff and Frierson, 2015). Due to the large increase in PET and
36 decrease in precipitation over some subtropical land areas, aridity index will decrease in some
37 drylands (Zhao and Dai, 2015), with one model estimating ~10% increase in hyper-arid areas globally
38 (Zeng and Yoon, 2009). Increases in PET are projected to continue due to climate change (Cook et al.,
39 2014a; Fu et al., 2016; Lin et al., 2015; Scheff and Frierson, 2015). However, as noted in sections
40 3.1.1 and 3.2.1, these PET calculations use assumptions that are not valid in an environment with
41 changing CO₂. Evidence from precipitation, runoff or photosynthetic uptake of CO₂ suggest that a
42 future warmer world will be less arid (Roderick et al., 2015). Observations in recent decades indicate
43 that the Hadley cell has expanded poleward in both hemispheres (Fu et al., 2006; Hu and Fu, 2007;
44 Johanson et al., 2009; Seidel and Randel, 2007), and under all RCPs would continue expanding
45 (Johanson et al., 2009; Lu et al., 2007). This expansion leads to the poleward extension of sub-tropical
46 dry zones and hence an expansion in drylands on the poleward edge (Scheff and Frierson, 2012).

1 Overall, this suggests that while aridity will increase in some places (*high confidence*), there is
2 insufficient evidence to suggest a global change in dryland aridity (*medium confidence*).

3 Regional modelling studies confirm the outcomes of Global Climate Models (Africa: Terink et al.,
4 2013; China: Yin et al., 2015; Brazil: Marengo and Bernasconi, 2015; Cook et al., 2012; Greece:
5 Nastos et al., 2013; Italy: Coppola and Giorgi, 2009). According to the IPCC AR5 (IPCC, 2013),
6 decreases in soil moisture are detected in the Mediterranean, Southwest USA and southern African
7 regions. This is in line with alterations in the Hadley circulation and higher surface temperatures. This
8 surface drying will continue to the end of this century under the RCP8.5 scenario (*high confidence*).
9 Ramarao et al., (2015) showed that a future climate projection based on RCP4.5 scenario indicated the
10 possibility for detecting the summer-time soil drying signal over the Indian region during the 21st
11 century in response to climate change. The IPCC Special Report on Global Warming of 1.5°C (SR15,
12 Chapter 3) (Hoegh-Guldberg et al., 2018) report concluded with “*medium confidence*” that global
13 warming by more than 1.5°C increases considerably the risk of aridity for the Mediterranean area and
14 Southern Africa. Miao et al., (2015b) showed an acceleration of desertification trends under the
15 RCP8.5 scenario in the middle and northern part of Central Asia and some parts of north western
16 China. It is also useful to consider the effects of the dynamic–thermodynamical feedback of the
17 climate. Schewe and Levermann (2017) show increases up to 300 % in the central Sahel rainfall by
18 the end of the century due to an expansion of the West African monsoon. Warming could trigger an
19 intensification of monsoonal precipitation due to increases in ocean moisture availability.

20 The impacts of climate change on dust storm activity are not yet comprehensively studied and
21 represent an important knowledge gap. Currently, GCMs are unable to capture recent observed dust
22 emission and transport (Evan, 2018; Evan et al., 2014) limiting confidence in future projections.
23 Literature suggests that climate change decreases wind erosion/dust emission overall with regional
24 variation (*low confidence*). Mahowald et al. (2006) and Mahowald (2007) found that climate change
25 led to a decrease in desert dust source areas globally using CMIP3 GCMs. Wang et al. (2009) found a
26 decrease in sand dune movement by 2039 (increasing thereafter) when assessing future wind erosion
27 driven desertification in arid and semiarid China using a range of SRES scenarios and HadCM3
28 simulations. Dust activity in the US Southern Great Plains was projected to increase, while in the
29 Northern Great Plains it was projected to decrease under RCP 8.5 climate change scenario (Pu and
30 Ginoux, 2017). Evan et al. (2016) project a decrease in African dust emission associated with a
31 slowdown of the tropical circulation in the high CO₂ RCP8.5 scenario.

32 Global estimates of the impact of climate change on soil salinisation show that under the IS92a
33 emissions scenario (a scenario prepared in 1992 that contains “business as usual” assumptions)
34 (Leggett et al., 1992) the area at risk of salinisation would increase in the future (*limited evidence*,
35 *high agreement*; Schofield and Kirkby, 2003). Climate change has an influence on soil salinisation
36 that induces further land degradation through several mechanisms that vary in their level of
37 complexity. However, only a few examples can be found to illustrate this range of impacts, including
38 the effect of groundwater table depletion (Rengasamy, 2006) and irrigation management (Sivakumar,
39 2007), salt migration in coastal aquifers with decreasing water tables (Sherif and Singh, 1999; 4.10.7),
40 and surface hydrology and vegetation that affect wetlands and favour salinisation (Nielsen and Brock,
41 2009).

42

43 **3.5.1.1. Future Vulnerability and Risk to Desertification**

44 Following the conceptual framework developed in the Managing the Risks of Extreme Events and
45 Disasters to Advance Climate Change Adaptation special report (SREX) (IPCC, 2012), future risks
46 are assessed by examining changes in exposure (i.e. presence of people; livelihoods; species or
47 ecosystems; environmental functions, service, and resources; infrastructure; or economic, social or
48 cultural assets; see glossary), changes in vulnerability (i.e. propensity or predisposition to be

1 adversely affected; see glossary) and changes in the nature and magnitude of hazards (i.e. potential
2 occurrence of a natural or human-induced physical event that causes damage; see glossary). Climate
3 change is expected to further exacerbate the vulnerability of dryland ecosystems to desertification by
4 increasing PET globally (Sherwood and Fu, 2014). Temperature increases between 2°C and 4°C are
5 projected in drylands by the end of the 21st century under RCP4.5 and RCP8.5 scenarios, respectively
6 (IPCC, 2013). An assessment by (Carrão et al., 2017) showed an increase in drought hazards by late-
7 century (2071–2099) compared to a baseline (1971–2000) under high RCPs in drylands around the
8 Mediterranean, south-eastern Africa, and southern Australia. In Latin America, Morales et al. (2011)
9 indicated that areas affected by drought will increase significantly by 2100 under SRES scenarios A2
10 and B2. The countries expected to be affected include Guatemala, El Salvador, Honduras and
11 Nicaragua. In CMIP5 scenarios, Mediterranean types of climate are projected to become drier
12 (Alessandri et al., 2014; Polade et al., 2017), with the equatorward margins being potentially replaced
13 by arid climate types (Alessandri et al., 2014). Globally, climate change is predicted to intensify the
14 occurrence and severity of droughts (*medium confidence*) (2.2; Dai, 2013; Sheffield and Wood, 2008;
15 Swann et al., 2016; Wang, 2005; Zhao and Dai, 2015; Carrão et al., 2017; Naumann et al., 2018).
16 Ukkola et al. (2018) showed large discrepancies between CMIP5 models for all types of droughts,
17 limiting the confidence that can be assigned to projections of drought.

18 Drylands are characterised by high climatic variability. Climate impacts on desertification are not
19 only defined by projected trends in mean temperature and precipitation values but are also strongly
20 dependent on changes in climate variability and extremes (Reyer et al., 2013). The responses of
21 ecosystems depend on diverse vegetation types. Drier ecosystems are more sensitive to changes in
22 precipitation and temperature (Li et al., 2018; Seddon et al., 2016; You et al., 2018), increasing
23 vulnerability to desertification. It has also been reported that areas with high variability in
24 precipitation tend to have lower livestock densities and that those societies that have a strong
25 dependence on livestock that graze natural forage are especially affected (Sloat et al., 2018). Social
26 vulnerability in drylands increases as a consequence of climate change that threatens the viability of
27 pastoral food systems (Dougill et al., 2010; López-i-Gelats et al., 2016). Social drivers can also play
28 an important role with regards to future vulnerability (Máñez Costa et al., 2011). In the arid region of
29 north-western China, Liu et al. (2016b) estimated that under RCP4.5 areas of increased vulnerability
30 to climate change and desertification will surpass those with decreased vulnerability.

31 Using an ensemble of global climate, integrated assessment and impact models, Byers et al. (2018)
32 investigated 14 impact indicators at different levels of global mean temperature change and
33 socioeconomic development. The indicators cover water, energy and land sectors. Of particular
34 relevance to desertification are the water (e.g. water stress, drought intensity) and the land (e.g. habitat
35 degradation) indicators. Under shared socioeconomic pathway SSP2 (“Middle of the Road”) at 1.5°C,
36 2°C and 3°C of global warming, the numbers of dryland populations exposed (vulnerable) to various
37 impacts related to water, energy and land sectors (e.g. water stress, drought intensity, habitat
38 degradation) are projected to reach 951 (178) million, 1,152 (220) million and 1,285 (277) million,
39 respectively. While at global warming of 2°C, under SSP1 (sustainability), the exposed (vulnerable)
40 dryland population is 974 (35) million, and under SSP3 (Fragmented World) it is 1,267 (522) million.
41 Steady increases in the exposed and vulnerable populations are seen for increasing global mean
42 temperatures. However much larger differences are seen in the vulnerable population under different
43 SSPs. Around half the vulnerable population is in South Asia, followed by Central Asia, West Africa
44 and East Asia.

45 3.5.2. Future Projections of Impacts

46 Future climate change is expected to increase the potential for increased soil erosion by water in
47 dryland areas (*medium confidence*). Yang et al. (2003) use a Revised Universal Soil Loss Equation
48 (RUSLE) model to study global soil erosion under historical, present and future conditions of both

1 cropland and climate. Soil erosion potential has increased by about 17%, and climate change will
2 increase this further in the future. In northern Iran, under the SRES A2 emission scenario the mean
3 erosion potential is projected to grow by 45% comparing the period 1991-2010 with 2031-2050 (Zare
4 et al., 2016). A strong decrease in precipitation for almost all parts of Turkey was projected for the
5 period of 2021–2050 compared to 1971-2000 using Regional Climate Model, RegCM4.4 of the
6 International Centre for Theoretical Physics (ICTP) under RCP4.5 and RCP8.5 scenarios (Türkeş et
7 al., 2019). The projected changes in precipitation distribution can lead to more extreme precipitation
8 events and prolonged droughts, increasing Turkey’s vulnerability to soil erosion (Türkeş et al.,
9 2019). In Portugal, a study comparing wet and dry catchments under A1B and B1 emission scenarios
10 showed an increase in erosion in dry catchments (Serpa et al., 2015). In Morocco an increase in
11 sediment load is projected as a consequence of reduced precipitation (Simonneaux et al., 2015). WGII
12 AR5 concluded the impact of increases in heavy rainfall and temperature on soil erosion will be
13 modulated by soil management practices, rainfall seasonality and land cover (Jiménez Cisneros et al.,
14 2014). Ravi et al. (2010) predicted an increase in hydrologic and aeolian soil erosion processes as a
15 consequence of droughts in drylands. However, there are some studies that indicate that soil erosion
16 will be reduced in Spain (Zabaleta et al., 2013), Greece (Nerantzaki et al., 2015) and Australia (Klik
17 and Eitzinger, 2010), while others project changes in erosion as a consequence of the expansion of
18 croplands (Borrelli et al., 2017).

19 Potential dryland expansion implies lower C sequestration and higher risk of desertification (Huang et
20 al., 2017), with severe impacts on land usability and threatening food security. At the level of biomes
21 (global-scale zones, generally defined by the type of plant life that they support in response to average
22 rainfall and temperature patterns; see glossary), soil C uptake is determined mostly by weather
23 variability. The area of the land in which dryness controls CO₂ exchange has risen by 6% since 1948
24 and is projected to expand by at least another 8% by 2050. In these regions net C uptake is about 27%
25 lower than elsewhere (Yi et al., 2014). Potential losses of soil C are projected to range from 9 to 12%
26 of the total C stock in the 0-20 cm layer of soils in the southern European Russia by end of this
27 century (Ivanov et al., 2018).

28 Desertification under climate change will threaten biodiversity in drylands (*medium confidence*).
29 Rodriguez-Rodriguez-Caballero et al. (2018) analysed the cover of biological soil crusts under current
30 and future environmental conditions utilising an environmental niche modelling approach. Their
31 results suggest that biological soil crusts currently cover ~1600 M ha in drylands. Under RCP
32 scenarios 2.6 to 8.5, 25–40% of this cover will be lost by 2070 with climate and land use contributing
33 equally. The predicted loss is expected to substantially reduce their contribution to N cycling (6.7–
34 9.9 Tg yr⁻¹ of N) and C cycling (0.16–0.24 Pg yr⁻¹ of C) (Rodriguez-Caballero et al., 2018). A study
35 in Colorado Plateau, USA showed that changes in climate in drylands may damage the biocrust
36 communities by promoting rapid mortality of foundational species (Rutherford et al., 2017), while in
37 southern California deserts climate change-driven extreme heat and drought may surpass the survival
38 thresholds of some desert species (Bachelet et al., 2016). In semiarid Mediterranean shrublands in
39 eastern Spain, plant species richness and plant cover could be reduced by climate change and soil
40 erosion (García-Fayos and Bochet, 2009). The main drivers of species extinctions are land use
41 change, habitat pollution, over-exploitation, and species invasion, while the climate change is
42 indirectly linked to species extinctions (Settele et al., 2014). Malcolm et al. (2006) found that more
43 than 2000 plant species located within dryland biodiversity hotspots could become extinct within 100
44 years starting 2004 (within the Cape Floristic Region, Mediterranean Basin and Southwest Australia).
45 Furthermore, it is suggested that land use and climate change could cause the loss of 17% of species
46 within shrublands and 8% within hot deserts by 2050 (van Vuuren et al., 2006) (*low confidence*). A
47 study in the semi-arid Chinese Altai Mountains showed that mammal species richness will decline,
48 and rates of species turnover will increase, and more than 50% of their current ranges will be lost (Ye
49 et al., 2018).

1 Changing climate and land use have resulted in higher aridity and more droughts in some drylands,
2 with the rising role of precipitation, wind and evaporation on desertification (Fischlin et al., 2007). In
3 a 2°C world, annual water discharge is projected to decline, and heatwaves are projected to pose risk
4 to food production by 2070 (Waha et al., 2017). However, Betts et al. (2018) found a mixed response
5 of water availability (runoff) in dryland catchments to global temperature increases from 1.5°C to 2°C.
6 The forecasts for Sub-Saharan Africa suggest that higher temperatures, increase in the number of
7 heatwaves, and increasing aridity, will affect the rainfed agricultural systems (Serdeczny et al., 2017).
8 A study by (Wang et al., 2009) in arid and semiarid China showed decreased livestock productivity
9 and grain yields from 2040 to 2099, threatening food security. In Central Asia, projections indicate a
10 decrease in crop yields, and negative impacts of prolonged heat waves on population health (3.7.2;
11 Reyner et al., 2017). World Bank (2009) projected that, without the C fertilisation effect, climate
12 change will reduce the mean yields for 11 major global crops, such as millet, field pea, sugar beet,
13 sweet potato, wheat, rice, maize, soybean, groundnut, sunflower, and rapeseed, by 15% in Sub-
14 Saharan Africa, 11% in Middle East and North Africa, 18% in South Asia, and 6% in Latin America
15 and Caribbean by 2046–2055, compared to 1996–2005. A separate meta-analysis suggested a similar
16 reduction in yields in Africa and South Asia due to climate change by 2050 (Knox et al., 2012).
17 Schlenker and Lobell (2010) estimated that in sub-Saharan Africa, crop production may be reduced by
18 17–22% due to climate change by 2050. At the local level, climate change impacts on crop yields vary
19 by location (5.2.2). Negative impacts of climate change on agricultural productivity contribute to
20 higher food prices. The imbalance between supply and demand for agricultural products is projected
21 to increase agricultural prices in the range of 31% for rice to 100% for maize by 2050 (Nelson et al.,
22 2010), and cereal prices in the range between a 32% increase and a 16% decrease by 2030 (Hertel
23 et al., 2010). In the southern European Russia, it is projected that the yields of grain crops will decline
24 by 5 to 10% by 2050 due to the higher intensity and coverage of droughts (Ivanov et al., 2018).

25
26 Climate change can have strong impacts on poverty in drylands (*medium confidence*) (Hallegatte and
27 Rozenberg, 2017; Hertel and Lobell, 2014). Globally, Hallegatte et al. (2015) project that without
28 rapid and inclusive progress on eradicating multidimensional poverty, climate change can increase the
29 number of the people living in poverty by 35 to 122 million people until 2030. Although these
30 numbers are global and not specific to drylands, the highest impacts in terms of the share of the
31 national populations being affected are projected to be in the drylands areas of the Sahel region,
32 eastern Africa and South Asia (Stephane Hallegatte et al., 2015). The impacts of climate change on
33 poverty vary depending on whether the household is a net agricultural buyer or seller. Modelling
34 results showed that poverty rates would increase by about one-third among the urban households and
35 non-agricultural self-employed in Malawi, Uganda, Zambia, and Bangladesh due to high agricultural
36 prices and low agricultural productivity under climate change (Hertel et al., 2010). On the contrary,
37 modelled poverty rates fell substantially among agricultural households in Chile, Indonesia,
38 Philippines and Thailand, because higher prices compensated for productivity losses (Hertel et al.,
39 2010).

40 41 **3.6. Responses to Desertification under Climate Change**

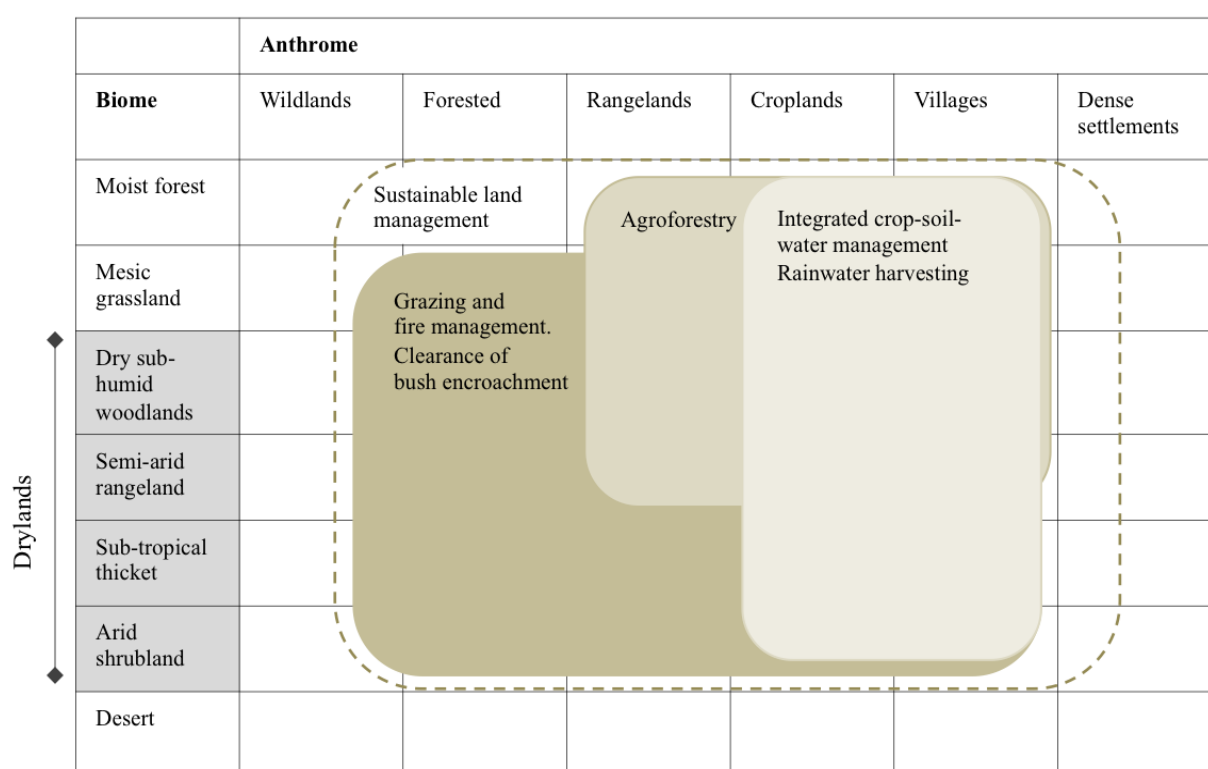

42 Achieving sustainable development of dryland livelihoods requires avoiding dryland degradation
43 through SLM and restoring and rehabilitating the degraded drylands due to their potential wealth of
44 ecosystem benefits and importance to human livelihoods and economies (Thomas, 2008). A broad
45 suite of on the ground response measures exist to address desertification (Scholes, 2009), be it in the
46 form of improved fire and grazing management, the control of erosion; integrated crop, soil and water
47 management, among others (Liniger and Critchley, 2007; Scholes, 2009). These actions are part of the
48 broader context of dryland development and long-term SLM within coupled socio-economic systems
49 (Reynolds et al., 2007; Stringer et al., 2017; Webb et al., 2017). Many of these response options

1 correspond to those grouped under land transitions in the IPCC Special Report on Global Warming of
 2 1.5°C (Table 6.4; Coninck et al., 2018). It is therefore recognised that such actions require financial,
 3 institutional and policy support for their wide-scale adoption and sustainability over time (3.6.3; 4.8.5;
 4 6.4.4).

5 **3.6.1. SLM Technologies and Practices: on the Ground Actions**

6 A broad range of activities and measures can help avoid, reduce and reverse degradation across the
 7 dryland areas of the world. Many of these actions also contribute to climate change adaptation and
 8 mitigation, with further sustainable development co-benefits for poverty reduction and food security
 9 (*high confidence*) (6.3). As preventing desertification is strongly preferable and more cost-effective
 10 than allowing land to degrade and then attempting to restore it (IPBES, 2018b; Webb et al., 2013),
 11 there is a growing emphasis on avoiding and reducing land degradation, following the Land
 12 Degradation Neutrality framework (Cowie et al., 2018; Orr et al., 2017; 4.8.5).

13

14

15 **Figure 3.10 The typical distribution of on-the-ground actions across global biomes and anthromes**

16

17 An assessment is made of six activities and measures practicable across the biomes and anthromes of
 18 the dryland domain (Figure 3.10). This suite of actions is not exhaustive, but rather a set of activities
 19 that are particularly pertinent to global dryland ecosystems. They are not necessarily exclusive to
 20 drylands and are often implemented across a range of biomes and anthromes (Figure 3.10). For
 21 afforestation, see 3.7.2, Cross-Chapter Box 2 in Chapter 1 and Chapter 4 (4.8.3). The use of
 22 anthromes as a structuring element for response options is based on the essential role of interactions
 23 between social and ecological systems in driving desertification within coupled socio-ecological
 24 systems (Cherlet et al., 2018). The concept of the anthromes is defined in the glossary and explored
 25 further in Chapters 1, 4 and 6.

1 The assessment of each action is twofold: firstly, to assess the ability of each action to address
2 desertification and enhance climate change resilience, and secondly, to assess the potential impact of
3 future climate change on the effectiveness of each action.

4 **3.6.1.1. Integrated Crop-Soil-Water Management**

5 Forms of integrated cropland management have been practiced in drylands for over thousands of
6 years (Knörzer et al., 2009). Actions include planting a diversity of species including drought tolerant
7 crops, reducing tillage, applying organic compost and fertiliser, adopting different forms of irrigation
8 and maintaining vegetation and mulch cover. In the contemporary era, several of these actions have
9 been adopted in response to climate change.

10 In terms of climate change *adaptation*, the resilience of agriculture to the impacts of climate change is
11 strongly influenced by the underlying health and stability of soils as well as improvements in crop
12 varieties, irrigation efficiency and supplemental irrigation, e.g. through rainwater harvesting (*medium*
13 *evidence, high agreement*, Altieri et al., 2015; Amundson et al., 2015; Derpsch et al., 2010; Lal, 1997;
14 de Vries et al., 2012). Desertification often leads to a reduction in ground cover that in turn results in
15 accelerated water and wind erosion and an associated loss of fertile topsoil that can greatly reduce the
16 resilience of agriculture to climate change (*medium evidence, high agreement*, (Touré et al., 2019;
17 Amundson et al., 2015; Borrelli et al., 2017; Pierre et al., 2017). Amadou et al. (2011) note that even a
18 minimal cover of crop residues (100 kg ha⁻¹) can substantially decrease wind erosion.

19 Compared to conventional (flood or furrow) irrigation, drip irrigation methods are more efficient in
20 supplying water to the plant root zone, resulting in lower water requirements and enhanced water use
21 efficiency (*robust evidence and high agreement*) (Ibragimov et al., 2007; Narayanamoorthy, 2010;
22 Niaz et al., 2009). For example, in the rainfed area of Fetejjang, Pakistan, the adoption of drip
23 methods reduced water usage by 67-68% during the production of tomato, cucumber and bell peppers,
24 resulting in a 68-79% improvement in water use efficiency compared to previous furrow irrigation
25 (Niaz et al., 2009). In India, drip irrigation reduced the amount of water consumed in the production
26 of sugarcane by 44%, grapes by 37%, bananas by 29% and cotton by 45%, while enhancing the yields
27 by up to 29% (Narayanamoorthy, 2010). Similarly, in Uzbekistan, drip irrigation increased the yield
28 of cotton by 10-19% while reducing water requirements by 18-42% (Ibragimov et al., 2007).

29 A prominent response that addresses soil loss, health and cover is altering cropping methods. The
30 adoption of intercropping (inter- and intra- row planting of companion crops) and relay cropping
31 (temporally differentiated planting of companion crops) maintains soil cover over a larger fraction of
32 the year, leading to an increase in production, soil N, species diversity and a decrease in pest
33 abundance (*robust evidence and medium agreement*, (Altieri and Koochafkan, 2008; Tanveer et al.,
34 2017; Wilhelm and Wortmann, 2004). For example, intercropping maize and sorghum with
35 *Desmodium* (an insect repellent forage legume) and *Brachiaria* (an insect trapping grass), which is
36 being promoted in drylands of East Africa, led to a two-three fold increase in maize production and
37 an 80% decrease in stem boring insects (Khan et al., 2014). In addition to changes in cropping
38 methods, forms of agroforestry and shelter belts are often used to reduce erosion and improve soil
39 conditions (3.7.2). For example, the use of tree belts of mixed species in northern China led to a
40 reduction of surface wind speed and an associated reduction in soil temperature by up to 40% and an
41 increase in soil moisture by up to 30% (Wang et al., 2008).

42 A further measure that can be of increasing importance under climate change is rainwater harvesting
43 (RWH), including traditional zai (small basins used to capture surface runoff), earthen bunds and
44 ridges (Nyamadzawo et al., 2013), *fanya juu* infiltration pits (Nyagumbo et al., 2019), contour stone
45 bunds (Garrity et al., 2010) and semi-permeable stone bunds (often referred to by the French term
46 "digue filtrante") (Taye et al., 2015). RWH increases the amount of water available for agriculture and
47 livelihoods through the capture and storage of runoff, while at the same time, reducing the intensity of
48 peak flows following high intensity rainfall events. It is therefore often highlighted as a practical

1 response to dryness (i.e. long-term aridity and low seasonal precipitation) and rainfall variability
2 projected to become more acute over time in some dryland areas (Dile et al., 2013; Vohland and
3 Barry, 2009). For example, for Wadi Al-Lith drainage in Saudi Arabia, the use of rainwater harvesting
4 was suggested as a key climate change adaptation action (Almazroui et al., 2017). There is *robust*
5 *evidence and high agreement* that the implementation of RWH systems leads to an increase in
6 agricultural production in drylands (see reviews by Biazin et al., 2012; Bouma and Wösten, 2016;
7 Dile et al., 2013). A global meta-analysis of changes in crop production due to the adoption of RWH
8 techniques noted an average increase in yields of 78%, ranging from –28% to 468% (Bouma and
9 Wösten, 2016). Of particular relevance to climate change in drylands is that the relative impact of
10 RWH on agricultural production generally increases with increasing dryness. Relative yield
11 improvements due to the adoption of RWH were significantly higher in years with less than 330 mm
12 rainfall, compared to years with more than 330 mm (Bouma and Wösten, 2016). Despite delivering a
13 clear set of benefits, there are some issues that need to be considered. The impact RWH may vary at
14 different temporal and spatial scales (Vohland and Barry, 2009). At a plot scale, RWH structures may
15 increase available water and enhance agricultural production, SOC and nutrient availability, yet at a
16 catchment scale, they may reduce runoff to downstream uses (Meijer et al., 2013; Singh et al., 2012;
17 Vohland and Barry, 2009; Yosef and Asmamaw, 2015). Inappropriate storage of water in warm
18 climates can lead to an increase in water related diseases unless managed correctly, for example,
19 schistosomiasis and malaria (see review by Boelee et al., 2013).

20 Integrated crop-soil-water management may also deliver climate change *mitigation* benefits through
21 avoiding, reducing and reversing the loss of SOC (Table 6.5). Approximately 20-30 Pg of SOC have
22 been released into the atmosphere through desertification processes, for example, deforestation,
23 overgrazing and conventional tillage (Lal, 2004). Activities, such as those associated with
24 conservation agriculture (minimising tillage, crop rotation, maintaining organic cover and planting a
25 diversity of species), reduce erosion, improve water use efficiency and primary production, increase
26 inflow of organic material and enhance SOC over time, contributing to climate change mitigation
27 and adaptation (*high confidence*) (Plaza-Bonilla et al., 2015; Lal, 2015; Srinivasa Rao et al., 2015;
28 Sombrero and de Benito, 2010). Conservation agriculture practices also lead to increases in SOC
29 (*medium confidence*). However, sustained C sequestration is dependent on net primary productivity
30 and on the availability of crop-residues that may be relatively limited and often consumed by
31 livestock or used elsewhere in dryland contexts (Cheesman et al., 2016; Plaza-Bonilla et al., 2015).
32 For this reason, expected rates of C sequestration following changes in agricultural practices in
33 drylands are relatively low (0.04-0.4 t C ha⁻¹) and it may take a protracted period of time, even several
34 decades, for C stocks to recover if lost (*medium confidence*) (Farage et al., 2007; Hoyle, D'Antuono,
35 Overheu, and Murphy, 2013; Lal, 2004). This long recovery period enforces the rationale for
36 prioritising avoiding and reducing land degradation and loss of C, in addition to restoration activities.

37

38 **3.6.1.2. Grazing and Fire Management in Drylands**

39 Rangeland management systems such as sustainable grazing approaches and re-vegetation increase
40 rangeland productivity (*high confidence*) (Table 6.5). Open grassland, savanna and woodland are
41 home to the majority of world's livestock production (Safriel et al., 2005). Within these drylands
42 areas, prevailing grazing and fire regimes play an important role in shaping the relative abundance of
43 trees versus grasses (Scholes and Archer, 1997; Staver et al., 2011; Stevens et al., 2017), as well as
44 the health of the grass layer in terms of primary production, species richness and basal cover (the
45 proportion of the plant that is in the soil) (Plaza-Bonilla et al., 2015; Short et al., 2003). This in turn
46 influences levels of soil erosion, soil nutrients, secondary production and additional ecosystem
47 services (Divinsky et al., 2017; Pellegrini et al., 2017). A further set of drivers, including soil type,
48 annual rainfall and changes in atmospheric CO₂ may also define observed rangeland structure and

1 composition (Devine et al., 2017; Donohue et al., 2013), but the two principal factors that pastoralists
2 can manage are grazing and fire by altering their frequency, type and intensity.

3
4 The impact of grazing and fire regimes on biodiversity, soil nutrients, primary production and further
5 ecosystem services is not constant and varies between locations (Divinsky et al., 2017; Fleischner,
6 1994; van Oijen et al., 2018). Trade-offs may therefore need to be considered to ensure that rangeland
7 diversity and production are resilient to climate change (Plaza-Bonilla et al., 2015; van Oijen et al.,
8 2018). In certain locations, even light to moderate grazing have led to a significant decrease in the
9 occurrence of particular species, especially forbs (O'Connor et al., 2011; Scott-shaw and Morris,
10 2015). In other locations, species richness is only significantly impacted by heavy grazing and is able
11 to withstand light to moderate grazing (Divinsky et al., 2017). A context specific evaluation of how
12 grazing and fire impact particular species may therefore be required to ensure the persistence of target
13 species over time (Marty, 2005). A similar trade-off may need to be considered between soil C
14 sequestration and livestock production. As noted by Plaza-Bonilla et al. (2015) increasing grazing
15 pressure has been found to both increase and decrease SOC stocks in different locations. Where it has
16 led to a decrease in soil C stocks, for example in Mongolia (Han et al., 2008) and Ethiopia (Bikila et
17 al., 2016), trade-offs between C sequestration and the value of livestock to local livelihoods need be
18 considered.

19
20 Although certain herbaceous species may be unable to tolerate grazing pressure, a complete lack of
21 grazing or fire may not be desired in terms of ecosystems health. It can lead to a decrease in basal
22 cover and the accumulation of moribund, unpalatable biomass that inhibits primary production
23 (Manson et al., 2007; Scholes, 2009). The utilisation of the grass sward through light to moderate
24 grazing stimulates the growth of biomass, basal cover and allows water services to be sustained over
25 time (Papanastasis et al., 2017; Scholes, 2009). Even, moderate to heavy grazing in periods of higher
26 rainfall may be sustainable, but constant heavy grazing during dry periods and especially droughts can
27 lead to a reduction in basal cover, SOC, biological soil crusts, ecosystem services and an accelerated
28 erosion (*high agreement, robust evidence*, (Archer et al., 2017; Conant and Paustian, 2003; D'Odorico
29 et al., 2013; Geist and Lambin, 2004; Havstad et al., 2006; Huang et al., 2007; Manzano and N avar,
30 2000; Pointing and Belnap, 2012; Weber et al., 2016). For this reason, the inclusion of drought
31 forecasts and contingency planning in grazing and fire management programs is crucial to avoid
32 desertification (Smith and Foran, 1992; Torell et al., 2010). It is an important component of avoiding
33 and reducing early degradation. Although grasslands systems may be relatively resilient and can often
34 recover from a moderately degraded state (Khishigbayar et al., 2015; Porensky et al., 2016), if a
35 tipping point has been exceeded, restoration to a historic state may not be economical or ecologically
36 feasible (D'Odorico et al., 2013).

37
38 Together with livestock management (Table 6.5), the use of fire is an integral part of rangeland
39 management and can be applied to remove moribund and unpalatable forage, exotic weeds and woody
40 species (Archer et al., 2017). Fire has less of an effect on SOC and soil nutrients in comparison to
41 grazing (Abril et al., 2005), yet elevated fire frequency has been observed to lead to a decrease in soil
42 C and N (Abril et al., 2005; Bikila et al., 2016; Bird et al., 2000; Pellegrini et al., 2017). Although the
43 impact of climate change on fire frequency and intensity may not be clear due to its differing impact
44 on fuel accumulation, suitable weather conditions and sources of ignition (Abatzoglou et al., 2018;
45 Littell et al., 2018; Moritz et al., 2012), there is an increasing use of prescribed fire to address several
46 global change phenomena, for example, the spread of invasive species and bush encroachment as well
47 as the threat of intense runaway fires (Fernandes et al., 2013; McCaw, 2013; van Wilgen et al., 2010).
48 Cross-Chapter Box 3 located in Chapter 2 provides a further review of the interaction between fire
49 and climate change.

1 There is often much emphasis on reducing and reversing the degradation of rangelands due to the
2 wealth of benefits they provide, especially in the context of assisting dryland communities to adapt to
3 climate change (Webb et al., 2017; Woollen et al., 2016). The emerging concept of ecosystem-based
4 adaptation has highlighted the broad range of important ecosystem services that healthy rangelands
5 can provide in a resilient manner to local residents and downstream economies (Kloos and Renaud,
6 2016; Reid et al., 2018). In terms of climate change mitigation, the contribution of rangelands,
7 woodland and sub-humid dry forest (e.g. Miombo woodland in south-central Africa) is often
8 undervalued due to relatively low C stocks per hectare. Yet due to their sheer extent, the amount of C
9 sequestered in these ecosystems is substantial and can make a valuable contribution to climate change
10 mitigation (Lal, 2004; Pelletier et al., 2018).

11 **3.6.1.3. Clearance of Bush Encroachment**

12 The encroachment of open grassland and savanna ecosystems by woody species has occurred for at
13 least the past 100 years (Archer et al., 2017; O'Connor et al., 2014; Schooley et al., 2018). Dependent
14 on the type and intensity of encroachment, it may lead to a net loss of ecosystem services and be
15 viewed as a form of desertification (Dougill et al., 2016; O'Connor et al., 2014). However, there are
16 circumstances where bush encroachment may lead to a net increase in ecosystem services, especially
17 at intermediate levels of encroachment, where the ability of the landscape to produce fodder for
18 livestock is retained, while the production of wood and associated products increases (Eldridge et al.,
19 2011; Eldridge and Soliveres, 2014). This may be particularly important in regions such as southern
20 Africa and India where over 65% of rural households depend on fuelwood from surrounding
21 landscapes as well as livestock production (Komala and Prasad, 2016; Makonese et al., 2017;
22 Shackleton and Shackleton, 2004).

23
24
25 This variable relationship between the level of encroachment, C stocks, biodiversity, provision of
26 water and pastoral value (Eldridge and Soliveres, 2014) can present a conundrum to policy makers,
27 especially when considering the goals of three Rio Conventions - UNFCCC, UNCCD and UNCBD.
28 Clearing intense bush encroachment may improve species diversity, rangeland productivity, the
29 provision of water and decrease desertification, thereby contributing to the goals of the UNCBD,
30 UNCCD as well as adaptation aims of the UNFCCC. However, it would lead to the release of biomass
31 C stocks into the atmosphere and potentially conflict with the mitigation aims of the UNFCCC.

32
33 For example, Smit et al. (2015) observed an average increase in above-ground woody C stocks of 44 t
34 C ha⁻¹ in savannas in northern Namibia. However, since bush encroachment significantly inhibited
35 livestock production, there are often substantial efforts to clear woody species (Stafford-Smith et al.,
36 2017). Namibia has an early national programme aimed at clearing woody species through
37 mechanical measures (harvesting of trees) as well as the application of arboricides (Smit et al., 2015).
38 However, the long-term success of clearance and subsequent improved fire and grazing management
39 remains to be evaluated, especially restoration back towards an 'original open grassland state'. For
40 example, in northern Namibia, the rapid reestablishment of woody seedlings has raised questions
41 about whether full clearance and restoration is possible (Smit et al., 2015). In arid landscapes, the
42 potential impact of elevated atmospheric CO₂ (Donohue et al., 2013; Kgope et al., 2010) and
43 opportunity to implement high intensity fires that remove woody species and maintain rangelands in
44 an open state has been questioned (Bond and Midgley, 2000). If these drivers of woody plant
45 encroachment cannot be addressed, a new form of "emerging ecosystem" (Milton, 2003) may need to
46 be explored that includes both improved livestock and fire management as well as the utilisation of
47 biomass as a long-term commodity and source of revenue (Smit et al., 2015). Initial studies in
48 Namibia and South Africa (Stafford-Smith et al., 2017) indicate that there may be good opportunity to
49 produce sawn timber, fencing poles, fuel wood and commercial energy, but factors such as the cost of
50 transport can substantially influence the financial feasibility of implementation.

1
2 The benefit of proactive management that prevents land from being degraded (altering grazing
3 systems or treating bush encroachment at early stages before degradation has been initiated) is more
4 cost-effective in the long-term and adds resistance to climate change than treating lands after
5 degradation has occurred (Webb et al., 2013; Weltz and Spaeth, 2012). The challenge is getting
6 producers to alter their management paradigm from short-term objectives to long-term objectives.
7

8 **3.6.1.4. Combating sand and dust storms through sand dune stabilisation**

9 Dust and sand storms have a considerable impact on natural and human systems (3.4.1, 3.4.2).
10 Application of sand dune stabilisation techniques contributes to reducing sand and dust storms (*high*
11 *confidence*). Using a number of methods, sand dune stabilisation aims to avoid and reduce the
12 occurrence of dust and sand storms (Mainguet and Dumay, 2011). Mechanical techniques include
13 building palisades to prevent the movement of sand and reduce sand deposits on infrastructure.
14 Chemical methods include the use of calcium bentonite or using silica gel to fix mobile sand
15 (Aboushook et al., 2012; Rammal and Jubair, 2015). Biological methods include the use of mulch to
16 stabilise surfaces (Sebaa et al., 2015; Yu et al., 2004) and establishing permanent plant cover using
17 pasture species that improve grazing at the same time (Abdelkebir and Ferchichi, 2015; Zhang et al.,
18 2015; 3.7.1.3). When the dune is stabilised, woody perennials are introduced that are selected
19 according to climatic and ecological conditions (FAO, 2011). For example, such revegetation
20 processes have been implemented on the shifting dunes of the Tengger Desert in northern China
21 leading to the stabilisation of sand and the sequestration of up to 10 t C ha⁻¹ over a period of 55 years
22 (Yang et al., 2014).

23 **3.6.1.5 Use of Halophytes for the Revegetation of Saline Lands**

24 Soil salinity and sodicity can severely limit the growth and productivity of crops (Jan et al., 2017) and
25 lead to a decrease in available arable land. Leaching and drainage provides a possible solution, but
26 can be prohibitively expensive. An alternative, more economical option, is the growth of halophytes
27 (plants that are adapted to grow under highly saline conditions) that allow saline land to be used in a
28 productive manner (Qadir et al., 2000). The biomass produced can be used as forage, food, feed,
29 essential oils, biofuel, timber, fuelwood (Chughtai et al., 2015; Mahmood et al., 2016; Sharma et al.,
30 2016). A further co-benefit is the opportunity to mitigate climate change through the enhancement of
31 terrestrial C stocks as land is revegetated (Dagar et al., 2014; Wicke et al., 2013). The combined use
32 of salt-tolerant crops, improved irrigation practices, chemical remediation measures and appropriate
33 mulch and compost is effective in reducing the impact of secondary salinisation (*medium confidence*).

34 In Pakistan, where about 6.2 M ha of agricultural land is affected by salinity, pioneering work on
35 utilising salt tolerant plants for the revegetation of saline lands (Biosaline Agriculture) was done in the
36 early 1970s (NIAB, 1997). A number of local and exotic varieties were initially screened for salt
37 tolerance in lab- and greenhouse based studies, and then distributed to similar saline areas (Ashraf et
38 al., 2010). These included tree species (*Acacia ampliceps*, *A. nilotica*, *Eucalyptus camaldulensis*,
39 *Prosopis juliflora*, *Azadirachta indica*) (Awan and Mahmood, 2017), forage plants (*Leptochloa fusca*,
40 *Sporobolus arabicus*, *Brachiaria mutica*, *Echinochloa* sp., *Sesbania* and *Atriplex* spp.) and crop
41 species including varieties of barley (*Hordeum vulgare*), cotton, wheat (*Triticum aestivum*) and
42 *Brassica* spp (Mahmood et al., 2016) as well as fruit crops in the form of Date Palm (*Phoenix*
43 *dactylifera*) that has high salt tolerance with no visible adverse effects on seedlings (Yaish and
44 Kumar, 2015; Al-Mulla et al., 2013; Alrasbi et al., 2010). Pomegranate (*Punica granatum L.*) is
45 another fruit crop of moderate to high salt tolerance. Through regulating growth form and nutrient
46 balancing, it can maintain water content, chlorophyll fluorescence and enzyme activity at normal
47 levels (Ibrahim, 2016; Okhovatian-Ardakani et al., 2010).

1 In India and elsewhere, tree species including *Prosopis juliflora*, *Dalbergia sissoo*, *Eucalyptus*
2 *tereticornis* have been used to revegetate saline land. Certain biofuel crops in the form of *Ricinus*
3 *communis* (Abideen et al., 2014), *Euphorbia antisyphilitica* (Dagar et al., 2014), *Karelinia caspia*
4 (Akinshina et al., 2016) and *Salicornia* spp. (Sanandiyana and Siddhanta, 2014) are grown in saline
5 areas, and *Panicum turgidum* (Koyro et al., 2013) and *Leptochloa fusca* (Akhter et al., 2003) have
6 been grown as fodder crop on degraded soils with brackish water. In China, intense efforts are being
7 made on the use of halophytes (Sakai et al., 2012; Wang et al., 2018). These examples reveal that
8 there is great scope still use saline areas in a productive manner through the utilisation of halophytes.
9 The most productive species often have yields equivalent to conventional crops, at salinity levels
10 matching even that of sea water.

11 **3.6.2. Socio-economic Responses**

12 Socio-economic and policy responses are often crucial in enhancing the adoption of SLM practices
13 (Cordingley et al., 2015; Fleskens and Stringer, 2014; Nyanga et al., 2016) and for assisting
14 agricultural households to diversify their sources of income (Barrett et al., 2017; Shiferaw and Djido,
15 2016). Technology and socio-economic responses are not independent, but continuously interact.

16 **3.6.2.1. Socio-economic Responses for Combating Desertification Under Climate Change**

17 Desertification limits the choice of potential climate change mitigation and adaptation response
18 options by reducing climate change adaptive capacities. Furthermore, many additional factors, for
19 example, a lack of access to markets or insecurity of land tenure, hinder the adoption of SLM. These
20 factors are largely beyond the control of individuals or local communities and require broader policy
21 interventions (3.6.3). Nevertheless, local collective action and indigenous and local knowledge are
22 still crucial to the ability of households to respond to the combined challenge of climate change and
23 desertification. Raising awareness, capacity building and development to promote collective action
24 and indigenous and local knowledge contribute to avoiding, reducing and reversing desertification
25 under changing climate.

26 ***The use of indigenous and local knowledge*** enhances the success of SLM and its ability to address
27 desertification (Altieri and Nicholls, 2017; Engdawork and Bork, 2016). Using indigenous and local
28 knowledge for combating desertification could contribute to climate change adaptation strategies
29 (Belfer et al., 2017; Codjoe et al., 2014; Etchart, 2017; Speranza et al., 2010; Makondo and Thomas,
30 2018; Maldonado et al., 2016; Nyong et al., 2007). There are abundant examples of how indigenous
31 and local knowledge, which are an important part of broader agroecological knowledge (Altieri,
32 2018), have allowed livelihood systems in drylands to be maintained despite environmental
33 constraints. An example is the numerous traditional water harvesting techniques that are used across
34 the drylands to adapt to dry spells and climate change. These include creating planting pits (“zai”,
35 “ngoro”) and micro-basins, contouring hill slopes and terracing (Biazin et al., 2012) (3.6.1).
36 Traditional “ndiva” water harvesting system in Tanzania enables the capture of runoff water from
37 highland areas to downstream community-managed micro-dams for subsequent farm delivery through
38 small scale canal networks (Enfors and Gordon, 2008). A further example are pastoralist communities
39 located in drylands who have developed numerous methods to sustainably manage rangelands.
40 Pastoralist communities in Morocco developed the “agdal” system of seasonally alternating use of
41 rangelands to limit overgrazing (Dominguez, 2014) as well as to manage forests in the Moroccan
42 High Atlas Mountains (Auclair et al., 2011). Across the Arabian Peninsula and North Africa, a
43 rotational grazing system “hema” was historically practiced by the Bedouin communities (Hussein,
44 2011; Louhaichi and Tastad, 2010). The Beni-Amer herders in the Horn of Africa have developed
45 complex livestock breeding and selection systems (Fre, 2018). Although well adapted to resource-
46 sparse dryland environments, traditional practices are currently not able to cope with increased
47 demand for food and environmental changes (Enfors and Gordon, 2008; Engdawork and Bork, 2016).
48 Moreover, there is *robust evidence* documenting the marginalisation or loss of indigenous and local

1 knowledge (Dominguez, 2014; Fernández-Giménez and Fillat Estaque, 2012; Hussein, 2011;
2 Kodirekkala, 2017; Moreno-Calles et al., 2012). Combined use of indigenous and local knowledge
3 and new SLM technologies can contribute to raising resilience to the challenges of climate change and
4 desertification (*high confidence*) (Engdawork and Bork, 2016; Guzman et al., 2018).

5 **Collective action** has the potential to contribute to SLM and climate change adaptation (*medium*
6 *confidence*) (Adger, 2003; Engdawork and Bork, 2016; Eriksen and Lind, 2009; Ostrom, 2009;
7 Rodima-Taylor et al., 2012). Collective action is a result of social capital. Social capital is divided
8 into structural and cognitive forms, structural corresponding to strong networks (including outside
9 one's immediate community) and cognitive encompassing mutual trust and cooperation within
10 communities (van Rijn et al., 2012; Woolcock and Narayan, 2000). Social capital is more important
11 for economic growth in settings with weak formal institutions, and less so in those with strong
12 enforcement of formal institutions (Ahlerup et al., 2009). There are cases throughout the drylands
13 showing that community bylaws and collective action successfully limited land degradation and
14 facilitated SLM (Ajayi et al., 2016; Infante, 2017; Kassie et al., 2013; Nyangena, 2008; Willy and
15 Holm-Müller, 2013; Wossen et al., 2015). However, there are also cases when they did not improve
16 SLM where they were not strictly enforced (Teshome et al., 2016). Collective action for implementing
17 responses to dryland degradation is often hindered by local asymmetric power relations and "elite
18 capture" (Kihui, 2016; Stringer et al., 2007). This illustrates that different levels and types of social
19 capital result in different levels of collective action. In a sample of East, West and southern African
20 countries, structural social capital in the form of access to networks outside one's own community
21 was suggested to stimulate the adoption of agricultural innovations, whereas cognitive social capital,
22 associated with inward-looking community norms of trust and cooperation, was found to have a
23 negative relationship with the adoption of agricultural innovations (van Rijn et al., 2012). The latter is
24 indirectly corroborated by observations of the impact of community-based rangeland management
25 organisations in Mongolia. Although levels of cognitive social capital did not differ between them,
26 communities with strong links to outside networks were able to apply more innovative rangeland
27 management practices in comparison to communities without such links (Ulambayar et al., 2017).

28 **Farmer-led innovations.** Agricultural households are not just passive adopters of externally
29 developed technologies, but are active experimenters and innovators (Reij and Waters-Bayer, 2001;
30 Tambo and Wünscher, 2015; Waters-Bayer et al., 2009). SLM technologies co-generated through
31 direct participation of agricultural households have higher chances of being accepted by them
32 (*medium confidence*) (Bonney et al., 2016; Vente et al., 2016). Usually farmer-driven innovations are
33 more frugal and better adapted to their resource scarcities than externally introduced technologies
34 (Gupta et al., 2016). Farmer-to-farmer sharing of their own innovations and mutual learning positively
35 contribute to higher technology adoption rates (Dey et al., 2017). This innovative ability can be given
36 a new dynamism by combining it with emerging external technologies. For example, emerging low-
37 cost phone applications that are linked to soil and water monitoring sensors can provide farmers with
38 previously inaccessible information and guidance (Cornell et al., 2013; Herrick et al., 2017; McKinley
39 et al., 2017; Steger et al., 2017).

40 Currently, the adoption of SLM practices remains insufficient to address desertification and contribute
41 to climate change adaptation and mitigation more extensively. This is due to the constraints on the use
42 of indigenous and local knowledge and collective action, as well as economic and institutional
43 barriers for SLM adoption (3.1.4.2; 3.6.3; Banadda, 2010; Cordingley et al., 2015; Lokonon and
44 Mbaye, 2018; Mulinge et al., 2016; Wildemeersch et al., 2015). Sustainable development of drylands
45 under these socio-economic and environmental (climate change, desertification) conditions will also
46 depend on the ability of dryland agricultural households to diversify their livelihoods sources
47 (Boserup, 1965; Safriel and Adeel, 2008).

3.6.2.2. Socio-Economic Responses for Economic Diversification

Livelihood diversification through non-farm employment increases the resilience of rural households against desertification and extreme weather events by diversifying their income and consumption (*high confidence*). Moreover, it can provide the funds to invest into SLM (Belay et al., 2017; Bryan et al., 2009; Dumenu and Obeng, 2016; Salik et al., 2017; Shiferaw et al., 2009). Access to non-agricultural employment is especially important for poorer pastoral households as their small herd sizes make them less resilient to drought (Fratkin, 2013; Lybbert et al., 2004). However, access to alternative opportunities is limited in the rural areas of many developing countries, especially for women and marginalised groups who lack education and social networks (Reardon et al., 2008).

Migration is frequently used as an adaptation strategy to environmental change (*medium confidence*). Migration is a form of livelihood diversification and a potential response option to desertification and increasing risk to agricultural livelihoods under climate change (Walther et al., 2002). Migration can be short-term (e.g., seasonal) or long-term, internal within a country or international. There is *medium evidence* showing rural households responding to desertification and droughts through all forms of migration, for example: during the Dust Bowl in the United States in the 1930s (Hornbeck, 2012); during droughts in Burkina Faso in the 2000s (Barbier et al., 2009); in Mexico in the 1990s (Nawrotzki et al., 2016); and by the Aymara people of the semiarid Tarapacá region in Chile between 1820-1970 responding to declines in rainfall and growing demands for labor outside the region (Lima et al., 2016). There is *robust evidence and high agreement* showing that migration decisions are influenced by a complex set of different factors, with desertification and climate change playing relatively lesser roles (Liehr et al., 2016) (3.4.2). Barrios et al. (2006) found that urbanisation in Sub-Saharan Africa was partially influenced by climatic factors during the 1950 to 2000 period, in parallel to liberalisation of internal restrictions on labour movements: with 1% reduction in rainfall associated with 0.45% increase in urbanisation. This migration favoured more industrially-diverse urban areas in Sub-Saharan Africa (Henderson et al., 2017), because they offer more diverse employment opportunities and higher wages. Similar trends were also observed in Iran in response to water scarcity (Madani et al., 2016). However, migration involves some initial investments. For this reason, reductions in agricultural incomes due to climate change or desertification have the potential to decrease out-migration among the poorest agricultural households who become less able to afford migration (Cattaneo and Peri, 2016), thus increasing social inequalities. There is *medium evidence and high agreement* that households with migrant worker members are more resilient against extreme weather events and environmental degradation compared to non-migrant households who are more dependent on agricultural income (Liehr et al., 2016; Salik et al., 2017; Sikder and Higgins, 2017). Remittances from migrant household members potentially contribute to SLM adoptions, however, substantial out-migration was also found to constrain the implementation of labour-intensive land management practices (Chen et al., 2014; Liu et al., 2016a).

3.6.3. Policy Responses

The adoption of SLM practices depends on the compatibility of the technology with prevailing socio-economic and biophysical conditions (Sanz et al., 2017). Globally, it was shown that every USD invested into restoring degraded lands yields social returns, including both provisioning and non-provisioning ecosystem services, in the range of USD 3–6 over a 30-year period (Nkonya et al., 2016a). A similar range of returns from land restoration activities were found in Central Asia (Mirzabaev et al., 2016), Ethiopia (Gebreselassie et al., 2016), India (Mythili and Goedecke, 2016), Kenya (Mulinge et al., 2016), Niger (Moussa et al., 2016) and Senegal (Sow et al., 2016). Despite these relatively high returns, there is *robust evidence* that the adoption of SLM practices remains low (Cordingley et al., 2015; Giger et al., 2015; Lokonon and Mbaye, 2018). Part of the reason for these low adoption rates is that the major share of the returns from SLM are social benefits, namely in the form of non-provisioning ecosystem services (Nkonya et al., 2016a). The adoption of SLM

1 technologies does not always provide implementers with immediate private benefits (Schmidt et al.,
2 2017). High initial investment costs, institutional and governance constraints and a lack of access to
3 technologies and equipment may inhibit their adoption further (Giger et al., 2015; Sanz et al., 2017;
4 Schmidt et al., 2017). However, not all SLM practices have high upfront costs. Analysing the World
5 Overview of Conservation Approaches and Technologies (WOCAT) database, a globally
6 acknowledged reference database for SLM, Giger et al. (2015) found that the upfront costs of SLM
7 technologies ranged from about USD 20 to USD 5000, with the median cost being around USD 500 .
8 Many SLM technologies are profitable within three to 10 years (*medium evidence, high agreement*)
9 (Djanibekov and Khamzina, 2016; Giger et al., 2015; Moussa et al., 2016; Sow et al., 2016). About
10 73% of 363 SLM technologies evaluated were reported to become profitable within three years, while
11 97% were profitable within 10 years (Giger et al., 2015). Similarly, it was shown that social returns
12 from investments in restoring degraded lands will exceed their costs within six years in many settings
13 across drylands (Nkonya et al., 2016a). However, even with affordable upfront costs, market failures
14 in the form of lack of access to credit, input and output markets, and insecure land tenure (3.1.3) result
15 in the lack of adoption of SLM technologies (Moussa et al., 2016). Payments for ecosystem services,
16 subsidies for SLM, encouragement of community collective action can lead to a higher level of
17 adoption of SLM and land restoration activities (*medium confidence*) (Bouma and Wösten, 2016;
18 Lambin et al., 2014; Reed et al., 2015; Schiappacasse et al., 2012; van Zanten et al., 2014; 3.6.3).
19 Enabling policy responses discussed in this section contribute to overcoming these market failures.

20 Many socio-economic factors shaping individual responses to desertification typically operate at
21 larger scales. Individual households and communities do not exercise control over these factors, such
22 as land tenure insecurity, lack of property rights, lack of access to markets, availability of rural
23 advisory services, and agricultural price distortions. These factors are shaped by national government
24 policies and international markets. As in the case with socio-economic responses, policy responses are
25 classified below in two ways: those which seek to combat desertification under changing climate; and
26 those which seek to provide alternative livelihood sources through economic diversification. These
27 options are mutually complementary and contribute to all the three hierarchical elements of the Land
28 Degradation Neutrality (LDN) framework, namely, avoiding, reducing and reversing land degradation
29 (Cowie et al., 2018; Orr et al., 2017; 4.8.5; Table 7.2; 7.4.5). Enabling policy environment is a critical
30 element for the achievement of LDN (Chasek et al., 2019). Implementation of LDN policies can
31 contribute to climate change adaptation and mitigation (*high confidence*) (3.6.1, 3.7.2).

3.6.3.1. Policy Responses towards Combating Desertification under Climate Change

32 Policy responses to combat desertification take numerous forms (Marques et al., 2016). Below we
33 discuss major policy responses consistently highlighted in the literature in connection with SLM and
34 climate change, because these response options were found to strengthen adaptation capacities and to
35 contribute to climate change mitigation. They include improving market access, empowering women,
36 expanding access to agricultural advisory services, strengthening land tenure security, payments for
37 ecosystem services, decentralised natural resource management, investing into research and
38 monitoring of desertification and dust storms, and investing into modern renewable energy sources.

39
40 ***Policies aiming at improving market access***, that is the ability to access output and input markets at
41 lower costs, help farmers and livestock producers earn more profit from their produce. Increased
42 profits both motivate and enable them to invest more in SLM. Higher access to input, output and
43 credit markets was consistently found as a major factor in the adoption of SLM practices in a wide
44 number of settings across the drylands (*medium confidence*) (Aw-Hassan et al., 2016; Gebreselassie et
45 al., 2016; Mythili and Goedecke, 2016; Nkonya and Anderson, 2015; Sow et al., 2016). Lack of
46 access to credit limits adjustments and agricultural responses to the impacts of desertification under
47 changing climate, with long-term consequences on the livelihoods and incomes, as was shown for the
48 case of the American Dust Bowl during 1930s (Hornbeck, 2012). Government policies aimed at

1 improving market access usually involve constructing and upgrading rural-urban transportation
2 infrastructure and agricultural value chains, such as investments into construction of local markets,
3 abattoirs and cold storage warehouses, as well as post-harvest processing facilities (Mcpeak et al.,
4 2006). However, besides infrastructural constraints, providing improved access often involves
5 relieving institutional constraints to market access (Little, 2010), such as improved coordination of
6 cross-border food safety and veterinary regulations (Ait Hou et al., 2015; Keiichiro et al., 2015;
7 Mcpeak et al., 2006; Unnevehr, 2015), and availability and access to market information systems
8 (Bobojonov et al., 2016; Christy et al., 2014; Nakasone et al., 2014).

9 **Women's empowerment.** A greater emphasis on understanding gender-specific differences over land-
10 use and land management practices as an entry point can make land restoration projects more
11 successful (*medium confidence*) (Broeckhoven and Cliquet, 2015; Carr and Thompson, 2014;
12 Catacutan and Villamor, 2016; Dah-gbeto and Villamor, 2016). In relation to representation and
13 authority to make decisions in land management and governance, women's participation remains
14 lacking particularly in the dryland regions. Thus, ensuring women's rights means accepting women as
15 equal members of the community and citizens of the state (Nelson et al., 2015). This includes
16 equitable access of women to resources (including extension services), networks, and markets. In
17 areas where socio-cultural norms and practices devalue women and undermine their participation,
18 actions for empowering women will require changes in customary norms, recognition of women's
19 (land) rights in government policies and programmes to assure that their interests are better
20 represented (1.4.2; Cross-Chapter Box 11: Gender, Chapter 7). In addition, several novel concepts are
21 recently applied for an in-depth understanding of gender in relation to science-policy interface.
22 Among these are the concepts of intersectionality, i.e. how social dimensions of identity and gender
23 are bound up in systems of power and social institution (Thompson-Hall et al., 2016), bounded
24 rationality for gendered decision making, related to incomplete information interacting with limits to
25 human cognition leading to judgement errors or objectively poor decision making (Villamor and van
26 Noordwijk, 2016), anticipatory learning for preparing for possible contingencies and consideration of
27 long-term alternatives (Dah-gbeto and Villamor, 2016) and systematic leverage points for
28 interventions that produce, mark, and entrench gender inequality within communities (Manlosa et al.,
29 2018), which all aim to improve gender equality within agro-ecological landscapes through a systems
30 approach.

31 **Education and expanding access to agricultural services.** Providing access to information about
32 SLM practices facilitates their adoption (*medium confidence*) (Kassie et al., 2015; Nkonya et al.,
33 2015; Nyanga et al., 2016). Moreover, improving the knowledge of climate change, capacity building
34 and development in rural areas can help strengthen climate change adaptive capacities (Berman et al.,
35 2012; Chen et al., 2018; Descheemaeker et al., 2018; Popp et al., 2009; Tambo, 2016; Yaro et al.,
36 2015). Agricultural initiatives to improve the adaptive capacities of vulnerable populations were more
37 successful when they were conducted through reorganised social institutions and improved
38 communication, e.g. in Mozambique (Osbaahr et al., 2008). Improved communication and education
39 could be facilitated by wider use of new information and communication technologies (Peters et al.,
40 2015). Investments into education were associated with higher adoption of soil conservation
41 measures, e.g. in Tanzania (Tenge et al., 2004). Bryan et al. (2009) found that access to information
42 was the prominent facilitator of climate change adaptation in Ethiopia. However, resource constraints
43 of agricultural services, and disconnects between agricultural policy and climate policy can hinder the
44 dissemination of climate smart agricultural technologies (Morton, 2017). Lack of knowledge was also
45 found to be a significant barrier to implementation of soil rehabilitation programmes in the
46 Mediterranean region (Reichardt, 2010). Agricultural services will be able to facilitate SLM best
47 when they also serve as platforms for sharing indigenous and local knowledge and farmer innovations
48 (Mapfumo et al., 2016). Participatory research initiatives conducted jointly with farmers have higher
49 chances of resulting in technology adoption (Bonney et al., 2016; Rusike et al., 2006; Vente et al.,

1 2016). Moreover, rural advisory services are often more successful in disseminating technological
2 innovations when they adopt commodity/value chain approaches, remain open to engagement in input
3 supply, make use of new opportunities presented by information and communication technologies
4 (ICTs), facilitate mutual learning between multiple stakeholders (Morton, 2017), and organise science
5 and SLM information in a location-specific manner for use in education and extension (Bestelmeyer
6 et al., 2017).

7 **Strengthening land tenure security.** Strengthening land tenure security is a major factor contributing
8 to the adoption of soil conservation measures in croplands (*high confidence*) (Bambio and Bouayad
9 Agha, 2018; Higgins et al., 2018; Holden and Ghebru, 2016; Paltasingh, 2018; Rao et al., 2016;
10 Robinson et al., 2018) , thus, contributing to climate change adaptation and mitigation. Moreover,
11 land tenure security can lead to more investment in trees (Deininger and Jin, 2006; Etongo et al.,
12 2015). Land tenure recognition policies were found to lead to higher agricultural productivity and
13 incomes, although with inter-regional variations, requiring an improved understanding of overlapping
14 formal and informal land tenure rights (Lawry et al., 2017). For example, secure land tenure increased
15 investments into SLM practices in Ghana, however, without affecting farm productivity (Abdulai et
16 al., 2011). Secure land tenure, especially for communally managed lands, helps reduce arbitrary
17 appropriations of land for large scale commercial farms (Aha and Ayitey, 2017; Baumgartner, 2017;
18 Dell'Angelo et al., 2017). In contrast, privatisation of rangeland tenures in Botswana and Kenya led to
19 the loss of communal grazing lands and actually increased rangeland degradation (Basupi et al., 2017;
20 Kihui, 2016) as pastoralists needed to graze livestock on now smaller communal pastures. Since food
21 insecurity in drylands is strongly affected by climate risks, there is *robust evidence and high*
22 *agreement* that resilience to climate risks is higher with flexible tenure for allowing mobility for
23 pastoralist communities, and not fragmenting their areas of movement (Behnke, 1994; Holden and
24 Ghebru, 2016; Liao et al., 2017; Turner et al., 2016; Wario et al., 2016). More research is needed on
25 the optimal tenure mix, including low-cost land certification, redistribution reforms, market-assisted
26 reforms and gender-responsive reforms, as well as collective forms of land tenure such as communal
27 land tenure and cooperative land tenure (see 7.6.5 for a broader discussion of land tenure security
28 under climate change).

29 **Payment for ecosystem services (PES)** provide incentives for land restoration and SLM (*medium*
30 *confidence*) (Lambin et al., 2014; Li et al., 2018; Reed et al., 2015; Schiappacasse et al., 2012).
31 Several studies illustrate that social cost of desertification are larger than its private cost (Costanza et
32 al., 2014; Nkonya et al., 2016a). Therefore, although SLM can generate public goods in the form of
33 provisioning ecosystem services, individual land custodians underinvest in SLM as they are unable to
34 reap these benefits fully. Payment for ecosystem services provides a mechanism through which some
35 of these benefits can be transferred to land users, thereby stimulating further investment in SLM. The
36 effectiveness of PES schemes depends on land tenure security and appropriate design taking into
37 account specific local conditions (Börner et al., 2017). However, PES has not worked well in
38 countries with fragile institutions (Karsenty and Ongolo, 2012). Equity and justice in distributing the
39 payments for ecosystem services were found to be key for the success of the PES programmes in
40 Yunnan, China (He and Sikor, 2015). Yet, when reviewing the performance of PES programmes in
41 the tropics, Calvet-Mir et al. (2015), found that they are generally effective in terms of environmental
42 outcomes, despite being sometimes unfair in terms of payment distribution. It is suggested that the
43 implementation of PES will be improved through decentralised approaches giving local communities
44 a larger role in the decision making process (He and Lang, 2015).

45 **Empowering local communities for decentralised natural resource management.** Local institutions
46 often play a vital role in implementing SLM initiatives and climate change adaptation (*high*
47 *confidence*) (Gibson et al., 2005; Smucker et al., 2015). Pastoralists involved in community-based
48 natural resource management in Mongolia had greater capacity to adapt to extreme winter frosts

1 resulting in less damage to their livestock (Fernandez-Gimenez et al., 2015). Decreasing the power
2 and role of traditional community institutions, due to top-down public policies, resulted in lower
3 success rates in community-based programmes focused on rangeland management in Dirre, Ethiopia
4 (Abdu and Robinson, 2017). Decentralised governance was found to lead to improved management in
5 forested landscapes (Dressler et al., 2010; Ostrom and Nagendra, 2006). However, there are also cases
6 when local elites were placed in control, decentralised natural resource management negatively
7 impacted the livelihoods of the poorer and marginalised community members due to reduced access
8 to natural resources (Andersson and Ostrom, 2008; Cullman, 2015; Dressler et al., 2010). The success
9 of decentralised natural resource management initiatives depends on increased participation and
10 empowerment of diverse set of community members, not only local leaders and elites, in the design
11 and management of local resource management institutions (Kadirbeyoglu and Özertan, 2015;
12 Umutoni et al., 2016), while considering the interactions between actors and institutions at different
13 levels of governance (Andersson and Ostrom, 2008; Carlisle and Gruby, 2017; McCord et al., 2017).
14 An example of such programmes where local communities played a major role in land restoration and
15 rehabilitation activities is the cooperative project on “The National Afforestation and Erosion Control
16 Mobilization Action Plan” in Turkey, initiated by the Turkish Ministry of Agriculture and Forestry
17 (Çalışkan and Boydak, 2017), with the investment of USD 1.8 billion between 2008 and 2012. The
18 project mobilised local communities in cooperation with public institutions, municipalities, and non-
19 governmental organisations, to implement afforestation, rehabilitation and erosion control measures,
20 resulting in the afforestation and reforestation of 1.5 M ha (Yurtoglu, 2015). Moreover, some 1.75 M
21 ha of degraded forest and 37880 ha of degraded rangelands were rehabilitated. Finally, the project
22 provided employment opportunities for 300,000 rural residents for six months every year, combining
23 land restoration and rehabilitation activities with measures to promote socio-economic development in
24 rural areas (Çalışkan and Boydak, 2017).

25 ***Investing in research and development.*** Desertification has received substantial research attention
26 over recent decades (Turner et al., 2007). There is also a growing research interest on climate change
27 adaptation and mitigation interventions that help address desertification (Grainger, 2009). Agricultural
28 research on SLM practices has generated a significant number of new innovations and technologies
29 that increase crop yields without degrading the land, while contributing to climate change adaptation
30 and mitigation (3.6.1). There is *robust evidence* that such technologies help improve the food security
31 of smallholder dryland farming households (Harris and Orr, 2014, 6.3.5). Strengthening research on
32 desertification is of high importance not only to meet SDGs but also effectively manage ecosystems
33 based on solid scientific knowledge. More investment in research institutes and training the younger
34 generation of researchers is needed for addressing the combined challenges of desertification and
35 climate change (Akhtar-Schuster et al., 2011; Verstraete et al., 2011). This includes improved
36 knowledge management systems that allow stakeholders to work in a coordinated manner by
37 enhancing timely, targeted and contextualised information sharing (Chasek et al., 2011). Knowledge
38 and flow of knowledge on desertification is currently highly fragmented, constraining effectiveness of
39 those engaged in assessing and monitoring the phenomenon at various levels (Reed et al., 2011).
40 Improved knowledge and data exchange and sharing increase the effectiveness of efforts to address
41 desertification (*high confidence*).

42 ***Developing modern renewable energy sources.*** Transitioning to renewable energy resources
43 contributes to reducing desertification by lowering reliance on traditional biomass in dryland regions
44 (*medium confidence*). Populations in most developing countries continue to rely on traditional
45 biomass, including fuelwood, crop straws and livestock manure, for a major share of their energy
46 needs, with the highest dependence in Sub-Saharan Africa (Amugune et al., 2017; IEA, 2013). Use of
47 biomass for energy, mostly fuelwood (especially as charcoal), was associated with deforestation in
48 some dryland areas (Iiyama et al., 2014; Mekuria et al., 2018; Neufeldt et al., 2015; Zulu, 2010),
49 while in some other areas there was no link between fuelwood collection and deforestation (Simon

1 and Peterson, 2018; Swemmer et al., 2018; Twine and Holdo, 2016). Moreover, the use of traditional
2 biomass as a source of energy was found to have negative health effects through indoor air pollution
3 (de la Sota et al., 2018; Lim and Seow, 2012), while also being associated with lower female labor
4 force participation (Burke and Dundas, 2015). Jiang et al., (2014) indicated that providing improved
5 access to alternative energy sources such as solar energy and biogas could help reduce the use of
6 fuelwood in south-western China, thus alleviating the spread of rocky desertification. The conversion
7 of degraded lands into cultivation of biofuel crops will affect soil C dynamics (Albanito et al., 2016;
8 Nair et al., 2011; Cross-Chapter Box 7: Bioenergy and BECCS, Chapter 6). The use of biogas slurry
9 as soil amendment or fertiliser can increase soil C (Galvez et al., 2012; Negash et al., 2017). Large-
10 scale installation of wind and solar farms in the Sahara desert was projected to create a positive
11 climate feedback through increased surface friction and reduced albedo, doubling precipitation over
12 the neighbouring Sahel region with resulting increases in vegetation (Li et al., 2018). Transition to
13 renewable energy sources in high-income countries in dryland areas primarily contributes to reducing
14 greenhouse gas emissions and mitigating climate change, with some other co-benefits such as
15 diversification of energy sources (Bang, 2010), while the impacts on desertification are less evident.
16 The use of renewable energy has been proposed as an important mitigation option in dryland areas as
17 well (El-Fadel et al., 2003). Transitions to renewable energy are being promoted by governments
18 across drylands (Cancino-Solórzano et al., 2016; Hong et al., 2013; Sen and Ganguly, 2017) including
19 in fossil-fuel rich countries (Farnoosh et al., 2014; Dehkordi et al., 2017; Stambouli et al., 2012;
20 Vidadili et al., 2017), despite important social, political and technical barriers to expanding renewable
21 energy production (Afsharzade et al., 2016; Baker et al., 2014; Elum and Momodu, 2017; Karatayev
22 et al., 2016). Improving the social awareness about the benefits of transitioning to renewable energy
23 resources and access to hydro-energy, solar and wind energy contributes to their improved adoption
24 (Aliyu et al., 2017; Katikiro, 2016).

25 ***Developing and strengthening climate services relevant for desertification.*** Climate services provide
26 climate, drought and desertification-related information in a way that assists decision making by
27 individuals and organisations. For monitoring desertification, integration of biogeophysical (climate,
28 soil, ecological factors, biodiversity) and socio-economic aspects (use of natural resources by local
29 population) provides a basis for better vulnerability prediction and assessment (OSS, 2012; Vogt et
30 al., 2011). Examples of relevant services include: drought monitoring and early warning systems often
31 implemented by national climate and meteorological services but also encompassing regional and
32 global systems (Pozzi et al., 2013); and the Sand and Dust Storm Warning Advisory and Assessment
33 System (SDS-WAS), created by WMO in 2007, in partnership with the World Health Organization
34 (WHO) and the United Nations Environment Program (UNEP). Currently, there is also a lack of
35 ecological monitoring in arid and semi-arid regions to study surface winds, dust and sandstorms, and
36 their impacts on ecosystems and human health (Bergametti et al., 2018; Marticorena et al., 2010).
37 Reliable and timely climate services, relevant to desertification, can aid the development of
38 appropriate adaptation and mitigation options reducing the impact of desertification under changing
39 climate on human and natural systems (*high confidence*) (Beegum et al., 2016; Beegum et al., 2018;
40 Cornet, 2012; Haase et al., 2018; Sergeant, Moynahan, & Johnson, 2012).

41 ***3.6.3.2. Policy Responses Supporting Economic Diversification***

42 Despite policy responses for combating desertification, climate change, growing food demands, as
43 well as the need to reduce poverty and strengthen food security, will put strong pressures on the land
44 (Cherlet et al., 2018; 6.1.4; 7.2.2). Sustainable development of drylands and their resilience to
45 combined challenges of desertification and climate change will thus also depend on the ability of
46 governments to promote policies for economic diversification within agriculture and in non-
47 agricultural sectors in order make dryland areas less vulnerable to desertification and climate change.

1 **Investing into irrigation.** Investments into expanding irrigation in dryland areas can help increase the
2 resilience of agricultural production to climate change, improve labour productivity and boost
3 production and income revenue from agriculture and livestock sectors (Geerts and Raes, 2009;
4 Olayide et al., 2016; Oweis and Hachum, 2006). This is particularly true for Sub-Saharan Africa,
5 where currently only 6% of the cultivated areas are irrigated (Nkonya et al., 2016b). While renewable
6 groundwater resources could help increase the share of irrigated land to 20.5%-48.6% of croplands in
7 the region (Altchenko and Villholth, 2015). On the other hand, over-extraction of groundwaters,
8 mainly for irrigating crops, is becoming an important environmental problem in many dryland areas
9 (Cherlet et al., 2018), requiring careful design and planning of irrigation expansion schemes and use
10 of water efficient irrigation methods (Bjornlund, van Rooyen, and Stirzaker, 2017; Woodhouse et al.,
11 2017). For example, in Saudi Arabia, improving the efficiency of water management, e.g. through the
12 development of aquifers, water recycling and rainwater harvesting is part of policy actions to combat
13 desertification (Bazza, et al., 2018; Kingdom of Saudi Arabia, 2016). The expansion of irrigation to
14 riverine areas, crucial for dry season grazing of livestock, needs to consider the loss of income from
15 pastoral activities, which is not always lower than income from irrigated crop production (Behnke and
16 Kerven, 2013). Irrigation development could be combined with the deployment of clean energy
17 technologies in economically viable ways (Chandel et al., 2015). For example, solar-powered drip
18 irrigation was found to increase household agricultural incomes in Benin (Burney et al., 2010). The
19 sustainability of irrigation schemes based on solar-powered extraction of groundwaters depends on
20 measures to avoid over-abstraction of groundwater resources and associated negative environmental
21 impacts (Closas and Rap, 2017).

22 **Expanding agricultural commercialisation.** Faster poverty rate reduction and economic growth
23 enhancement is realised when countries transition into the production of non-staple, high value
24 commodities and manage to build a robust agro-industry sector (Barrett et al., 2017). Ogotu and Qaim
25 (2019) found that agricultural commercialisation increased incomes and decreased multidimensional
26 poverty in Kenya. Similar findings were earlier reported by Muriithi and Matz (2015) for
27 commercialisation of vegetables in Kenya. Commercialisation of rice production was found to have
28 increased smallholder welfare in Nigeria (Awotide et al., 2016). Agricultural commercialisation
29 contributed to improved household food security in Malawi, Tanzania and Uganda (Carletto et al.,
30 2017). However, such a transition did not improve farmers' livelihoods in all cases (Reardon et al.,
31 2009). High value cash crop/animal production can be bolstered by wide-scale use of technologies,
32 for example, mechanisation, application of inorganic fertilisers, crop protection and animal health
33 products. Market oriented crop/animal production facilitates social and economic progress with labour
34 increasingly shifting out of agriculture into non-agricultural sectors (Cour, 2001). Modernised
35 farming, improved access to inputs, credit and technologies enhances competitiveness in local and
36 international markets (Reardon et al., 2009).

37 **Facilitating structural transformations** in rural economies implies that the development of non-
38 agricultural sectors encourages the movement of labour from land-based livelihoods, vulnerable to
39 desertification and climate change, to non-agricultural activities (Haggblade et al., 2010). The
40 movement of labour from agriculture to non-agricultural sectors is determined by relative labour
41 productivities in these sectors (Shiferaw and Djido, 2016). Given already high underemployment in
42 the farm sector, increasing labour productivity in the non-farm sector was found as the main driver of
43 labour movements from farm sector to non-farm sector (Shiferaw and Djido, 2016). More investments
44 into education can facilitate this process (Headey et al., 2014). However, in some contexts, such as
45 pastoralist communities in Xinjiang, China, income diversification was not found to improve the
46 welfare of pastoral households (Liao et al., 2015). Economic transformations also occur through
47 urbanisation, involving the shift of labour from rural areas into gainful employment in urban areas
48 (Jedwab and Vollrath, 2015). The larger share of world population will be living in urban centres in
49 the 21st century and this will require innovative means of agricultural production with minimum

1 ecological footprint and less dependence on fossil fuels (Revi and Rosenzweig, 2013), while
2 addressing the demand of cities (see 4.9.1 for discussion on urban green infrastructure). Although
3 there is some evidence of urbanisation leading to the loss of indigenous and local ecological
4 knowledge, however, indigenous and local knowledge systems are constantly evolving, and are also
5 getting integrated into urban environments (Júnior et al., 2016; Reyes-García et al., 2013; van Andel
6 and Carvalheiro, 2013). Urban areas are attracting an increasing number of rural residents across the
7 developing world (Angel et al., 2011; Cour, 2001; Dahiya, 2012). Urban development contributes to
8 expedited agricultural commercialisation by providing market outlet for cash and high value crop and
9 livestock products. At the same time, urbanisation also poses numerous challenges in the form of
10 rapid urban sprawl and pressures on infrastructure and public services, unemployment and associated
11 social risks, which have considerable implications on climate change adaptive capacities (Bulkeley,
12 2013; Garschagen and Romero-Lankao, 2015).

13

14

15 **Cross-Chapter Box 5: Policy Responses to Drought**

16 Alisher Mirzabaev (Germany/Uzbekistan), Margot Hurlbert (Canada), Muhammad Mohsin Iqbal
17 (Pakistan), Joyce Kimutai (Kenya), Lennart Olsson (Sweden), Fasil Tena (Ethiopia), Murat Türkeş
18 (Turkey)

19

20 Drought is a highly complex natural hazard (for floods, see Box 7.2). It is difficult to precisely
21 identify its start and end. It is usually slow and gradual (Wilhite and Pulwarty, 2017), but sometimes
22 can evolve rapidly (Ford and Labosier, 2017; Mo and Lettenmaier, 2015). It is context-dependent, but
23 its impacts are diffuse, both direct and indirect, short-term and long-term (Few and Tebboth, 2018;
24 Wilhite and Pulwarty, 2017). Following the Synthesis Report (SYR) of the IPCC Fifth Assessment
25 Report (AR5), drought is defined here as “a period of abnormally dry weather long enough to cause a
26 serious hydrological imbalance” (Mach et al., 2014). Although drought is considered abnormal
27 relative to the water availability under the mean climatic characteristics, it is also a recurrent element
28 of any climate, not only in drylands, but also in humid areas (Cook et al., 2014b; Seneviratne and
29 Ciais, 2017; Spinoni et al., 2019; Türkeş, 1999; Wilhite et al., 2014). Climate change is projected to
30 increase the intensity or frequency of droughts in some regions across the world (for detailed
31 assessment see 2.2, and IPCC Special Report on Global Warming of 1.5°C (Hoegh-Guldberg et al.,
32 2018, Chapter 3)). Droughts often amplify the effects of unsustainable land management practices,
33 especially in drylands, leading to land degradation (Cook et al., 2009; Hornbeck, 2012). Especially in
34 the context of climate change, the recurrent nature of droughts requires pro-actively planned policy
35 instruments both to be well-prepared to respond to droughts when they occur and also undertake ex
36 ante actions to mitigate their impacts by strengthening the societal resilience against droughts (Gerber
37 and Mirzabaev, 2017).

38 Droughts are among the costliest of natural hazards (*robust evidence, high agreement*). According to
39 the International Disaster Database (EM-DAT), droughts affected more than 1.1 billion people
40 between 1994-2013, with the recorded global economic damage of USD 787 billion (CRED, 2015),
41 corresponding to an average of USD 41.4 billion per year. Drought losses in the agricultural sector
42 alone in the developing countries were estimated to equal USD 29 billion between 2005-2015 (FAO,
43 2018). Usually, these estimates capture only direct and on-site costs of droughts. However, droughts
44 have also wide-ranging indirect and off-site impacts, which are seldom quantified. These indirect
45 impacts are both biophysical and socio-economic, with the poor households and communities being
46 particularly exposed to them (Winsemius et al., 2018). Droughts affect not only water quantity, but
47 also water quality (Mosley, 2014). The costs of these water quality impacts are yet to be adequately

1 quantified. Socio-economic indirect impacts of droughts are related to food insecurity, poverty,
2 lowered health and displacement (Gray and Mueller, 2012; Johnstone and Mazo, 2011; Linke et al.,
3 2015; Lohmann and Lechtenfeld, 2015; Maystadt and Ecker, 2014; Yusa et al., 2015 see also 3.4.2.9,
4 Box 5.5), which are difficult to quantify comprehensively. Research is required for developing
5 methodologies that could allow for more comprehensive assessment of these indirect drought costs.
6 Such methodologies require the collection of highly granular data, which is currently lacking in many
7 countries due to high costs of data collection. However, the opportunities provided by remotely
8 sensed data and novel analytical methods based on big data and artificial intelligence, including use of
9 citizen science for data collection, could help in reducing these gaps.

10 There are three broad (and sometimes overlapping) policy approaches for responding to droughts
11 (also see 7.4.8). These approaches are often pursued simultaneously by many governments. Firstly,
12 responding to drought when it occurs by providing direct drought relief, known as crisis management.
13 Crisis management is also the costliest among policy approaches to droughts because it often
14 incentivises the continuation of activities vulnerable to droughts (Botterill and Hayes, 2012; Gerber
15 and Mirzabaev, 2017).

16 The second approach involves development of drought preparedness plans, which coordinate the
17 policies for providing relief measures when droughts occur. For example, combining resources to
18 respond to droughts at regional level in Sub-Saharan Africa was found more cost-effective than
19 separate individual country drought relief funding (Clarke and Hill, 2013). Effective drought
20 preparedness plans require well-coordinated and integrated government actions - a key lesson learnt
21 from 2015-2017 drought response in Cape Town, South Africa (Visser, 2018). Reliable, relevant and
22 timely climate and weather information helps respond to droughts appropriately (Sivakumar and
23 Ndiang'ui, 2007). Improved knowledge and integration of weather and climate information can be
24 achieved by strengthening drought early warning systems at different scales (Verbist et al., 2016).
25 Every USD invested into strengthening hydro-meteorological and early warning services in
26 developing countries was found to yield between USD 4 to 35 (Hallegatte, 2012). Improved access
27 and coverage by drought insurance, including index insurance, can help alleviate the impacts of
28 droughts on livelihoods (Guerrero-Baena et al., 2019; Kath et al., 2019; Osgood et al., 2018; Ruiz et
29 al., 2015; Tadesse et al., 2015).

30 The third category of responses to droughts involves drought risk mitigation. Drought risk mitigation
31 is a set of proactive measures, policies and management activities aimed at reducing the future
32 impacts of droughts (Vicente-Serrano et al., 2012). For example, policies aimed at improving water
33 use efficiency in different sectors of the economy, especially in agriculture and industry, or public
34 advocacy campaigns raising societal awareness and bringing about behavioural change to reduce
35 wasteful water consumption in the residential sector are among such drought risk mitigation policies
36 (Tsakiris, 2017). Public outreach and monitoring of communicable diseases, air and water quality
37 were found useful for reducing health impacts of droughts (Yusa et al., 2015). The evidence from
38 household responses to drought in Cape Town, South Africa, between 2015-2017, suggests that media
39 coverage and social media could play a decisive role in changing water consumption behaviour, even
40 more so than official water consumption restrictions (Booyesen et al., 2019). Drought risk mitigation
41 approaches are less costly than providing drought relief after the occurrence of droughts. To illustrate,
42 Harou et al. (2010) found that establishment of water markets in California considerably reduced
43 drought costs. Application of water saving technologies reduced drought costs in Iran by USD 282
44 million (Salami et al., 2009). Booker et al. (2005) calculated that interregional trade in water could
45 reduce drought costs by 20–30% in the Rio Grande basin, USA. Increasing rainfall variability under
46 climate change can make the forms of index insurance based on rainfall less efficient (Kath et al.,
47 2019). A number of diverse water property instruments, including instruments allowing water
48 transfer, together with the technological and institutional ability to adjust water allocation, can

1 improve timely adjustment to droughts (Hurlbert, 2018). Supply-side water management providing for
2 proportionate reductions in water delivery prevents the important climate change adaptation option of
3 managing water according to need or demand (Hurlbert and Mussetta, 2016). Exclusive use of a water
4 market to govern water allocation similarly prevents the recognition of the human right to water at
5 times of drought (Hurlbert, 2018). Policies aiming to secure land tenure, to expand access to markets,
6 agricultural advisory services and effective climate services, as well as to create off-farm employment
7 opportunities can facilitate the adoption of drought risk mitigation practices (Alam, 2015; Kusunose
8 and Lybbert, 2014), increasing the resilience to climate change (3.6.3), while also contributing to
9 SLM (3.6.3, 4.8.1, Table 5.7).

10 The excessive burden of drought relief funding on public budgets is already leading to a paradigm
11 shift towards proactive drought risk mitigation instead of reactive drought relief measures (Verner et
12 al., 2018; Wilhite, 2016). Climate change will reinforce the need for such proactive drought risk
13 mitigation approaches. Policies for drought risk mitigation that are already needed now will be even
14 more relevant under higher warming levels (Jerneck and Olsson, 2008; McLeman, 2013; Wilhite et
15 al., 2014). Overall, there is *high confidence* that responding to droughts through ex post drought relief
16 measures is less efficient compared to ex ante investments into drought risk mitigation, particularly
17 under climate change.

18 3.6.4. Limits to Adaptation, Maladaptation, and Barriers for Mitigation

19 Chapter 16 in the Fifth Assessment Report of IPCC (Klein et al., 2015) discusses the existence of soft
20 and hard limits to adaptation, highlighting that values and perspectives of involved agents are relevant
21 to identify limits (4.8.5.1, 7.4.9). In that sense, adaptation limits vary from place to place and are
22 difficult to generalise (Barnett et al., 2015; Dow et al., 2013; Klein et al., 2015). Currently, there is a
23 lack of knowledge on adaptation limits and potential maladaptation to combined effects of climate
24 change and desertification (see 4.8.6 in Chapter 4 for discussion on resilience, thresholds, and
25 irreversible land degradation also relevant for desertification). However, the potential for residual
26 risks and maladaptive outcomes is high (*high confidence*). Some examples of residual risks are
27 illustrated below (those risks which remain after adaptation efforts were taken, irrespective whether
28 they are tolerable or not, tolerability being a subjective concept). Although SLM measures can help
29 lessen the effects of droughts, they cannot fully prevent water stress in crops and resulting lower
30 yields (Eekhout and de Vente, 2019). Moreover, although in many cases SLM measures can help
31 reduce and reverse desertification, there would be still short-term losses in land productivity.
32 Irreversible forms of land degradation (e.g. loss of topsoil, severe gully erosion) can lead to the
33 complete loss of land productivity. Even when solutions are available, their costs could be prohibitive
34 presenting the limits to adaptation (Dixon et al., 2013). If warming in dryland areas surpasses human
35 thermal physiological thresholds (Klein et al., 2015; Waha et al., 2013), adaptation could eventually
36 fail (Kamali et al., 2018). Catastrophic shifts in ecosystem functions and services, e.g. coastal erosion
37 (4.9.8; Chen et al., 2015; Schneider and Kéfi, 2016), and economic factors can also result in
38 adaptation failure (Evans et al., 2015). Despite the availability of numerous options that contribute to
39 combating desertification, climate change adaptation and mitigation, there are also chances of
40 maladaptive actions (*medium confidence*) (Glossary). Some activities favouring agricultural
41 intensification in dryland areas can become maladaptive due to their negative impacts on the
42 environment (*medium confidence*). Agricultural expansion to meet food demands can come through
43 deforestation and consequent diminution of C sinks (Godfray and Garnett, 2014; Stringer et al., 2012).
44 Agricultural insurance programs encouraging higher agricultural productivity and measures for
45 agricultural intensification can result in detrimental environmental outcomes in some settings
46 (Guodaar et al., 2019; Müller et al., 2017; Table 6.12). Development of more drought-tolerant crop
47 varieties is considered as a strategy for adaptation to shortening rainy season, but this can also lead to
48 a loss of local varieties (Al Hamndou and Requier-Desjardins, 2008). Livelihood diversification to

1 collecting and selling firewood and charcoal production can exacerbate deforestation (Antwi-Agyei et
2 al., 2018). Avoiding maladaptive outcomes can often contribute both to reducing the risks from
3 climate change and combating desertification (Antwi-Agyei et al., 2018). Avoiding, reducing and
4 reversing desertification would enhance soil fertility, increase C storage in soils and biomass, thus
5 reducing C emissions from soils to the atmosphere (3.7.2; Cross-Chapter Box 2: Implications of large-
6 scale conversion from non-forest to forest land, Chapter 1). In specific locations, there may be barriers
7 for some of these activities. For example, afforestation and reforestation programs can contribute to
8 reducing sand storms and increasing C sinks in dryland regions (3.6.1, 3.7.2) (Chu et al., 2019).
9 However, implementing agroforestry measures in arid locations can be constrained by lack of water
10 (Apuri et al., 2018), leading to a trade-off between soil C sequestration and other water uses (Cao et
11 al., 2018).

13 **3.7. Hotspots and Case Studies**

14 The challenges of desertification and climate change in dryland areas across the world often have very
15 location-specific characteristics. The five case studies in this section present rich experiences and
16 lessons learnt on: 1) soil erosion, 2) afforestation and reforestation through “green walls”, 3) invasive
17 plant species, 4) oases in hyper-arid areas, and 5) integrated watershed management. Although it is
18 impossible to cover all hotspots of desertification and on the ground actions from all dryland areas,
19 these case studies present a more focused assessment of these five issues that emerged as salient in the
20 group discussions and several rounds of review of this chapter. The choice of these case studies was
21 also motivated by the desire to capture a wide diversity of dryland settings.

22 **3.7.1. Climate Change and Soil Erosion**

23 ***3.7.1.1. Soil Erosion under Changing Climate in Drylands***

24 Soil erosion is a major form of desertification occurring in varying degrees in all dryland areas across
25 the world (3.2), with negative effects on dryland ecosystems (3.4). Climate change is projected to
26 increase soil erosion potential in some dryland areas through more frequent heavy rainfall events and
27 rainfall variability than currently (see Section 3.5.2 for more detailed assessment, (Achite and Ouillon,
28 2007; Megnounif and Ghenim, 2016; Vachtman et al., 2013; Zhang and Nearing, 2005). There are
29 numerous soil conservation measures that can help reduce soil erosion (3.6.1). Such soil management
30 measures include afforestation and reforestation activities, rehabilitation of degraded forests, erosion
31 control measures, prevention of overgrazing, diversification of crop rotations, and improvement in
32 irrigation techniques, especially in sloping areas (Anache et al., 2018; ÇEMGM, 2017; Li and Fang,
33 2016; Poesen, 2018; Ziadat and Taimeh, 2013). Effective measures for soil conservation can also use
34 spatial patterns of plant cover to reduce sediment connectivity, and the relationships between
35 hillslopes and sediment transfer in eroded channels (García-Ruiz et al., 2017). The following three
36 examples present lessons learnt from the soil erosion problems and measures to address them in
37 different settings of Chile, Turkey and the Central Asian countries.

38 ***3.7.1.2. No-Till Practices for Reducing Soil Erosion in Central Chile***

39 Soil erosion by water is an important problem in Chile. National assessments conducted in 1979,
40 which examined 46% of the continental surface of the country, concluded that very high levels of soil
41 erosion affected 36% of the territory. The degree of soil erosion increases from south to north. The
42 leading locations in Chile are the region of Coquimbo with 84% of eroded soils (Lat 29°S, Semiarid
43 climate), the region of Valparaíso with 57% of eroded souls (Lat 33° S, Mediterranean climate) and
44 the region of O'Higging with 37% of eroded soils (Lat 34°S Mediterranean climate). The most
45 important drivers of soil erosion are soil, slope, climate erosivity (i.e., precipitation, intensity, duration
46 and frequency) due to a highly concentrated rainy season, and vegetation structure and cover. In the
47 region of Coquimbo, goat and sheep overgrazing have aggravated the situation (CIREN, 2010).

1 Erosion rates reach up to 100 t ha⁻¹ annually, having increased substantially over the last 50 years
2 (Ellies, 2000). About 10.4% of central Chile exhibits high erosion rates (greater than 1.1 t ha⁻¹
3 annually) (Bonilla et al., 2010).

4 Over the last few decades there has been an increasing interest in the development of no-till (also
5 called zero tillage) technologies to minimise soil disturbance, reduce the combustion of fossil fuels
6 and increase soil organic matter. No-till in conjunction with the adoption of strategic cover crops have
7 positively impacted soil biology with increases in soil organic matter. Early evaluations by Crovetto,
8 (1998) showed that no-till application (after seven years) had doubled the biological activity
9 indicators compared to traditional farming and even surpassed those found in pasture (grown for the
10 previous 15 years). Besides erosion control, additional benefits are an increase of water holding
11 capacity and reduction in bulk density. Currently, the above no-till farm experiment has lasted for 40
12 years and continues to report benefits to soil health and sustainable production (Reicosky and
13 Crovetto, 2014). The influence of this iconic farm has resulted in the adoption of soil conservation
14 practices and specially no-till in dryland areas of the Mediterranean climate region of central Chile
15 (Martínez et al., 2011). Currently, it has been estimated that the area under no-till farming in Chile
16 varies between 0.13 and 0.2 M ha (Acevedo and Silva, 2003).

17 ***3.7.1.3. Combating Wind Erosion and Deflation in Turkey: The Greening Desert of*** 18 ***Karapınar***

19 In Turkey, the amount of sediment recently released through erosion into seas was estimated to be 168
20 Mt yr⁻¹, which is considerably lower than the 500 Mt yr⁻¹ that was estimated to be lost in the 1970s
21 (ÇEMGM, 2017). The decrease in erosion rates is attributed to an increase in spatial extent of forests,
22 rehabilitation of degraded forests, erosion control, prevention of overgrazing, and improvement in
23 irrigation technologies. Soil conservation measures conducted in the Karapınar district, Turkey,
24 exemplify these activities. The district is characterised by a semi-arid climate and annual average
25 precipitation of 250–300 mm (Türkeş, 2003; Türkeş and Tatlı, 2011). In areas where vegetation was
26 overgrazed or inappropriately tilled, the surface soil horizon was removed through erosion processes
27 resulting in the creation of large drifting dunes that threatened settlements around Karapınar
28 (Groneman, 1968). Such dune movement had begun to affect the Karapınar settlement in 1956
29 (Kantarıcı et al., 2011). Consequently, by early 1960s, Karapınar town and nearby villages were
30 confronted with the danger of abandonment due to out-migration in early 1960s (Figure 3.11-1). The
31 reasons for increasing wind erosion in the Karapınar district can be summarised as follows: sandy
32 material was mobilised following drying of the lake; hot and semi-arid climate conditions;
33 overgrazing and use of pasture plants for fuel; excessive tillage; and strong prevailing winds.

34

1 **Figure 3.11 (1) A general view of a nearby village of Karapınar town in early 1960s (Çarkacı, 1999). (2) A**
 2 **view of the Karapınar wind erosion area in 2013 (Photograph: Murat Türkeş, 17.06.2013). (3)**
 3 **Construction of cane screens in early 1960s in order to decrease speed of the wind and prevent**
 4 **movement of the sand accumulations and dunes, which was one of the physical measures during the**
 5 **prevention and mitigation period (Çarkacı, 1999). (4) A view of mix vegetation in most of the Karapınar**

 7 **their resistance to the arid continental climate conditions along with a warm/hot temperature regime over**
 8 **the district (Photograph: Murat Türkeş, 17.06.2013)**

9
 10 Restoration and mitigation strategies were initiated in 1959 and today, 4300 ha of land have been
 11 restored (Akay and Yildirim, 2010) (Figure 3.11-2), using specific measures: (1) Physical measures:
 12 construction of cane screens to decrease wind speed and prevent sand movement (Figure 3.11); (2)
 13 Restoration of cover: increasing grass cover between screens using seeds collected from local pastures
 14 or the cultivation of rye (*Secale* sp.) and wheat grass (*Agropyron elongatum*) that are known to grow
 15 in arid and hot conditions; (3) Afforestation: saplings obtained from nursery gardens were planted and
 16 grown between these screens. Main tree species selected were oleaster (*Eleagnus* sp.), acacia (*Robinia*
 17 *pseudeaccacia*), ash (*Fraxinus* sp.), elm (*Ulmus* sp.) and maple (*Acer* sp.) (Figure 3.11-4). Economic
 18 growth occurred after controlling erosion and new tree nurseries have been established with modern
 19 irrigation. Potential negative consequences through the excessive use of water can be mitigated
 20 through engagement with local stakeholders and transdisciplinary learning processes, as well as by
 21 restoring the traditional land uses in the semi-arid Konya closed basin (Akça et al., 2016).

22 **3.7.1.4. Soil Erosion in Central Asia under Changing Climate**

23
 24 Soil erosion is widely acknowledged to be a major form of degradation of Central Asian drylands,
 25 affecting considerable share of croplands and rangelands. However, up-to-date information on the
 26 actual extent of eroded soils at the regional or country level is not available. The estimates compiled
 27 by Pender et al. (2009), based on the Central Asian Countries Initiative for Land Management

1 (CACILM), indicate that about 0.8 M ha of the irrigated croplands were subject to high degree of soil
2 erosion in Uzbekistan. In Turkmenistan, soil erosion was indicated to be occurring in about 0.7 M ha
3 of irrigated land. In Kyrgyzstan, out of 1 M ha irrigated land in the foothill zones, 0.76 M ha were
4 subject to soil erosion by water, leading to losses in crop yields of 20-60% in these eroded soils.
5 About 0.65 M ha of arable land were prone to soil erosion by wind (Mavlyanova et al., 2017).
6 Soil erosion is widespread in rainfed and irrigated areas in Kazakhstan (Saparov, 2014). About 5 M ha
7 of rainfed croplands were subject to high levels of soil erosion (Pender et al., 2009). Soil erosion by
8 water was indicated to be a major concern in sloping areas in Tajikistan (Pender et al., 2009).

9 The major causes of soil erosion in Central Asia are related to human factors, primarily excessive
10 water use in irrigated areas (Gupta et al., 2009), deep ploughing and lack of maintenance of vegetative
11 cover in rainfed areas (Suleimenov et al., 2014), and overgrazing in rangelands (Mirzabaev et al.,
12 2016). Lack of good maintenance of watering infrastructure for migratory livestock grazing and
13 fragmentation of livestock herds led to overgrazing near villages, increasing the soil erosion by wind
14 (Alimaev et al., 2008). Overgrazing in the rangeland areas of the region (e.g. particularly in
15 Kyzylkum) contributes to dust storms, coming primarily from Ustyurt Plateau, desertified areas of
16 Amudarya and Syrdarya rivers' deltas, dried seabed of the Aral Sea (now called Aralkum), and the
17 Caspian Sea (Issanova and Abuduwaili, 2017; Xi and Sokolik, 2015). Xi and Sokolik (2015)
18 estimated that total dust emissions in Central Asia were 255.6 Mt in 2001, representing 10-17% of the
19 global total.

20 Central Asia is one of the regions highly exposed to climate change, with warming levels projected to
21 be higher than the global mean (Hoegh-Guldberg et al., 2018), leading to more heat extremes (Reyer
22 et al., 2017). There is no clear trend in precipitation extremes, with some potential for moderate rise in
23 occurrence of droughts. The diminution of glaciers is projected to continue in the Pamir and Tian
24 Shan mountain ranges, a major source of surface waters along with seasonal snowmelt. Glacier
25 melting will increase the hazards from moraine-dammed glacial lakes and spring floods (Reyer et al.,
26 2017). Increased intensity of spring floods creates favourable conditions for higher soil erosion by
27 water especially in the sloping areas in Kyrgyzstan and Tajikistan. The continuation of some of the
28 current unsustainable cropland and rangeland management practices may lead to elevated rates of soil
29 erosion particularly in those parts of the region where climate change projections point to increases in
30 floods (Kyrgyzstan, Tajikistan) or increases in droughts (Turkmenistan, Uzbekistan) (Hijioka et al.,
31 2014). Increasing water use to compensate for higher evapotranspiration due to growing temperatures
32 and heat waves could increase soil erosion by water in the irrigated zones, especially sloping areas
33 and crop fields with uneven land levelling (Bekchanov et al., 2010). The desiccation of the Aral Sea
34 resulted in hotter and drier regional microclimate, adding to the growing wind erosion in adjacent
35 deltaic areas and deserts (Kust, 1999).

36 There are numerous sustainable land and water management practices available in the region for
37 reducing soil erosion (Abdullaev et al., 2007; Gupta et al., 2009; Kust et al., 2014; Nurbekov et al.,
38 2016). These include: improved land levelling and more efficient irrigation methods such as drip,
39 sprinkler and alternate furrow irrigation (Gupta et al., 2009); conservation agriculture practices,
40 including no-till methods and maintenance of crop residues as mulch in the rainfed and irrigated areas
41 (Kienzler et al., 2012; Pulatov et al., 2012); rotational grazing; institutional arrangements for pooling
42 livestock for long-distance mobile grazing; reconstruction of watering infrastructure along the
43 livestock migratory routes (Han et al., 2016; Mirzabaev et al., 2016); afforesting degraded marginal
44 lands (Djanibekov and Khamzina, 2016; Khamzina et al., 2009; Khamzina et al., 2016); integrated
45 water resource management (Dukhovny et al., 2013; Kazbekov et al., 2009), planting salt and drought
46 tolerant halophytic plants as windbreaks in sandy rangelands (Akinshina et al., 2016; Qadir et al.,
47 2009; Toderich et al., 2009; Toderich et al., 2008), and potentially the dried seabed of the former Aral
48 Sea (Breckle, 2013). The adoption of enabling policies, such as those discussed in Section 3.6.3, can

1 facilitate the adoption of these sustainable land and water management practices in Central Asia (*high*
2 *confidence*) (Aw-Hassan et al., 2016; Bekchanov et al., 2016; Bobojonov et al., 2013; Djanibekov et
3 al., 2016; Hamidov et al., 2016; Mirzabaev et al., 2016).

4 **3.7.2. Green Walls and Green Dams**

5 This case study evaluates the experiences of measures and actions implemented to combat soil
6 erosion, decrease dust storms, and to adapt to and mitigate climate change under the Green Wall and
7 Green Dam programmes in East Asia (e.g., China) and Africa (e.g., Algeria, Sahara and the Sahel
8 region). These measures have also been implemented in other countries, such as Mongolia (Do &
9 Kang, 2014; Lin et al., 2009), Turkey (Yurtoglu, 2015; Çalışkan and Boydak, 2017) and Iran
10 (Amiraslani and Dragovich, 2011), and are increasingly considered as part of many national and
11 international initiatives to combat desertification (Goffner et al., 2019; Cross-Chapter Box 2, chapter
12 1). Afforestation and reforestation programs can contribute to reducing sand storms and increasing C
13 sinks in dryland regions (*high confidence*). On the other hand, Green Wall and Green Dam
14 programmes also decrease the albedo and hence increase the surface absorption of radiation,
15 increasing the surface temperature. The net effect will largely depend on the balance between these
16 and will vary from place to place depending on many factors.

17 **3.7.2.1. The Experiences of Combating Desertification in China**

18 Arid and semiarid areas of China, including north-eastern, northern and north-western regions, cover
19 an area of more than 509 M ha, with annual rainfall of below 450 mm. Over the past several centuries,
20 more than 60% of the areas in arid and semiarid regions were used as pastoral and agricultural lands.
21 The coupled impacts of past climate change and human activity have caused desertification and dust
22 storms to become a serious problem in the region (Xu et al., 2010). In 1958, the Chinese government
23 recognised that desertification and dust storms jeopardised livelihoods of nearly 200 million people,
24 and afforestation programmes for combating desertification have been initiated since 1978. China is
25 committed to go beyond the Land Degradation Neutrality objective as indicated by the following
26 programmes that have been implemented. The Chinese Government began the Three North's Forest
27 Shelterbelt programme in Northeast China, North China, and Northwest China, with the goal to
28 combat desertification and to control dust storms by improving forest cover in arid and semiarid
29 regions. The project is implemented in three stages (1978–2000, 2001–2020, and 2021–2050). In
30 addition, the Chinese government launched Beijing and Tianjin Sandstorm Source Treatment Project
31 (2001–2010), Returning Farmlands to Forest Project (2003–present), Returning Grazing Land to
32 Grassland Project (2003–present) to combat desertification, and for adaptation and mitigation of
33 climate change (State Forestry Administration of China, 2015; Tao, 2014; Wang et al., 2013).

34 The results of the fifth period monitoring (2010–2014) showed: (1) Compared with 2009, the area of
35 degraded land decreased by 12,120 km² over a five-year period; (2) In 2014, the average coverage of
36 vegetation in the sand area was 18.33%, an increase of 0.7% compared with 17.63% in 2009, and the
37 C sequestration increased by 8.5%; (3) Compared with 2009, the amount of wind erosion decreased
38 by 33%, the average annual occurrence of sandstorms decreased by 20.3% in 2014; (4) As of 2014,
39 203,700 km² of degraded land were effectively managed, accounting for 38.4% of the 530,000 km² of
40 manageable desertified land; (5) The restoration of degraded land has created an annual output of
41 53.63 M tonnes of fresh and dried fruits, accounting for 33.9% of the total national annual output of
42 fresh and dried fruits (State Forestry Administration of China, 2015). This has become an important
43 pillar for economic development and a high priority for peasants as a method to eradicate poverty
44 (State Forestry Administration of China, 2015).

45 Stable investment mechanisms for combating desertification have been established along with tax
46 relief policies and financial support policies for guiding the country in its fight against desertification.
47 The investments in scientific and technological innovation for combating desertification have been
48 improved, the technologies for vegetation restoration under drought conditions have been developed,

1 the popularisation and application of new technologies has been accelerated, and the training of
2 technicians for farmers and herdsman has been strengthened. To improve the monitoring capability
3 and technical level of desertification, the monitoring network system has been strengthened, and the
4 popularisation and application of modern technologies are intensified (e.g., information and remote
5 sensing) (Wu et al., 2015). Special laws on combating desertification have been decreed by the
6 government. The provincial government responsibilities for desertification prevention and controlling
7 objectives and laws have been strictly implemented.

8 Many studies showed that the projects generally played an active role in combating desertification and
9 fighting against dust storms in China over the past several decades (*high confidence*) (Cao et al.,
10 2018; State Forestry Administration of China, 2015; Wang et al., 2013; Wang et al., 2014; Yang et al.
11 2013). At the beginning of the project, some problems appeared in some places due to lack of enough
12 knowledge and experience (*low confidence*) (Jiang, 2016; Wang et al., 2010). For example, some tree
13 species selected were not well suited to local soil and climatic conditions (Zhu et al., 2007), and there
14 was an inadequate consideration of the limitation of the amount of effective water on the carrying
15 capacity of trees in some arid regions (Dai, 2011; Feng et al., 2016; 3.6.4). In addition, at the
16 beginning of the project, there was an inadequate consideration of the effects of climate change on
17 combating desertification (Feng et al., 2015; Tan and Li, 2015). Indeed, climate change and human
18 activities over past years have influenced the desertification and dust storm control effects in China
19 (Feng et al., 2015; Wang et al., 2009; Tan and Li, 2015), and future climate change will bring new
20 challenges for combating desertification in China (Wang et al., 2017; Yin et al., 2015; Xu et al.,
21 2019). In particular, the desertification risk in China will be enhanced at 2°C compared to 1.5°C
22 global temperature rise (Ma et al., 2018). Adapting desertification control to climate change involves:
23 improving the adaptation capacity to climate change for afforestation and grassland management by
24 executing SLM practices; optimising the agricultural and animal husbandry structure; and using big
25 data to fulfil the water resources regulation (Zhang and Huisinsh, 2018). In particular, improving
26 scientific and technological supports in desertification control is crucial for adaptation to climate
27 change and combating desertification, including protecting vegetation in desertification-prone lands
28 by planting indigenous plant species, facilitating natural restoration of vegetation to conserve
29 biodiversity, employing artificial rain or snow, water saving irrigation and water storage technologies
30 (Jin et al., 2014; Yang et al., 2013).

31 32 **3.7.2.2. The Green Dam in Algeria**

33 After independence in 1962, the Algerian government initiated measures to replant forests destroyed
34 by the war and the steppes affected by desertification among its top priorities (Belaaz, 2003). In 1972,
35 the government invested in the “Green Dam” (“Barrage Vert”) project. This was the first significant
36 experiment to combat desertification, influence the local climate and decrease the aridity by restoring
37 a barrier of trees. The Green Dam extends across arid and semi-arid zones between the isohyets 300
38 and 200 mm. It is a 3 M ha band of plantation running from east to west (Figure 3.12). It is over 1,200
39 km long (from the Algerian-Moroccan border to the Algerian-Tunisian border) and has an average
40 width of about 20 km. The soils in the area are shallow, low in organic matter and susceptible to
41 erosion. The main objectives of the project were to conserve natural resources, improve the living
42 conditions of local residents and avoid their exodus to urban areas. During the first four decades
43 (1970–2000) the success rate was low (42%) due to lack of participation by the local population and
44 the choice of species (Bensaid, 1995).

1

2

3 **Figure 3.12 Localisation of the Green Dam in Algeria (Saifi et al., 2015). Note: The green coloured band**
 4 **represents the location of the Green Dam; the yellow band delineates the national border of Algeria.**
 5 **Source: GoogleEarth**

6

7 The Green Dam did not have the desired effects. Despite tree planting efforts, desertification
 8 intensified on the steppes, especially in south-western Algeria due to the prolonged drought during the
 9 1980s. Rainfall declined from 18% to 27%, and the dry season has increased by two months in the last
 10 century (Belala et al., 2018). Livestock numbers in the Green Dam regions, mainly sheep, have grown
 11 exponentially, leading to severe overgrazing, causing trampling and soil compaction, which greatly
 12 increased the risk of erosion. Wind erosion, very prevalent in the region, is due to climatic conditions
 13 and the strong anthropogenic action that reduced the vegetation cover. The action of the wind carries
 14 fine particles such as sands and clays and leaves on the soil surface a lag gravel pavement, which is
 15 unproductive. Water erosion is largely due to torrential rains in the form of severe thunderstorms that
 16 disintegrate the bare soil surface from raindrop impact (Achite et al., 2016). The detached soil and
 17 nutrients are transported offsite via runoff resulting in loss of fertility and water holding capacity. The
 18 risk of and severity of water erosion is a function of human land use activities that increase soil loss
 19 through removal of vegetative cover. The National Soil Sensitivity to Erosion Map (Salamani et al.,
 20 2012) shows that more than 3 M ha of land in the steppe provinces are currently experiencing intense
 21 wind activity (Houyou et al., 2016) and are areas at particular risk of soil erosion. Mostephaoui et al.
 22 (2013), estimates that each year there is a loss of 7 t h^{-1} of soils due to erosion. Nearly 0.6 M ha of
 23 land in the steppe zone are fully degraded without the possibility of biological recovery.

24

25 To combat the effects of erosion and desertification, the government has planned to relaunch the
 26 rehabilitation of the Green Dam by incorporating new concepts related to sustainable development,
 27 and adaptation to climate change. The experience of previous years has led to integrated rangeland

1 management, improved tree and fodder shrub plantations and the development of water conservation
2 techniques. Reforestation is carried out using several species, including fruit trees, to increase and
3 diversify the sources of income of the population.

4
5 The evaluation of the Green Dam from 1972 to 2015 (Merdas et al., 2015) shows that 0.3 M ha of
6 forest plantation have been planted, which represents 10% of the project area. Estimates of the success
7 rate of reforestation vary considerably between 30% and 75%, depending on the region. Through
8 demonstration, the Green Dam has inspired several African nations to build a Great Green Wall to
9 combat land degradation, mitigate climate change effects, loss of biodiversity and poverty in a region
10 that stretches from Senegal to Djibouti (Sahara and Sahel Observatory (OSS), 2016).

11 12 **3.7.2.3. The Great Green Wall of the Sahara and the Sahel Initiative**

13 The Great Green Wall is an initiative of the Heads of State and Government of the Sahelo-Saharan
14 countries to mitigate and adapt to climate change, and to improve the food security of the Sahel and
15 Saharan peoples (Sacande, 2018; M'Bow, 2017). Launched in 2007, this regional project aims to
16 restore Africa's degraded arid landscapes, reduce the loss of biodiversity and support local
17 communities to sustainable use of forests and rangelands. The Great Green Wall focuses on
18 establishing plantations and neighbouring projects covering a distance of 7,775 km from Senegal on
19 the Atlantic coast to Eritrea on the Red Sea coast, with a width of 15 km (Figure 3.13). The wall
20 passes through Djibouti, Eritrea, Ethiopia, Sudan, Chad, Niger, Nigeria, Mali, Burkina Faso and
21 Mauritania and Senegal.

22 The choice of woody and herbaceous species that will be used to restore degraded ecosystems is
23 based on biophysical and socio-economic criteria, including socio-economic value (food, pastoral,
24 commercial, energetic, medicinal, cultural); ecological importance (C sequestration, soil cover, water
25 infiltration) and species that are resilient to climate change and variability. The Pan-African Agency
26 of the Great Green Wall (PAGGW) was created in 2010 under the auspices of the African Union and
27 CEN-SAD to manage the project. The initiative is implemented at the level of each country by a
28 national structure. A monitoring and evaluation system has been defined, allowing nations to measure
29 outcomes and to propose the necessary adjustments.

30 In the past, reforestation programs in the arid regions of the Sahel and North Africa that have been
31 undertaken to stop desertification were poorly studied and cost a lot of money without significant
32 success (Benjaminsen and Hiernaux, 2019). Today, countries have changed their strategies and opted
33 for rural development projects that can be more easily funded. Examples of scalable practices for land
34 restoration: Managing water bodies for livestock and crop production, promoting fodder trees
35 reducing runoff (Mbow, 2017).

36 The implementation of the initiative has already started in several countries. For example, the FAO's
37 Action Against Desertification project was restoring 18000 hectares of land in 2018 through planting
38 native tree species in Burkina Faso, Ethiopia, the Gambia, Niger, Nigeria and Senegal (Sacande,
39 2018). Berrahmouni et al. (2016) estimated that 166 M ha can be restored in the Sahel, requiring the
40 restoration of 10 M ha per year to achieve Land Degradation Neutrality targets by 2030. Despite this
41 early implementation actions on the ground, the achievement of the planned targets is questionable
42 and challenging without significant additional funding.

 9

10 3.7.3. Invasive Plant Species

11 3.7.3.1. Introduction

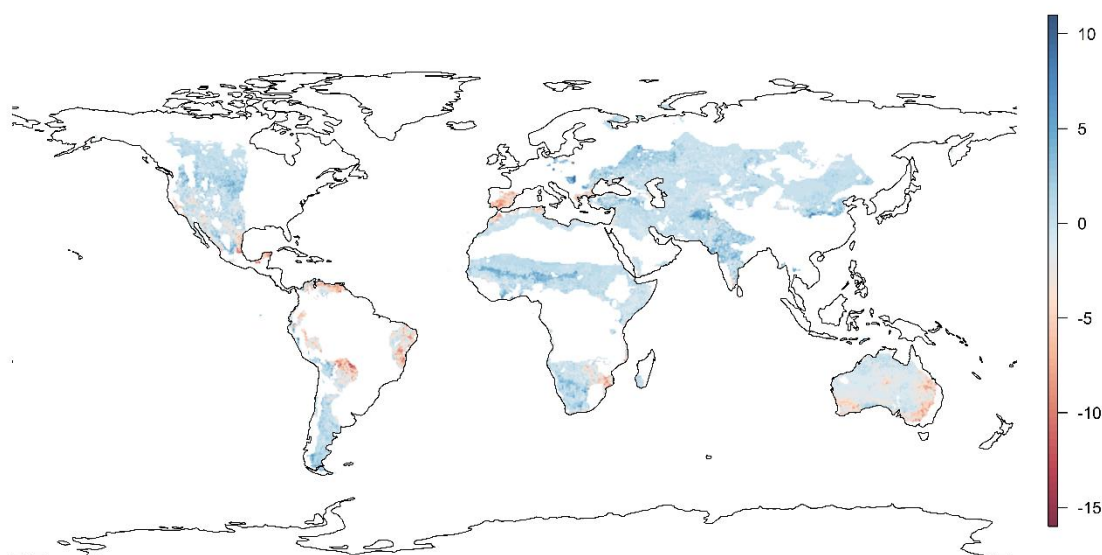

12 The spread of invasive plants can be exacerbated by climate change (Bradley et al., 2010; Davis et al.,
 13 2000). In general, it is expected that the distribution of invasive plant species with high tolerance to
 14 drought or high temperatures may increase under most climate change scenarios (*medium to high*
 15 *confidence*; Bradley et al., 2010; Settele et al., 2014; Scasta et al., 2015). Invasive plants are
 16 considered a major risk to native biodiversity and can disturb the nutrient dynamics and water balance
 17 in affected ecosystems (Ehrenfeld, 2003). Compared to more humid regions, the number of species
 18 that succeed in invading dryland areas is low (Bradley et al., 2012), yet they have a considerable
 19 impact on biodiversity and ecosystem services (Le Maitre et al., 2015; 2011; Newton et al., 2011).
 20 Moreover, human activities in dryland areas are responsible for creating new invasion opportunities
 21 (Safriel et al., 2005).

22 Current drivers of species introductions include expanding global trade and travel, land degradation
 23 and changes in climate (Chytrý et al., 2012; Richardson et al., 2011; Seebens et al., 2018). For
 24 example, Davis et al. (2000) suggests that high rainfall variability promotes the success of alien plant
 25 species - as reported for semiarid grasslands and Mediterranean-type ecosystems (Cassidy et al., 2004;
 26 Reynolds et al., 2004; Sala et al., 2006). Furthermore, Panda et al. (2018) demonstrated that many
 27 invasive species could withstand elevated temperature and moisture scarcity caused by climate

1 change. Dukes et al. (2011) observed that the invasive plant yellow-star thistle (*Centaurea solstitialis*)
2 grew six time larger under elevated atmospheric CO₂ expected in future climate change scenarios.

3 Climate change is *likely* going to aggravate the problem as existing species continue to spread
4 unabated and other species develop invasive characteristics (Hellmann et al., 2008). Although the
5 effects of climate change on invasive species distributions have been relatively well explored, the
6 greater impact on ecosystems is less well understood (Bradley et al., 2010; Eldridge et al., 2011).

7 Due to the time lag between the initial release of invasive species and their impact, the consequence
8 of invasions is not immediately detected and may only be noticed centuries after introduction (Rouget
9 et al., 2016). Climate change and invading species may act in concert (Bellard et al., 2013; Hellmann
10 et al., 2008; Seebens et al., 2015). For example, invasion often changes the size and structure of fuel
11 loads, which can lead to an increase in the frequency and intensity of fire (Evans et al., 2015). In areas
12 where the climate is becoming warmer, an increase in the likelihood of suitable weather conditions for
13 fire may promote invasive species, which in turn may lead to further desertification. Conversely, fire
14 may promote plant invasions via several of mechanisms (by reducing cover of competing vegetation,
15 destroying native vegetation and clearing a path for invasive plants or creating favourable soil
16 conditions) (Brooks et al., 2004; Grace et al., 2001; Keeley and Brennan, 2012).

17
18 **Figure 3.14 Difference between the number of invasive alien species (n=99, from(Bellard et al., 2013))**
19 **predicted to occur by 2050 (under A1B scenario) and current period “2000” within the dryland areas.**

20 At a regional scale, Bellard et al. (2013) predicted increasing risk in Africa and Asia, with declining
21 risk in Australia (Figure 3.14). This projection does not represent an exhaustive list of invasive alien
22 species occurring in drylands.

23 A set of four case studies in Ethiopia, Mexico, the USA and Pakistan is presented below to describe
24 the nuanced nature of invading plant species, their impact on drylands and their relationship with
25 climate change.

26 3.7.3.2. Ethiopia

27 The two invasive plants that inflict the heaviest damage to ecosystems, especially biodiversity, are the
28 annual herbaceous weed, *Parthenium hysterophorus* (*Asteraceae*) also known as Congress weed; and
29 the tree species, *Prosopis juliflora* (*Fabaceae*) also called Mesquite both originating from
30 southwestern United States to central - south America (Adkins and Shabbir, 2014). *Prosopis* was
31 introduced in the 1970s and has since spread rapidly. *Prosopis*, classified as the highest priority
32 invader in the country, is threatening livestock production and challenging the sustainability of the

1 pastoral systems. *Parthenium* is believed to have been introduced along with relief aid during the
2 debilitating droughts of the early 1980s, and a recent study reported that *the weed* has spread into 32
3 out of 34 districts in Tigray, the northernmost region of Ethiopia (Teka, 2016). A study by Etana et al.
4 (2011) indicated that *Parthenium* caused a 69% decline in the density of herbaceous species in Awash
5 National Park within a few years of introduction. In the presence of *Parthenium*, the growth and
6 development of crops is suppressed due to its allelopathic properties. McConnachie et al. (2011)
7 estimated a 28% crop loss across the country, including a 40-90% reduction in sorghum yield in
8 eastern Ethiopia alone (Tamado et al., 2002). The weed is a substantial agricultural and natural
9 resource problem and constitutes a significant health hazard (Fasil, 2011). *Parthenium* causes acute
10 allergic respiratory problems, skin dermatitis, and reportedly mutagenicity both in human and
11 livestock (Mekonnen, 2017; Patel, 2011). The eastern belt of Africa including Ethiopia presents a
12 very suitable habitat, and the weed is expected to spread further in the region in the future (Mainali et
13 al., 2015).

14 There is neither a comprehensive intervention plan nor a clear institutional mandate to deal with
15 invasive weeds, however, there are fragmented efforts involving local communities even though they
16 are clearly inadequate. The lessons learned are related to actions that have contributed to the current
17 scenario are several. First, lack of coordination and awareness - mesquite was introduced by
18 development agencies as a drought tolerant shade tree with little consideration of its invasive nature.
19 If research and development institutions had been aware, a containment strategy could have been
20 implemented early on. The second major lesson is the cost of inaction. When research and
21 development organisations did sound the alarm, but the warnings went largely unheeded, resulting in
22 the spread and buildup of two of the worst invasive plant species in the world (Fasil, 2011).

23 3.7.3.3. Mexico

24 Buffelgrass (*Cenchrus ciliaris* L.), a native species from southern Asia and East Africa, was
25 introduced into Texas and northern Mexico in the 1930s and 1940s, as it is highly productive in
26 drought conditions (Cox et al., 1988; Rao et al., 1996). In the Sonoran desert of Mexico, the
27 distribution of buffelgrass has increased exponentially, covering 1 M ha in Sonora State (Castellanos-
28 Villegas et al., 2002). Furthermore, its potential distribution extended to 53% of Sonora State and
29 12% of semiarid and arid ecosystems in Mexico (Arriaga et al., 2004). Buffelgrass has also been
30 reported as an aggressive invader in Australia and the United States resulting in altered fire cycles that
31 enhance further spread of this plant and disrupts ecosystem processes (Marshall et al., 2012; Miller et
32 al., 2010; Schlesinger et al., 2013).

33 Castellanos et al. (2016) reported that soil moisture was lower in the buffelgrass savanna cleared 35
34 years ago than in the native semi-arid shrubland, mainly during the summer. The ecohydrological
35 changes induced by buffelgrass can therefore displace native plant species over the long term.
36 Invasion by buffelgrass can also affect landscape productivity, as it is not as productive as native
37 vegetation (Franklin and Molina-Freaner, 2010). Incorporation of buffelgrass is considered a good
38 management practice by producers and the government. For this reason, no remedial actions are
39 undertaken.

40 3.7.3.4. United States

41 Sagebrush ecosystems have declined from 25 to 13 M ha since the late 1800s (Miller et al., 2011). A
42 major cause is the introduction of non-native cheatgrass (*Bromus tectorum*), which is the most prolific
43 invasive plant in the United States. Cheatgrass infests more than 10 M ha in the Great Basin and is
44 expanding every year (Balch et al., 2013). It provides a fine-textured fuel that increases the intensity,
45 frequency and spatial extent of fire (Balch et al., 2013). Historically, wildfire frequency was 60 to 110
46 years in Wyoming big sagebrush communities and has increased to five years following the
47 introduction of cheatgrass (Balch et al., 2013; Pilliod et al., 2017).

1 The conversion of the sagebrush steppe biome into to annual grassland with higher fire frequencies
2 has severely impacted livestock producers as grazing is not possible for a minimum of two years after
3 fire. Furthermore, cheatgrass and wildfires reduce critical habitat for wildlife and negatively impact
4 species richness and abundance – for example, the greater sage-grouse (*Centrocercus urophasianus*)
5 and pygmy rabbit (*Brachylagus idahoensis*) which are on the verge of being listed for federal
6 protection (Crawford et al., 2004; Larrucea and Brussard, 2008; Lockyer et al., 2015).

7 Attempts to reduce cheatgrass impacts through reseeding of both native and adapted introduced
8 species have occurred for more than 60 years (Hull and Stewart, 1949) with little success. Following
9 fire, cheatgrass becomes dominant and recovery of native shrubs and grasses is improbable,
10 particularly in relatively low elevation sites with minimal annual precipitation (less than 200 mm yr⁻¹)
11 (Davies et al., 2012; Taylor et al., 2014). Current rehabilitation efforts emphasise the use of native and
12 non-native perennial grasses, forbs, and shrubs (Bureau of Land Management, 2005). Recent
13 literature suggests that these treatments are not consistently effective at displacing cheatgrass
14 populations or re-establishing sage-grouse habitat with success varying with elevation and
15 precipitation (Arkle et al., 2014; Knutson et al., 2014). Proper post-fire grazing rest, season-of-use,
16 stocking rates, and subsequent management are essential to restore resilient sagebrush ecosystems
17 before they cross a threshold and become an annual grassland (Chambers et al., 2014; Miller et al.,
18 2011; Pellant et al., 2004). Biological soil crust protection may be an effective measure to reduce
19 cheatgrass germination, as biocrust disturbance has been shown to be a key factor promoting
20 germination of non-native grasses (Hernandez and Sandquist, 2011). Projections of increasing
21 temperature (Abatzoglou and Kolden, 2011), and observed reductions in and earlier melting of
22 snowpack in the Great Basin region (Harpold and Brooks, 2018; Mote et al., 2005) suggest that there
23 is a need to understand current and past climatic variability as this will drive wildfire and invasions of
24 annual grasses.

25 3.7.3.5. Pakistan

26 The alien plants invading local vegetation in Pakistan include *Brossentia papyrifera* (found in
27 Islamabad Capital territory), *Parthenium hysterophorus* (found in Punjab and Khyber Pakhtunkhwa
28 provinces), *Prosopis juliflora* (found all over Pakistan), *Eucalyptus camaldulensis* (found in Punjab
29 and Sindh provinces), *Salvinia* (aquatic plant widely distributed in water bodies in Sindh), *Cannabis*
30 *sativa* (found in Islamabad Capital Territory), *Lantana camara* and *Xanthium strumarium* (found in
31 upper Punjab and Khyber Pakhtunkhwa provinces) (Khan et al., 2010; Qureshi et al., 2014). Most of
32 these plants were introduced by the Forest Department decades ago for filling the gap between
33 demand and supply of timber, fuelwood and fodder. These non-native plants have some uses but their
34 disadvantages outweigh their benefits (Marwat et al., 2010; Rashid et al., 2014).

35 Besides being a source of biological pollution and a threat to biodiversity and habitat loss, the alien
36 plants reduce the land value and cause huge losses to agricultural communities (Rashid et al., 2014).
37 *Brossentia papyrifera*, commonly known as Paper Mulberry, is the root cause of inhalant pollen
38 allergy for the residents of lush green Islamabad during spring. From February to April, the pollen
39 allergy is at its peak with symptoms of severe persistent coughing with difficulty in breathing and
40 wheezing. The pollen count, although variable at different times and days, can be as high as 55,000
41 m⁻³. Early symptoms of the allergy include sneezing, itching in the eyes and skin, and blocked nose.
42 With changing climate, the onset of disease is getting earlier, and pollen count is estimated to cross
43 55,000 m⁻³ (Rashid et al., 2014). About 45% of allergic patients in the twin cities of Islamabad and
44 Rawalpindi showed positive sensitivity to the pollens (Marwat et al., 2010). Millions of rupees have
45 been spent by the Capital Development Authority on pruning and cutting of Paper Mulberry trees but
46 because of its regeneration capacity growth is regained rapidly (Rashid et al., 2014). Among other
47 invading plants, *Prosopis juliflora* has allelopathic properties, and *Eucalyptus* is known to transpire
48 huge amounts of water and deplete the soil of its nutrient elements (Qureshi et al., 2014).

1 Although Biodiversity Action Plan exists in Pakistan, it is not implemented in letter and spirit. The
 2 Quarantine Department focuses only on pests and pathogens but takes no notice of plant and animal
 3 species being imported. Also, there is no provision of checking the possible impacts of imported
 4 species on the environment (Rashid et al., 2014) and of carrying out bio assays of active allelopathic
 5 compounds of alien plants.

6 **3.7.4. Oases in Hyper-arid Areas in the Arabian Peninsula and Northern Africa**

7 Oases are isolated areas with reliable water supply from lakes and springs located in hyper-arid and
 8 arid zones (Figure 3.15). Oasis agriculture has long been the only viable crop production system
 9 throughout the hot and arid regions of the Arabian Peninsula and North Africa. Oases in hyper-arid
 10 climates are usually subject to water shortage as evapotranspiration exceeds rainfall. This often causes
 11 salinisation of soils. While many oases have persisted for several thousand years, many others have
 12 been abandoned, often in response to changes in climate or hydrologic conditions (Jones et al., 2019),
 13 providing testimony to societies' vulnerability to climatic shifts and raising concerns about similarly
 14 severe effects of anthropogenic climate change (Jones et al., 2019).

15 **Figure 3.15. Oases across the Arabian Peninsula and North Africa (alphabetically by country):**

 21 **Generic license.**

22 On the Arabian Peninsula and in North Africa, climate change is projected to have substantial and
 23 complex effects on oasis areas (Abatzoglou and Kolden, 2011; Ashkenazy et al., 2012; Bachelet et al.,

1 2016; Guan et al., 2018; Iknayan and Beissinger, 2018; Ling et al., 2013). To illustrate, by the 2050s,
2 the oases in southern Tunisia are expected to be affected by hydrological and thermal changes, with
3 an average temperature increase of 2.7°C, a 29% decrease in precipitation and a 14% increase in
4 evapotranspiration rate (Ministry of Agriculture and Water Resources of Tunisia and GIZ, 2007). In
5 Morocco, declining aquifer recharge is expected to impact the water supply of the Figuig oasis (Jilali,
6 2014), as well as for the Draa Valley (Karmaoui et al., 2016). Saudi Arabia is expected to experience
7 a 1.8–4.1°C increase in temperatures by 2050, which is forecast to raise agricultural water demand by
8 5-15% in order to maintain the level of production equal to that in 2011 (Chowdhury and Al-Zahrani,
9 2013). The increase of temperatures and variable pattern of rainfall over the central, north and south-
10 western regions of Saudi Arabia may pose challenges for sustainable water resource management
11 (Tarawneh and Chowdhury, 2018). Moreover, future climate scenarios are expected to increase the
12 frequency of floods and flash floods, such as in the coastal areas along the central parts of the Red Sea
13 and the south-southwestern areas of Saudi Arabia (Almazroui et al., 2017).

14 While many oases are cultivated with very heat-tolerant crops such as date palms, even such crops
15 eventually lose in their productivity when temperatures exceed certain thresholds or hot conditions
16 prevail for extended periods. Projections so far do not indicate severe losses in land suitability for date
17 palm for the Arabian Peninsula (Aldababseh et al., 2018; Shabani et al., 2015). It is unclear, however,
18 how reliable the climate response parameters in the underlying models are, and actual responses may
19 differ substantially. Date palms are routinely assumed to be able to endure very high temperatures, but
20 recent transcriptomic and metabolomic evidence suggests that heat stress reactions already occur at
21 35°C (Safronov et al., 2017), which is not exceptionally warm for many oases in the region. Given
22 current assumptions about the heat-tolerance of date palm, however, adverse effects are expected to
23 be small (Aldababseh et al., 2018; Shabani et al., 2015). For some other perennial oasis crops, impacts
24 of temperature increases are already apparent. Between 2004-2005 and 2012-2013, high-mountain
25 oases of Al Jabal Al Akhdar in Oman lost almost all fruit and nut trees of temperate-zone origin, with
26 the abundance of peaches, apricots, grapes, figs, pears, apples, and plums dropping by between 86%
27 and 100% (Al-Kalbani et al., 2016). This implies that that the local climate may not remain suitable
28 for species that depend on cool winters to break their dormancy period (Luedeling et al., 2009). A
29 similar impact is very probable in Tunisia and Morocco, as well as in other oasis locations in the
30 Arabian Peninsula and North Africa (Benmoussa et al., 2007). All these studies expect strong
31 decreases in winter chill, raising concerns that many currently well-established species will no longer
32 be viable in locations where they are grown today. The risk of detrimental chill shortfalls is expected
33 to increase gradually, slowly diminishing the economic prospects to produce such species. Without
34 adequate adaptation actions, the consequences of this development for many traditional oasis
35 settlements and other plantations of similar species could be highly negative.

36 At the same time, population growth and agricultural expansion in many oasis settlements are leading
37 to substantial increases in water demand for human consumption (Al-Kalbani et al., 2014). For
38 example, a large unmet water demand has been projected for future scenarios for the valley of
39 Seybouse in East Algeria (Aoun-Sebaiti et al., 2014), and similar conclusions were drawn for Wadi El
40 Natrun in Egypt (Switzman et al., 2018). Modelling studies have indicated long-term decline in
41 available water and increasing risk of water shortages, e.g. for oases in Morocco (Johannsen et al.,
42 2016; Karmaoui et al., 2016), the Dakhla oasis in Egypt's Western Desert (Sefelnasr et al., 2014) and
43 for the large Upper Mega Aquifer of the Arabian Peninsula (Siebert et al., 2016). Mainly due to the
44 risk of water shortages, Souissi et al. (2018) classified almost half of all farmers in Tunisia as non-
45 resilient to climate change, especially those relying on tree crops, which limit opportunities for short-
46 term adaptation actions.

1 The maintenance of the oasis systems and the safeguarding of their population's livelihoods are
2 currently threatened by continuous water degradation, increasing soil salinisation, and soil
3 contamination (Besser et al., 2017). Waterlogging and salinisation of soils due to rising saline
4 groundwater tables coupled with inefficient drainage systems have become common to all continental
5 oases in Tunisia, most of which are concentrated around saline depressions, known locally as chotts
6 (Ben Hassine et al., 2013). Similar processes of salinisation are also occurring in the oasis areas of
7 Egypt due to agricultural expansion, excessive use of water for irrigation and deficiency of the
8 drainage systems (Abo-Ragab, 2010; Masoud and Koike, 2006). A prime example for this is Siwa
9 oasis (Figure 3.16), a depression extending over 1050 km² in the north-western desert of Egypt in the
10 north of the sand dune belt of the Great Sand Sea (Abo-Ragab, and Zaghoul, 2017). Siwa oasis has
11 been recognised as a Globally Important Agricultural Heritage Site (GIAHS) by the FAO for being an
12 *in situ* repository of plant genetic resources, especially of uniquely adapted varieties of date palm,
13 olive and secondary crops that are highly esteemed for their quality and continue to play a significant
14 role in rural livelihoods and diets (FAO, 2016).

15
16 **Figure 3.16. The Satellite Image of the Siwa Oasis, Egypt. Source: Google Maps.**

17
18 The population growth in Siwa is leading rapid agricultural expansion and land reclamation. The
19 Siwan farmers are converting the surrounding desert into reclaimed land by applying their old
20 inherited traditional practices. Yet, agricultural expansion in the oasis mainly depends on non-
21 renewable groundwaters. Soil salinisation and vegetation loss have been accelerating since 2000 due
22 to water mismanagement and improper drainage systems (Masoud and Koike, 2006). Between 1990-
23 2008, the cultivated area increased from 53 to 88 km², lakes from 60 to 76 km², sabkhas (salt flats)
24 from 335 to 470 km², and the urban area from 6 to 10 km² (Abo-Ragab, 2010). The problem of rising
25 groundwater tables was exacerbated by climatic changes (Askri et al., 2010; Gad and Abdel-Baki,
26 2002; Marlet et al., 2009).

1
2 Water supply is *likely* to become even scarcer for oasis agriculture under changing climate in the
3 future than it is today, and viable solutions are difficult to find. While some authors stress the
4 possibility to use desalinated water for irrigation (Aldababseh et al., 2018), the economics of such
5 options, especially given the high evapotranspiration rates in the Arabian Peninsula and North Africa,
6 are debatable. Many oases are located far from water sources that are suitable for desalination, adding
7 further to feasibility constraints. Most authors therefore stress the need to limit water use (Sefelnasr et
8 al., 2014), e.g. by raising irrigation efficiency (Switzman et al., 2018), reducing agricultural areas
9 (Johannsen et al., 2016) or imposing water use restrictions (Odhiambo, 2017), and to carefully
10 monitor desertification (King and Thomas, 2014). Whether adoption of crops with low water demand,
11 such as sorghum (*Sorghum bicolor* (L.) Moench) or jojoba (*Simmondsia chinensis* (Link) C. K.
12 Schneid.) (Aldababseh et al., 2018), can be a viable option for some oases remains to be seen, but
13 given their relatively low profit margins compared to currently grown oasis crops, there are reasons to
14 doubt the economic feasibility of such proposals. While it is currently unclear, to what extent oasis
15 agriculture can be maintained in hot locations of the region, cooler sites offer potential for shifting
16 towards new species and cultivars. Especially for tree crops, which have particular climatic needs
17 across seasons. Resilient options can be identified, but procedures to match tree species and cultivars
18 with site climate need to be improved to facilitate effective adaptation.

19 There is *high confidence* that many oases of North Africa and the Arabian Peninsula are vulnerable to
20 climate change. While the impacts of recent climate change are difficult to separate from the
21 consequences of other change processes, it is *likely* that water resources have already declined in
22 many places and the suitability of the local climate for many crops, especially perennial crops, has
23 already decreased. This decline of water resources and thermal suitability of oasis locations for
24 traditional crops is *very likely* to continue throughout the 21st century. In the coming years, the people
25 living in oasis regions across the world will face challenges due to increasing impacts of global
26 environmental change (Chen et al., 2018). Hence, efforts to increase their adaptive capacity to climate
27 change can facilitate the sustainable development of oasis regions globally. This will concern
28 particularly addressing the trade-offs between environmental restoration and agricultural livelihoods
29 (Chen et al., 2018). Ultimately, sustainability in oasis regions will depend on policies integrating the
30 provision of ecosystem services and social and human welfare needs (Wang et al., 2017).

31

32 **3.7.5. Integrated Watershed Management**

33 Desertification has resulted in significant loss of ecosystem processes and services as described in
34 detail in this chapter. The techniques and processes to restore degraded watersheds are not linear and
35 integrated watershed management (IWM) must address physical, biological and social approaches to
36 achieve SLM objectives (German et al., 2007).

37 **3.7.5.1. Jordan**

38 Population growth, migration into Jordan and changes in climate have resulted in desertification of the
39 Jordan Badia region. The Badia region covers more than 80% of the country's area and receives less
40 than 200 mm of rainfall per year, with some areas receiving less than 100 mm (Al-Tabini et al., 2012).
41 Climate analysis has indicated a generally increasing dryness over the West Asia and Middle Eastern
42 region (AlSarmi and Washington, 2011; Tanarhte et al., 2015) with reduction in average annual
43 rainfall in Jordan's Badia area (De Pauw et al., 2015). The incidence of extreme rainfall events has
44 not declined over the region. Locally increased incidence of extreme events over the Mediterranean
45 region have been proposed (Giannakopoulos et al., 2009).

46 The practice of intensive and localised livestock herding, in combination with deep ploughing and
47 unproductive barley agriculture, are the main drivers of severe land degradation and depletion of the
48 rangeland natural resources. This affected both the quantity and the diversity of vegetation as native

1 plants with a high nutrition value were replaced with invasive species with low palatability and
 2 nutritional content (Abu-Zanat et al., 2004). The sparsely covered and crusted soils in Jordan's Badia
 3 area have a low rainfall interception and infiltration rate, which leads to increased surface runoff and
 4 subsequent erosion and gullying, speeding up the drainage of rainwater from the watersheds that can
 5 result in downstream flooding in Amman, Jordan (Oweis, 2017).

12

13 **Figure 3.18 Illustration of enhanced soil water retention in the Mechanized Micro Rainwater Harvesting**
 14 **compared to untreated Badia rangelands in Jordan, showing precipitation (PCP), sustained stress level**
 15 **resulting in decreased production, Field Capacity and Wilting Point for available soil moisture, and then**
 16 **measured soil moisture content between the two treatments (degraded rangeland and the restored**
 17 **rangeland with the Vallerani plow).**

18 To restore the desertified Badia an IWM plan was developed using hillslope implemented water
 19 harvesting micro catchments as a targeted restoration approach (Tabieh et al., 2015). Mechanized
 20 Micro Rainwater Harvesting (MIRWH) technology using the 'Vallerani plough' (Antinori and
 21 Vallerani, 1994; Gammoh and Oweis, 2011; Ngigi, 2003) is being widely applied for rehabilitation of
 22 highly degraded rangeland areas in Jordan. Tractor digs out small water harvesting pits on the contour
 23 of the slope (Figure 3.17) allowing the retention, infiltration and the local storage of surface runoff in
 24 the soil (Oweis, 2017). The micro catchments are planted with native shrub seedlings, such as
 25 saltbush (*Atriplex halimus*), with enhanced survival as a function of increased soil moisture (Figure
 26 3.18) and increased dry matter yields (>300 kg ha⁻¹) that can serve as forage for livestock (Oweis,
 27 2017; Tabieh et al., 2015).

1 Simultaneously to MIRWH upland measures, the gully erosion is being treated through intermittent
2 stone plug intervention (Figure 3.19), stabilising the gully beds, increasing soil moisture in proximity
3 of the plugs and dissipating the surface runoff's energy, and mitigating further back-cutting erosion
4 and quick drainage of water. Eventually, the treated gully areas silt up and dense vegetation cover can
5 re-establish. In addition, grazing management practices are implemented to increase the longevity of
6 the treatment. Ultimately, the recruitment processes and revegetation shall control the watershed's
7 hydrological regime through rainfall interception, surface runoff deceleration and filtration, combined
8 with the less erodible and enhanced infiltration characteristics of the rehabilitated soils. In-depth
9 understanding of the Badia's rangeland status transition, coupled with sustainable rangeland
10 management, are still subject to further investigation, development and adoption; required to mitigate
11 the ongoing degradation of the Middle Eastern rangeland ecosystems.

12
13 **Figure 3.19 Gully plug development in September 2017 (a) and post rainfall event in March 2018 (b)**
14 **near Amman, Jordan. Source: Stefan Strohmeire.**

15 Oweis (2017) indicated that costs of the fully automated Vallerani technique was approximately USD
16 32 ha⁻¹. The total cost of the restoration package included the production, planting, and maintenance
17 of the shrub seedlings (USD 11 ha⁻¹). Tabieh et al. (2015) calculated a benefit cost ratio (BCR) of >
18 1.5 for revegetation of degraded Badia areas through MIRWH and saltbush. However, costs vary
19 based on the seedling's costs and availability of trained labour.

20 Water harvesting is not a recent scientific advancement. Water harvesting has been documented
21 having evolved during the Bronze Age and was widely practiced in the Negev Desert during the
22 Byzantine time period (1300-1600 years ago) (Fried et al., 2018; Stavi et al., 2017). Through
23 construction of various structures made for packed clay and stone, water was either held on site in
24 half-circular dam structures (Hafir) that faced up slope to capture runoff or on terraces that slowed
25 water allowing it to infiltrate and to be stored in the soil profile. Numerous other systems were
26 designed to capture water in below ground cisterns to be used later to provide water to livestock or for
27 domestic use. Other water harvesting techniques divert runoff from hillslopes or wadis and spread the
28 water in a systematic manner across playas and the toe slope of a hillslope. These systems allow
29 production of crops in areas with 100 mm of average annual precipitation by harvesting an additional
30 300+ mm of water (Beckers et al., 2013). Water harvesting provides a proven technology to mitigate
31 or adapt to climate change where precipitation maybe reduced and allow for small scale crop and
32 livestock production to continue supporting local needs.

33 3.7.5.2. India

34 The Green Revolution that transformed irrigated agriculture in India had little effect on agricultural
35 productivity in the rainfed and semi-arid regions, where land degradation and drought were serious
36 concerns. In response to this challenge, integrated watershed management (IWM) projects were
37 implemented over large areas in semi-arid biomes over the past few decades. IWM was meant to
38 become a key factor in meeting a range of social development goals in many semi-arid rainfed
39 agrarian landscapes in India (Bouma et al., 2007; Kerr et al., 2002). Over the years, watershed
40 development has become the fulcrum of rural development that has the potential to achieve the twin

1 objectives of ecosystem restoration and livelihood assurance in the drylands of India (Joy et al.,
2 2004).

3 Some reports indicate significant improvements in mitigation of drought impacts, raising crop, fodder
4 and livestock productivity, expanding the availability of drinking water and increasing incomes as a
5 result of IWM (Rao, 2000), but overall the positive impact of the programme has been questioned and
6 except in a few cases the performance has not lived up to expectations (Joy et al., 2004; JM Kerr et
7 al., 2002). Rigorous comparisons of catchments with and without IWM projects have shown no
8 significant enhancement of biomass (Bhalla et al., 2013). The factors contributing to the successful
9 cases were found to include effective participation of stakeholders in management (Rao, 2000; Ratna
10 Reddy et al., 2004) .

11 Attribution of success to soil and water conservation measures was confounded by inadequate
12 monitoring of rainfall variability and lack of catchment hydrologic indicators (Bhalla et al., 2013).
13 Social and economic trade-offs included bias of benefits to downstream crop producers at the expense
14 of pastoralists, women and upstream communities. This biased distribution of IWM benefits could
15 potentially be addressed by compensation for environmental services between communities (Kerr et
16 al., 2002). The successes in some areas also led to increased demand for water, especially
17 groundwater, since there has been no corresponding social regulation of water use after improvement
18 in water regime (Samuel et al., 2007). Policies and management did not ensure water allocation to
19 sectors with the highest social and economic benefits (Batchelor et al., 2003). Limited field evidence
20 of the positive impacts of rainwater harvesting at the local scale is available, but there are several
21 potential negative impacts at the watershed scale (Glendenning et al., 2012). Furthermore, watershed
22 projects are known to have led to more water scarcity, higher expectations for irrigation water supply,
23 further exacerbating water scarcity (Bharucha et al., 2014).

24 In summary, the overall poor performance of IWM projects have been linked to several factors. These
25 include inequity in the distribution of benefits (Kerr et al., 2002), focus on institutional aspects rather
26 than application of appropriate watershed techniques and functional aspects of watershed restoration
27 (Joy et al., 2006; Vaidyanathan, 2006), mismatch between scales of focus and those that are optimal
28 for catchment processes (Kerr, 2007), inconsistencies in criteria used to select watersheds for IWM
29 projects (Bhalla et al., 2011), and in a few cases additional costs and inefficiencies of local non-
30 governmental organisations (Chandrasekhar et al., 2006; Deshpande, 2008). Enabling policy
31 responses for improvement of IWM performance include a greater emphasis on ecological restoration
32 rather than civil engineering, sharper focus on sustainability of livelihoods than just conservation,
33 adoption of a water justice as a normative goal and minimising externalities on non-stakeholder
34 communities, rigorous independent biophysical monitoring with feedback mechanisms and
35 integration with larger schemes for food and ecological security and maintenance of environmental
36 flows for downstream areas (Bharucha et al., 2014; Calder et al., 2008; Joy et al., 2006). Successful
37 adaptation of IWM would largely depend on how IWM creatively engages with dynamics of large
38 scale land use and hydrology under a changing climate, involvement of livelihoods and rural incomes
39 in ecological restoration, regulation of groundwater use and changing aspirations of rural population
40 (*robust evidence, high agreement*) (O'Brien et al., 2004; Samuel et al., 2007; Samuel and Joy, 2018).

41 **3.7.5.3. Limpopo River Basin**

42 Covering an area of 412938 km², the Limpopo River basin spans parts of Botswana, South Africa,
43 Zimbabwe and Mozambique, eventually entering into the Mozambique Channel. It has been selected
44 as a case study as it provides a clear illustration of the combined effect of desertification and climate
45 change, and why IWM may be crucial component of reducing exposure to climate change. It is
46 predominantly a semi-arid area with an average annual rainfall of 400 mm (Mosase and Ahiablame,
47 2018). Rainfall is both highly seasonal and variable with the prominent impact of the El Nino / La
48 Nina phenomena and the Southern Oscillation leading to severe droughts (Jury, 2016). It is also
49 exposed to tropical cyclones that sweep in from the Mozambique Channel often leading to extensive
50 casualties and the destruction of infrastructure (Christie and Hanlon, 2001). Furthermore, there is
51 good agreement across climate models that the region is going to become warmer and drier, with a
52 change in the frequency of floods and droughts (Engelbrecht et al., 2011; Zhu and Ringler, 2012).

1 Seasonality is predicted to increase, which in turn may increase the frequency of flood events in an
2 area that is already susceptible to flooding (Spaliviero et al., 2014) .

3 A clear need exists to both address exposure to flood events as well as predicted decreases in water
4 availability, which are already acute. Without the additional impact of climate change, the basin is
5 rapidly reaching a point where all available water has been allocated to users (Kahinda et al., 2016;
6 Zhu and Ringler, 2012). The urgency of the situation was identified several decades ago (FAO, 2004),
7 with the countries of the Basin recognising that responses are required at several levels, both in terms
8 of system governance as well as addressing land degradation.

9 Recent reviews of the governance and implementation of IWM within the basin recognise that an
10 integrated approach is needed and that a robust institutional, legal, political, operational, technical and
11 support is crucial (Alba et al., 2016; Gbetibouo et al., 2010; Machelte et al., 2004; Spaliviero et al.,
12 2011; van der Zaag and Savenije, 1999). Within the scope of emerging lessons, two principal ones
13 emerge. The first is capacity and resource constraints at most levels. Limited capacity within
14 Limpopo Watercourse Commission (LIMCOM) and national water management authorities
15 constrains the implementation of IWM planning processes (Kahinda et al., 2016; Spaliviero et al.,
16 2011). Whereas strategy development is often relatively well-funded and resourced through donor
17 funding, long-term implementation is often limited due to competing priorities. The second is
18 adequate representation of all parties in the process in order to address existing inequalities and ensure
19 full integration of water management. For example, within Mozambique, significant strides have been
20 made towards the decentralisation of river basin governance and IWM. Despite a good progress, Alba
21 et al. (2016) found that the newly implemented system may enforce existing inequalities as not all
22 stakeholders, particularly smallholder farmers, are adequately represented in emerging water
23 management structures and are often inhibited by financial and institutional constraints. Recognising
24 economic and socio-political inequalities and explicitly considering them to ensure the representation
25 of all participants can increase the chances of successful IWM implementation.

26

27 **3.8. Knowledge Gaps and Key Uncertainties**

28 • Desertification has been studied for decades and different drivers of desertification have been
29 described, classified, and are generally understood (e.g., overgrazing by livestock or
30 salinisation from inappropriate irrigation) (D’Odorico et al., 2013). However, there are
31 knowledge gaps on the extent and severity of desertification at global, regional, and local
32 scales (Zhang and Huisingsh, 2018; Zucca et al., 2012). Overall, improved estimation and
33 mapping of areas undergoing desertification is needed. This requires a combination of rapidly
34 expanding sources of remotely sensed data, ground observations and new modelling
35 approaches. This is a critical gap, especially in the context of measuring progress towards
36 achieving the Land Degradation Neutrality target by 2030 in the framework of SDGs.

37

38 • Despite numerous relevant studies, consistent indicators for attributing desertification to
39 climatic and/or human causes are still lacking due to methodological shortcomings.

40

41 • Climate change impacts on dust and sand storm activity remain a critical gap. In addition, the
42 impacts of dust and sand storms on human welfare, ecosystems, crop productivity and animal
43 health are not measured, particularly in the highly affected regions such as the Sahel, North
44 Africa, the Middle East and Central Asia. Dust deposition on snow and ice has been found in
45 many regions of the globe (e.g. Painter et al., 2018; Kaspari et al., 2014; Qian et al., 2015;
46 Painter et al. 2013), however, the quantification of the effect globally and estimation of future
47 changes in the extent of this effect remain knowledge gaps.

48

- 1 • Future projections of combined impacts of desertification and climate change on ecosystem
2 services, fauna and flora, are lacking, even though this topic is of considerable social
3 importance. Available information is mostly on separate, individual impacts of either (mostly)
4 climate change or desertification. Responses to desertification are species-specific and
5 mechanistic models are not yet able to accurately predict individual species responses to the
6 many factors associated with desertification under changing climate.
7
- 8 • Previous studies have focused on the general characteristics of past and current desertification
9 feedbacks to the climate system, however, the information on the future interactions between
10 climate and desertification (beyond changes in the aridity index) are lacking. The knowledge
11 of future climate change impacts on such desertification processes as soil erosion, salinisation,
12 and nutrient depletion remains limited both at the global and at the local levels.
13
- 14 • Further research to develop technologies and innovations needed to combat desertification is
15 required but also better understanding of reasons for the observed poor adoption of available
16 innovations is important to improve adoption rates.
17
- 18 • Desertification under changing climate has a high potential to increase poverty particularly
19 through the risks coming from extreme weather events (Olsson et al., 2014). However, the
20 evidence rigorously attributing changes in observed poverty to climate change impacts is
21 currently not available.
22
- 23 • The knowledge on limits to adaptation to combined effects of climate change and
24 desertification is insufficient. This is an important gap since the potential for residual risks
25 and maladaptive outcomes is high.
26
- 27 • Filling these gaps involves considerable investments in research and data collection. Using
28 Earth observation systems in a standardised approach could help fill some of these gaps. This
29 would increase data comparability and reduce uncertainty in approaches and costs.
30 Systematically collected data would provide far greater insights than incomparable
31 fragmented data.
32

33 Frequently Asked Questions

34 **FAQ 3.1 How does climate change affect desertification?**

35 Desertification is land degradation in drylands. Climate change and desertification have strong
36 interactions. Desertification affects climate change through loss of fertile soil and vegetation. Soils
37 contain large amounts of carbon some of which could be released to the atmosphere due to
38 desertification, with important repercussions for the global climate system. The impacts of climate
39 change on desertification are complex and knowledge on the subject is still insufficient. On the one
40 hand, some dryland regions will receive less rainfall and increases in temperatures can reduce soil
41 moisture harming plant growth. On the other hand, the increase of CO₂ in the atmosphere can enhance
42 plant growth if there are enough water and soil nutrients available.
43

44 **FAQ 3.2 How can climate change induced desertification be avoided, reduced or reversed?**

45
46 Managing land sustainably can help avoid, reduce or reverse desertification, and contribute to climate
47 change mitigation and adaptation. Such sustainable land management practices include reducing soil
48 tillage and maintaining plant residues to keep soils covered, planting trees on degraded lands, growing
49

1 a wider variety of crops, applying efficient irrigation methods, improving rangeland grazing by
2 livestock and many others.

4 **FAQ 3.2 How do sustainable land management practices affect ecosystem services and** 5 **biodiversity?**

6 Sustainable land management practices help improve ecosystems services and protect biodiversity.
7 For example, conservation agriculture and better rangeland management can increase the production
8 of food and fibres. Planting trees on degraded lands can improve soil fertility and fix carbon in soils.
9 Sustainable land management practices also support biodiversity through habitat protection.
10 Biodiversity protection allows to safeguard precious genetic resources, thus, contributing to human
11 wellbeing.
